Most studies of the effect of aging on anal squeeze pressures found decreasing pressures with advanced age [158-162, 169, 170] but not all. [146, 171-173] One report found decreasing anal squeeze pressures with age in women but not men.[170] The decrease in anal squeeze pressures does not correlate with easier fatigability of the external sphincter. Indeed, studies show no change with age [174] or that the external sphincter becomes more resistant to fatigue with age. [175] These findings are consistent with studies of skeletal muscle in general which show that reduction of muscle fibres with increasing age with a greater loss of Type II fibres which are less fatigue resistant. [176] The result is a weaker but more fatigue resistant muscle. One explanation of the change in the sphincter muscle is change in the neuronal control. A recent study compared motor unit action potential amplitude and firing rates in young and older women.[177] The investigators found a linear increase in amplitude and decrease in firing rates with age. One interpretation is that external sphincter weakness results from denervation of motor units and decreased upper neuron drive.

The decreased anal squeeze pressures might also be related to external sphincter atrophy. Thinning, presumed to be secondary to atrophy, of the external sphincter has been documented in both endoanal ultrasound and MRI studies. [163-165, 178-180] One study found excellent correlation of atrophy on imaging with the pathologic changes of atrophy.[181] Some studies found that atrophy is related to aging [165, 179] but not all. [146] Faecal incontinence did correlate with external sphincter atrophy. [146] Data from studies of nerve injury in animals reveals that sphincter atrophy and decreased function develops after nerve injury.[182-184] Muscle atrophy secondary to age related loss of anterior horn cell occurs.[185] Human studies demonstrate increased muscle fibre density suggesting reinnervation in the external sphincter with age.[162, 186]

Finally several studies found a decrease in rectal sensitivity with increasing age.[157, 169] One study found that decrease only in women.[160] The relationship of this finding to faecal incontinence is not clear.

5.2. Sex

Prevalence studies suggest that faecal incontinence occurs more frequently in young women but as people age, many studies report essentially equal incidence in men and women. [150, 152-154, 170, 187, 188] The mechanisms of faecal incontinence in men appear to differ from women. [5, 130, 135, 136, 189, 190]

Oestrogen and progesterone receptors are found in the IAS and EAS. Because of this finding, some proposed that menopause is a factor for incontinence in women. However, since aging and menopause are closely related, an independent relationship is difficult to prove. Symptomatic improvement from oral oestrogen replacement supports the proposed relationship; however a randomized trial comparing topical oestrogen to placebo showed no difference.[191] In addition one study found a 30% increased risk of incontinence in patients currently taking oral oestrogens.[192] At the present, the role of the hormone receptors and relationship of menopause to the onset of incontinence is uncertain. [193]

5.3. Diabetes

Diabetes is reported as a risk factor for faecal incontinence in several studies. [153, 154, 192, 194, 195] One study reported a 40% increase in the risk of faecal incontinence.[192] Another population based study found that both occasional and frequent episodes of incontinence were more common inpatients wiht diabetes (OR 2.7) [196] In a study of older Korean patients, diabetes was associated with faecal incontinence in women but not men. [197] A review of incontinence in community dwelling men did identify diabetes as a risk factor, however. [190] A case control investigation found that patients with diabetes had more frequent and severe episodes of faecal incontinence. [198]

Several reports found that incontinence was more frequent in patients with diabetic complications particularly neuropathy and retinopathy[198-200] It is uncertain whether longer duration of disease increases the likelihood of incontinence as one study found an association [199] but two did not.[198, 200] Faecal incontinence was associated with poor glycaemic control in one report, [198] but not another.[200]

The underlying mechanism (s) for faecal incontinence in diabetesis not clear. One likely contributor is oral medication taken for diabetic control. Metformin has been found to be independently related to faecal incontinence .[201] In addition, withdrawal of metformin was reported to eliminate the incontinence.[202] One confounding factor is that diarrhoea, a known risk factor for faecal incontinence, occurs in 5-35% of patients with diabetes. [196, 199, 203, 204]

Diabetes affects gastrointestinal functioning including functional and structural changes in the intestinal wall and central, sympathetic and parasympathetic nervous systems. [205] One hypothesis regarding the mechanism is that microvascular changes associated with diabetes result in damage to pelvic floor innervations and muscles.[206] . Another hypothesis is that poorly controlled hyperglycaemia results in formation of advanced glycation end products which can damage the structure of nerve cells. [205] A comparative study of anorectal physiology of controls, incontinent patients with diabetes and continent and incontinent patients with multiple sclerosis found that the incontinent, diabetic patients had higher sensory thresholds and lower resting and squeeze pressures. [207] An anal physiology study compared findings of patients with the diagnosis of diabetes for less than 10 years to those with the diagnosis for longer than 10 years. [208] Both groups of patients had lower resting and squeeze anal pressures ($P < 0.01$), impaired rectoanal inhibitory and anocutaneous reflexes, and reduced sensitivity in rectal distention. Although both groups had statistically significant differences from the control group, the patients with the longer duration of disease had lower sphincter pressures and more blunted sensation in addition to more frequent episodes of incontinence. The latter group also had more evidence of microvascular disease and neuropathy. Blunted rectal sensation and internal sphincter dysfunction were identified in patients with diabetes in two separate studies.[65, 209] These findings would be consistent with underlying neurological and/or microvascular changes as the underlying aetiology. It is unclear how to reconcile that hypothesis, however, with the lack of association of incontinence with neuropathy in some epidemiology studies. [203, 210]

5.4. Gastrointestinal disorders

5.4.1. Diarrhoea

Diarrhoea is consistently reported as a risk factor for faecal incontinence. For many patients, symptoms of diarrhoea include loose consistency of the stool and rectal urgency. Loose stool is an independent risk factor for incontinence and is additive to other risk factors such as obstetric sphincter injury.[5, 148, 150, 151, 156, 187, 190, 192, 211, 212] Diarrhoea has a significant impact on the development of incontinence with OR 53 in one study.[148] Loose stool is also reported to result in incontinence after pelvic irradiation. [213]

5.4.2. Rectal urgency

Rectal urgency is reported as an independent risk factor for faecal incontinence [150, 214] as well as a factor in worsening symptoms in patients with incontinence.[145] It is unclear whether the aetiology is rapid transit into the rectum overwhelming the reservoir function or hypersensitivity or some combination of factors.[150, 187] Several investigators found that rectal hypersensitivity to be a common finding but incontinence developed only in patients with associated sphincter weakness. [3, 145] Rectal urgency is often associated with diarrhoea but can occur in patients without diarrhoea. A recent study of patients who underwent anorectal physiology testing found that patients with diarrhoea and urgency demonstrated rectal hypersensitivity on testing but the patients with urgency without diarrhoea did not.[215] Urgency in patients without diarrhoea was significantly associated with urinary urgency incontinence. Rectal hypersensitivity has also been found to be associated with an abnormal colonic motility pattern in the sigmoid colon in incontinent patients.[126] The relationship of this finding to irritable bowel syndrome remains to be clarified.

5.4.3. Constipation/impaction

Constipation and incomplete evacuation of the rectum are associated with faecal incontinence in several studies.[149, 156] The combination of symptoms is often unrecognized; in one study 46.7% of patients referred for only faecal incontinence were found to have clinically significant constipation. [216] In a study of chronic constipation patients with and without faecal incontinence, the incontinent patients had a higher mean BMI and lower anal pressures and were less likely to have dyssynergia and rectocele. [217] In another comparison study, patients with isolated faecal incontinence to patients with both faecal incontinence and constipation, several significant differences were identified. [218]Patients with both symptoms had higher resting and squeeze pressures, were more likely to exhibit abnormal balloon expulsion tests and paradoxical EMG as well as higher rates of intra-anal intussusception.

A study of hospitalized older patients found that faecal impaction and diarrhoea were strongly associated with faecal incontinence. [219] Uncertainty exists regarding whether these two factors result in incontinence in patients with otherwise normal anorectal function. Overflow incontinence occurs in some patients with faecal impaction. The use of laxatives may exacerbate the problem. [220] One study of older patients with impaction compared to controls found that they had blunted rectal sensation and less frequent external sphincter contractions in response to rectal distension [221] In addition, the internal sphincter relaxed at lower levels of rectal distension. Studies of impacted patients without incontinence have not been reported.

5.4.4. Inflammatory bowel disease

A systematic review from 2018 identified studies of faecal incontinence in patients with inflammatory bowel disease without a history of ileoanal anastomosis. [222]There was a consistent prevalence of 24%; faecal incontinence was more common in inflammatory bowel disease patients than controls. In evaluation of pathophysiology, there were conflicting results about rectal compliance, anorectal sensitivity and sphincter function. Analysis of the National Health and Nutrition Examination Survey (N=5593) found an association of zinc intake with gas and liquid leakage. [223] A recent study of 500 patients found an equal incidence in ulcerative colitis and Crohn's patients.[224] Faecal incontinence was more likely in older patients and those with active disease. The rate did not differ by sex, location of disease or presence of perianal disease. In contrast, faecal incontinence was more common in patients with Crohn's disease than with ulcerative colitis in another study; active disease and

age remained risk factors. [225] With improvement in medical management of inflammatory bowel disease, more attention to associated functional disorders is necessary.

5.4.5. Irritable bowel syndrome

A number of studies found irritable bowel syndrome to be a risk factor for faecal incontinence. [148-150, 192, 226-228] Proposed mechanisms include age, loose stool consistency, rapid colonic motility and rectal hypersensitivity. [126, 229, 230]

5.5. Neurologic/psychiatric conditions

A recent review summarized the gastrointestinal neuromuscular and extrinsic and intrinsic nervous systems. [231] The author reviews specific altered mechanisms in a range of neurologic diseases associated with faecal incontinence and other gastrointestinal motility disorders.

5.5.1. Dementia

The prevalence of faecal incontinence is higher in patients with dementia compared to others of similar age. One study reported a prevalence of 32% in older patients with dementia.[232] Another study reported a rate of 34% in patients with dementia compared to 6.7% in those without dementia.[233] Although diarrhoea was the greatest risk factor for incontinence in a study of nursing home residents, dementia also contributed to the development of incontinence. [234] In the study of community-living older adults in the United States, the prevalence odds ratio of faecal incontinence decreased by 51% with each unit improvement in cognitive score.[235] Similarly, a higher Cognitive Dementia Rating score was predictive of incontinence in a study of East Asian long term care residents.[236] A Japanese study of community dwelling older adults found dementia to be a risk factor for double (dual) incontinence.[237] There is limited information available about the relationship of intellectual disability and faecal incontinence. [238] Proposed mechanisms for the specific contribution of dementia include lack of recognition or understanding of the urge to defaecate and lack of ability to articulate the need for the bathroom.

5.5.2. Depression

Several studies identified depression as a risk factor for faecal incontinence.[151, 153, 187, 190, 239] Many assume that the association occurs because of the psychological burden of the symptoms while it is also possible that side effects of anti-depressant medication contribute to the symptoms. Recently, however, an editorial challenged investigators to “clarify the link between the cerebral impact of neurotransmitters and anorectal physiology” given the role of serotonin in depression and gastrointestinal function.[240] Depression and faecal incontinence are both associated with poor nutritional status in older adults [241]; that association confounds understanding of any true causal relationship between any two of the conditions.

5.5.3. Spinal cord injury

Patients with SCI frequently report difficulty with both constipation and incontinence [242, 243]. The level of the injury determines the effect on continence. Supraconal lesions lead to delayed colonic transit and exaggerated rectal contractions and anal relaxation in response to rectal distension. Cauda equina lesions interrupt the efferent limb of the reflex arc which results in loss of rectal sensation and tone as well as impaired sphincter function [244] Paraplegics or persons with sacral neuronal lesions may retain some degree of sensory function, but virtually no sensation is felt if lesions reach the higher spine [63, 90]. Recent data suggests that spinal cord perfusion pressure in the immediate post-injury phase may influence the degree of impairment of anorectal function as measured by manometry, cough reflex and recto-anal inhibitory reflex.[245]

5.5.4. Stroke

In several large surveys, stroke is identified as a risk factor for incontinence.[153, 187, 190, 237] Studies of stroke patients demonstrate fairly consistent rates of faecal incontinence from 30-40% on admission.[232, 246-249] The rates decreased to 20% by the time of discharge [246, 248] and 7-11% at 6-12 months. [232, 247, 249]. The Copenhagen Stroke Study found that strokes in patients with incontinence were more likely to be haemorrhagic, larger in size and involve the cerebral cortex than in stroke patients without incontinence.[249] A population based study of over 32,000 people found the risk for incontinence is increased in both men and women up to 10 years after a stroke.[250]

5.5.5. Neurodegenerative disorders

Faecal incontinence is more common in several neurodegenerative disorders. Examples are multiple sclerosis[251, 252] and Huntington disease. [253] A study of multiple sclerosis patients found patient with incontinence had lesions in left supramarginal gyrus and the right parahippocampal gyrus and the amygdala. [254]

5.6. Nutrition

5.6.1. Obesity

Population based studies of faecal incontinence identify obesity as a significant risk factor. [148, 149, 192] In addition, studies of pelvic floor symptoms in obese patients find a higher incidence of faecal incontinence than generally found in the non-obese population with rates ranging from 16-68%. [255-262] A non-significant trend towards worsening incontinence was found in another study.[263] Four studies investigated the relationship between the rate of incontinence to the BMI; two found increasing rates of incontinence with increasing BMI. [192, 260, 264] Two did not. [262, 265] The relationship is further supported by data that weight loss after bariatric surgery decreases the incidence of faecal incontinence. [256, 260, 266, 267] While the findings of these studies are quite consistent a recent systemic review of obesity and pelvic floor disorders found the number of studies to be limited, primarily focused upon women, and usually lacking control groups and physiology testing. [268] A study published since that review did include men and anorectal physiology testing.[269] Obese patients were more likely to have a history of cholecystectomy and irritable bowel syndrome with diarrhoea as well as higher resting pressures, higher maximum tolerable volumes and abdominal pressure. Two confounding factors were noted in studies of this relationship. One is that diarrhoea, an independent risk factor for incontinence, is also frequently associated with obesity. [268] The second is the association of faecal incontinence with low fibre intake in obese women raising the question of dietary contribution to the increased incidence of faecal incontinence with obesity. [258] Chronically elevated intra-abdominal pressure, known to be associated with obesity, [270, 271] is typically proposed as the reason for pelvic floor dysfunction in obesity. Other factors including diabetes, neurological changes and intervertebral disc herniation, common in the obese population may very well contribute.

5.6.2. Vitamin D

Vitamin D deficiency is associated with urinary incontinence in men and women.[272, 273] One small study of ten patients with faecal incontinence found that all had either vitamin D deficiency or relative vitamin D insufficiency. [274]These rates are much higher than the 36-57% rate of deficiency or relative insufficiency from historical data of the general population. In a large study of 1881 women in the US, there was a non-significant trend towards an association between lower vitamin D levels and faecal incontinence. [272] It is known that vitamin D absorption and synthesis in the skin declines with age. [275, 276] Any association between lower levels of vitamin D and faecal incontinence may represent that both are common inolder adults. A randomized controlled study of post-menopausal women found that a low vitamin D level was associated with urinary but not faecal incontinence. The significance of vitamin D levels in patients with faecal incontinence is uncertain but potentially could represent an easily remediable factor.

5.7. Obstetrical injury

The impact of pregnancy and vaginal delivery on continence is described in the section on obstetric injury. While those injuries occur with reasonable frequency, quite often the patient does not develop clinical incontinence until later in life. The reasons for the onset of symptoms and the required combination of factors are poorly understood. Current thinking is that the main factors are pudendal and pelvic autonomic neuropathy and endo-pelvic fascial and ligamentous abnormalities. [73] However, the contribution of EAS defects to incontinence is supported by data demonstrating that clinical improvement after sphincteroplasty is more likely in patients with successful anatomical repair seen on ultrasound. [178, 277-279] The frequency of puborectalis or levator ani muscle injury as well as the degree to which it contributes to faecal incontinence is unclear but is being more actively investigated. [138, 140, 142, 280]

5.8. Physical mobility

Intuitively, adequate physical mobility to reach the toilet in a timely manner in response to the urge to defaecate is necessary for continence. Limited mobility was found to be a risk factor for incontinence in one population based study [187] and an investigation of nursing home residents [107]. In a study of urban dwelling older persons, the odds of prevalent incontinence increased by 20% for each unit decrease in the physical performance measure.[235] These findings were supported by data from the Nurses' Health Study.[265] , Immobility was one of the strongest predictors of incontinence in a study of long-term care patients. [281] In another study, the use of physical restraints (maximal limitation of mobility) was found to be the most significant cause of incontinence when the data were adjusted for other risk factors. [282] Even among women with spinal cord injuries, permanent use of a wheelchair significantly increased the odds of incontinence.[283]

5.9. Radiation

Faecal incontinence occurs after pelvic irradiation for prostate, gynaecological, anal and rectal cancer.[284-288] Radiation therapy adds to the risk of incontinence associated with rectal resection. [289-292] Comparisons of long and short course radiation therapy before surgery for rectal cancer have produced conflicting results. [293-296] Direct comparison trials powered to answer the question have completed recruitment. [297, 298]; oncologic but not functional results have been published. In a study of the relationship of radiation dosage to symptoms after prostate radiotherapy, faecal incontinence was associated primarily to radiation to the EAS and PR. [299] The exact mechanism(s) that radiation therapy causes incontinence is uncertain. The rectum may be stiffer and less compliant [300] and the anal pressures reduced either from muscle or nerve injury by the radiation.[290, 301, 302]

5.10. Mucosal, internal and full thickness rectal prolapse

A significant portion (48-63%) of patients with prolapsing haemorrhoids or mucosal prolapse report soiling.[303, 304] Symptoms resolve with successful treatment. [303-306]

External rectal prolapse is associated with faecal incontinence in up to 66% of patients.[307-310] Diminished anal resting tone commonly accompanies rectal prolapse [90, 308, 311]; that finding suggests that internal sphincter dysfunction perhaps from repeated stretching is one mechanism for incontinence. Other considerations include the presence of neuropathy; it is unclear if the prolapse results in prolonged pudendal nerve latencies [312, 313]or if both share a common etiology. The exact mechanism or combination of causes is uncertain. Other investigators, however, found that patients with rectal prolapse and persistent incontinence had evidence of sphincter defects either from surgical or obstetrical injury. [314, 315]

Internal rectal prolapse is also associated with faecal incontinence [316-319] and decreased anal pressures. [311] The risk of decreased resting tone is greater with recto-anal intussusception than recto-rectal intussusception. In addition, women with internal prolapse without a rectocele seem more likely to have reduced resting tone compared to ones with a rectocele. [320] While surgical intervention for internal rectal prolapse is controversial, several studies report improvement in their incontinence after rectopexy. [321-324]

5.11. Surgery

5.11.1. Anorectal surgery

Lateral internal sphincterotomy is the recommended surgical procedure for refractory anal fissures. Surgery involves division of the internal sphincter and may result in incontinence of flatus and stool. [325-330] Quite variable rates of post-operative incontinence from 0-36 % are reported. The definition of incontinence, type of follow-up and length of sphincterotomy contribute to the variability. Shorter length sphincterotomies are associated with reduced post-operative incontinence confirming that length of sphincterotomy is an important factor. [331, 332] Some authors suggest that pre-existing sphincter injury might predispose to incontinence [333, 334] Another author found evidence for increased sphincter asymmetry in the patients with incontinence after sphincterotomy compared to continent post-operative patients but no differences in pre-existing sphincter defects. [335] The development of symptoms of incontinence may be delayed similar to women with obstetric sphincter injuries. [336]

Incontinence is reported in 0-14% of patients after haemorrhoidectomy.[337-340] In the limited studies available, increased risk of incontinence has been related to previous vaginal deliveries [338], number of haemorrhoids excised [339] and post-operative internal sphincter defects. [338, 341] Some have argued that excision of the anal cushions is the reason for incontinence. [114]

Surgery for anal fistulae may result in faecal incontinence. The frequency depends upon the anatomy of the fistula, base-

line sphincter function and the surgical procedure performed. The reported rates of post-operative incontinence range from 0-50%. [342-354] The definition and measurement of incontinence varies among the studies. Treatment of high fistulae involving more sphincter muscle is more likely to be followed by incontinence.[326, 342, 349, 354] Injections of fibrin glue and endorectal advancement flaps have lower post-operative incontinence rates than other fistula procedures. [345] Age over 45 years old [342] sex[344, 353, 355] and previous anorectal surgery [355] were found to increase the risk in some studies. The mechanism appears to be iatrogenic (and sometimes intentional) sphincter injury.

5.11.2. Rectal resection

In a meta-analysis of functional outcomes after resection for rectal cancer from studies reported between 1978 and 2004, faecal incontinence of any kind occurred in 3-79% of patients. [287] Rates of incontinence of solid stool ranged from 0-40%, liquid stool 0-60% and flatus 9-76%. The pooled proportion of incontinence of solid stool was 14 % and liquid stool 29%. The risk of incontinence appears to depend upon the tumour location and level of the anastomosis [356] as well as occurrence of anastomotic leakage.[357] As surgical techniques evolve, new ones have been compared to existing techniques to determine if technical details impact functional outcomes. Transanal total mesorectal excision has recently been compared to laparoscopic total mesorectal excision, while some studies document higher incontinence [358, 359], a meta-analysis found no difference. [360] Theoretically, loss of the rectal reservoir is one contributor. The goal of replacing the reservoir function led to the development various types of reconstruction following resection (coloplasty, colonic J pouch, ileoanal reservoir). While long–term data are sparse, in the first 18 months post-operatively colonic J pouches result in lower rates of incontinence than straight anastomoses or coloplasty according to a Cochrane review.[361] Damage to the internal sphincter occurs during this type of resection presumably from transanal introduction of stapling devices and may contribute to incontinence as well. [362, 363] However a study comparing patients undergoing hand-sewn anastomoses to double stapled ones found no difference in faecal incontinence post-operatively or anorectal manometry results. [364] Another possible explanation for the incontinence after low resection is the disruption of the rectoanal inhibitory reflex. There is data to support the loss of the rectoanal inhibitory reflex post-operatively and its correlation with incontinence. [365-367] In a recent study 61% of patients who underwent an intersphincteric resection for rectal cancer recovered their rectoanal inhibitory reflex after 12 months; incontinence was significantly less common in that group compared to patients with a permanent loss. [365] It is interesting to note that recovery of the rectoanal inhibitory reflex did not correlate with the amount of internal sphincter resected. Diminished rectal sensation and changes in motility seen post-operatively indicate that nerve damage may also contribute. [364, 368, 369] Rectal sensation and the ability to defaecate can be abolished completely by resection of the nervi erigentes [370]. If parasympathetic innervation is absent, rectal filling is only perceived as a vague sensation of discomfort. Cadaver studies after total mesorectal excision reveal the close proximity of the levator ani nerve and pelvic splanchnic nerves to the plane of dissection particularly for low rectal resections. [371] Damage to those nerves would impact function of the sphincter mechanism. A recent small study found that approximately half of the patients with low anterior resection syndrome had qualitative changes in anal slow wave activity compared to healthy controls. [372] It is likely that multiple factors contribute to incontinence after rectal resection; more research is needed to understand the relative importance of each factor.

5.11.3. Hysterectomy

Several reports identified hysterectomy as a risk factor for faecal incontinence. [148, 187, 373] However several studies found either improvement or no association.[374] [192] [149] Gynecological cancer appears to have a more significant impact on pelvic floor symptoms including faecal incontinence than hysterectomy alone. [373, 375] However, it is not clear whether surgery or adjuvant therapies are responsible.

5.11.4. Cholecystectomy

Cholecystectomy results in diarrhoea in some patients. It is often assumed at incontinence occurring after cholecystectomy is related to the onset of diarrhoea. However, two studies identified cholecystectomy as a significant independent risk factor for incontinence. [148, 376]The underlying mechanism, if not associated loose stool, is uncertain but perhaps could be related to rectal urgency secondary to bile salt irritation.

5.12. Smoking

A study from the Mayo Clinic reported an association of incontinence in older adults with current smoking with an odds ratio of 4.7. [148] An earlier study reported the same finding in post-partum patients with faecal incontinence. The reason is unclear. [377] Chronic obstructive pulmonary disease has been associated with faecal incontinence [192] but in the Mayo Clinic study, pulmonary disease was not found to be a factor. Other proposed mechanisms include the anti-oestrogen effect of nicotine [378] or accelerated colonic transit secondary to nicotine induced high amplitude contractions in the colon.[379]

5.13. Trauma

Direct injury to the anal sphincter occurs in both military and civilian settings in addition to childbirth. However, there is limited literature about long term anorectal function of those patients. [380] Anal intercourse has been found to be a risk factor in both men and women, [381-383] In small studies of men with faecal incontinence and history of anal intercourse, reduced resting pressures were identified but no sphincter changes could be detected on ultrasound.[383, 384]

5.13.1. Urinary incontinence

Many studies report an association of urinary and faecal incontinence. It is likely that it is not a causative relationship but rather that the two conditions result from common aetiology.[148, 151, 154, 187, 192, 212, 385-387]

6. SUMMARY AND RESEARCH RECOMMENDATIONS

Multiple risk factors play a role in the development of faecal incontinence. As treatment patterns for diseases such a rectal cancer and inflammatory bowel disease change, early work on the functional consequences should be continued. Since the last report, increased focus has been placed on the role of rectal urgency, anorectal sensation and the involved nervous system. However, many questions remain. Understanding of the complex interaction of the pelvic floor musculature and nervous system in healthy patients and incontinent patients is incomplete.

Why some patients with similar risk factors are incontinent but not all is unclear. What combination of abnormalities is required for significant incontinence needs further investigation.

Clinicians need to know which of those abnormalities, including ones associated with aging, are remediable and if the possible remedies result in clinical improvement.

More detailed knowledge of the molecular pathways would be helpful in devising new treatment. Answers to those questions would might allow prevention, improve patient selection for various treatments and facilitate discovery of new treatment modalities

297. Protocol, S. The Stockholm III Trial on Different Preoperative Radiotherapy Regimens in Rectal Cancer. [cited 2012 February 4]; Preoperative radiotherapy (RT) is recommended to many patients with localised rectal cancer, not previously treated with pelvic RT. However, the optimum fractionation, the timing of surgery and the best use of concomitant chemotherapy remains controversial. Short-course, preoperative RT may induce both acute and late morbidity and has been claimed to cause more morbidity than long-course preoperative RT. There are theoretical reasons to believe that RT given in larger fractions during a shorter period of time might result in more late side effects than giving a conventional, more protracted RT. In addition, the optimum timing of surgery after RT, with respect to postoperative morbidity, mortality and potential downsizing of the tumour is not known.]. COMMITTEE 4A

INITIAL ASSESSMENT OF URINARY INCONTINENCE IN ADULT MALE AND FEMALE PATIENTS

Chairs

Castro-Diaz, David. Chair (Spain)
Robinson, Dudley. Co-Chair (United Kingdom)

Members

Arlandis Guzman, Salvador (Spain)
Bosch, JLH (Netherlands)
Costantini, Elisabetta (Italy)
Cotterill, Nikki (United Kingdom)
Espuña Pons, Montserrat (Spain)
Lemos, Nucelio (Canada)
López-Fando Lavalle, Luis (Spain)
Shelly, Elizabeth (United States)
Yoshida, Masaki (United Kingdom)

COMMITTEE 4A

INITIAL ASSESSMENT OF URINARY INCONTINENCE IN ADULT MALE AND FEMALE PATIENTS

ABBREVIATIONS **3**

I. INTRODUCTION **3**

II. GENERAL INFORMATION **3**
1. Terminology 3
   1.1. Types of urinary incontinence 4
   1.2. Bladder storage symptoms 4
   1.3. Bladder sensation 4
   1.4. Voiding and postmicturition symptoms 4
2. Assessment of Sub-populations Reviewed by Other Committees 5
3. Evidence Based Recommendations 5

III. INTIAL ASSESEMENT **5**
1. Purpose of Initial Assessment (Expert Opinion of the Committee) 5
2. Initial Assessment – General Recommedations 6
3. Initial Assessment – General Research Recommendations 6

IV. GENERAL POPULATIONS **7**
1. Initial Assessment of Urinary Incontinence 7
   1.1. History 7
   1.2. Bladder diaries 8
   1.3. Urgency scale 9
   1.4. Urinalysis 11
   1.5. Post voiding residual in the female and male patient 12

V. SPECIFIC POPULATIONS: EVALUATION OF THE FEMALE PATIENT **14**
1. Establishing the Type of Urinary Incontinence in Women 14
2. General Medical History 14
3. Symptom Assessment 14

I. INTRODUCTION

The aim of this report is to provide an update of the evidence-based recommendations from the 7th ICI regarding the initial assessment of urinary incontinence (Committee 5A) for adult men and women.

II. GENERAL INFORMATION

1. TERMINOLOGY

A critical step in the evaluation of urinary incontinence (UI) is the use of up-to-date terminology to describe different types of UI and their associated lower urinary tract symptoms (LUTS). LUTS includes both storage and emptying symptoms in contrast to overactive bladder syndrome (OAB) which describes a subset of storage symptoms (e.g., urgency, frequency, nocturia), with or without the symptom of UI. The use of standardised terminology during history taking of UI ensures an accurate characterisation of the type of UI experienced by each patient.

The ICS 2002 report (1) and the ICS /IUGA Joint Report (2) are recommended for reference, as well as an update of the terminology for nocturia (3). It should be noted however that a bibliometric and questionnaire analysis of the use of standardised terminology documents the low rate of acceptance of this terminology in both the literature and practice, and the slow abandonment of previously accepted common terms. (4)

The Standardisation Steering Committee (SSC) of the International Continence Society (ICS) "establishes terminology and methodology in the ICS's areas of activity, to underpin professional standards of clinical management and research. The value of the SSC is in promoting best standards when clinicians and allied professionals communicate with patients and colleagues, undertake diagnostic tests, proceed to therapeutic interventions and undertake research. Precise use of agreed terminology ensures clear understanding for collaborating centres and readers of publications. Adherence to the diagnostic testing standards gives patients and clinical colleagues confidence that conclusions on which important therapeutic decisions are reliable. Development of future insights into mechanisms and treatments of the disease areas relevant to the ICS is enhanced where research studies employ internationally standardised approaches.

The term "urinary incontinence" refers to the complaint of any involuntary loss of urine. The symptom of urinary incontinence can be volunteered by, or elicited from, the individual or may be described by the individual's caregiver. Urinary incontinence can be categorised into several distinct sub-types based on associated characteristics and circumstances surrounding episodes of urine leakage. Although defining the type of incontinence will not establish a definitive underlying diagnosis, it will ultimately guide investigation and treatment. The following are the accepted ICS definitions of these conditions unless referenced (1).

1.1. Types of urinary incontinence

a) Stress (urinary) incontinence: Complaint of involuntary loss of urine on effort or physical exertion e.g., sporting activities), or on sneezing or coughing. (Sporting activities)

b) Urgency (urinary) incontinence: Complaint of involuntary loss of urine associated with urgency.

c) Postural (urinary) incontinence: Complaint of involuntary loss of urine associated with change of body position, for example, rising from a seated or lying position.

d) Mixed (urinary) incontinence: Complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing.

e) Incontinence associated with chronic retention of urine: Complaint of involuntary loss of urine which occurs in conditions where the bladder does not empty completely as indicated by a significantly high residual urine volume and/or a non-painful bladder which remains palpable after the individual has passed urine. (Note: The ICS no longer recommends the term overflow incontinence. A significant residual urine volume denotes a minimum volume of 300 ml, although this figure has not been well established.)

f) Nocturnal enuresis: Complaint of involuntary loss of urine which occurs during sleep.

g) Continuous (urinary) incontinence: Complaint of continuous involuntary loss of urine.

h) Insensible (urinary) incontinence: Complaint of urinary incontinence where the individual is unaware of how it occurred

i) Coital incontinence (for women only): Complaint of involuntary loss of urine with coitus. This symptom can be further divided into that occurring with penetration and that occurring at orgasm.

j) Functional incontinence: Complaint of involuntary loss of urine that results from an inability to reach the toilet due to cognitive, functional or mobility impairments in the presence of an intact lower urinary tract system.

k) Multifactorial incontinence: Complaint of involuntary loss of urine related to multiple interacting risk factors, including factors both within and outside the lower urinary tract such as comorbidity, medication, age-related physiological changes and environmental factors.

Urinary incontinence can exist in isolation or may be associated with other lower urinary tract symptoms. The ICS classifies lower urinary tract symptoms (LUTS) into bladder storage, voiding and post-micturition, and pelvic organ prolapse symptoms. The following section summarises the definitions of LUTS described by the ICS-SSC.

1.2. Bladder storage symptoms

Bladder storage symptoms are experienced during the bladder filling phase:

a) Increased daytime urinary frequency: Complaint that micturition occurs more frequently during waking hours than previously deemed normal. Traditionally seven episodes of micturition during waking hours was considered as the upper limit of normal, although it may be higher in some populations.

b) Nocturia: Complaint of interruption of sleep one or more times because of the need to void. Each void is preceded and followed by sleep. The number of nocturia episodes and the degree of bother based on number has been questioned and the threshold of 2-3 per night has been suggested (5-10).

c) Urgency: Complaint of a sudden, compelling desire to pass urine which is difficult to defer. (Note: The ‘all or none‘ nature of ‘urgency’ has been questioned) (8).

d) Overactive bladder syndrome (OAB): Urinary urgency, usually accompanied by increased urinary frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology.

1.3. Bladder sensation

Asking patients about bladder sensory symptoms during bladder filling may be helpful in characterising certain types of incontinence.

a) Increased bladder sensation: Complaint that the desire to void during bladder filling occurs earlier or is more persistent to that previously experienced. This differs from urgency by the fact that micturition can be postponed despite the desire to void.

b) Reduced bladder sensation: Complaint that the definite desire to void occurs later than that previously experienced despite an awareness that the bladder is filling.

c) Absent bladder sensation: Complaint of both the absence of the sensation of bladder filling and a definite desire to void.

1.4. Voiding and postmicturition symptoms

Voiding symptoms are experienced during the voiding phase and post-micturition symptoms are experienced immediately after micturition.

a) Hesitancy: Complaint of a delay in initiating micturition.

b) Slow stream: The individual’s perception of reduced urine flow, usually compared to previous performance or in comparison to others.

c) Intermittent stream (intermittency): Complaint of urine flow which stops and starts, on one or more occasions, during micturition.

d) Straining to void: Describes the muscular effort used to initiate, maintain or improve the urinary stream.

e) Spraying (splitting) of urinary stream: Complaint that the urine sprays or splits rather than coming out as a single, discrete stream.

f) Terminal dribble: is the term used when an individual describes a prolonged final part of micturition, when the flow has slowed to a trickle/dribble.

g) Feeling of incomplete bladder emptying: Complaint that the bladder does not feel empty after passing urine.

h) Need to immediately re-void: Complaint that further micturition is necessary soon after passing urine.

i) Postmicturition leakage: Complaint of a further involuntary passage of urine following the completion of micturition.

j) Position-dependent micturition: Complaint of having to take specific positions to be able to micturate spontaneously or to improve bladder emptying, for example, leaning forwards or backwards on the toilet seat or voiding in the semi-standing position.

k) Dysuria: Complaint of burning or other discomfort during micturition. Discomfort may be intrinsic to the lower urinary tract or external (vulvar dysuria in women).

l) (Urinary) retention: Complaint of the inability to pass urine despite persistent effort.

2. ASSESSMENT OF SUB-POPULATIONS REVIEWED BY OTHER COMMITTEES

The targeted assessments and specific outcome measures for conditions of UI in Children (Cmte.9), Neurogenic Patients (Cmte.10), Frail Elderly (Cmte.11), Painful Bladder Syndrome (Cmte.19) and Faecal Incontinence (Cmte.16) are presented separately in the respective reports. The requirements of specific sub-populations negate the ability to recommend a 'universal' initial evaluation. Within the initial assessment of UI, these sub-populations / subgroups are recognised because of the differences within patient groups or the interrelationship between the conditions. Congenital and developmental issues are critical considerations in children. Specific risks for combined storage and emptying abnormalities and upper urinary tract deterioration in the neurogenic population demand a more involved initial and complex evaluation. The effects of ageing on the lower urinary tract, altered toileting functions, and medical co-morbidities in the frail elderly group present unique challenges. These subgroups also include patients with LUTS with and without incontinence and with the presence of pelvic pain or faecal incontinence.

The sub-sections in this report should be utilised in conjunction with other population or condition specific Committee Reports of the Consultation and with the final recommendations of the Consultation which are presented in simplified form in Appendix (1. Definitions). Recommendations for initial evaluation have been developed by the International Scientific Committee and are also published in Appendix (2. Evaluation). In addition, History and Symptom Assessment recommendations are further detailed as the initial steps in the evaluation of the index adult male (3. Initial Management, II. Male), and adult female (3. Initial Management, III. Female). The reader is encouraged to refer to these recommendations and algorithms in combination with this report.

3. EVIDENCE BASED RECOMMENDATIONS

The recommendations presented in this report are evidence-based and utilise the ICUD-EBM grades. A search of the available literature in English obtained from Medline and Pubmed by the individual committee members employed multiple search terms related to the initial assessment of the patient with urinary incontinence and patient reported outcome assessment.

III. INTIAL ASSESEMENT

1. PURPOSE OF INITIAL ASSESSMENT (EXPERT OPINION OF THE COMMITTEE)

As will be noted, especially in this committee report (5A), the amount and sophistication of the literature that is applicable for the development of evidence-based guidelines is limited. For this reason, the grade of recommendation in the area of "initial assessment" will often rely on 'expert opinion of the panel'. For the purpose of subsection 5A, the 'initial assessment' represents the components of the history, physical examination, laboratory tests, and basic office testing to:

1. Establish a presumptive or condition specific diagnosis and exclude underlying organ-specific related or unrelated conditions that would require intervention.
2. Assess the level of bother and desire for intervention from information obtained from the patient or caregivers, utilising objective measures or patient reported outcomes.
3. Prepare for the institution of empirical or disease specific primary therapy based on the risk and benefit of the untreated condition, the nature of the intervention and the alternative therapies including Conservative (Cmte.12) or Pharmacological (Cmte.8) therapies.
4. Prompt the recommendation of additional more complex testing or specialist referral (when indicated).
5. Assess the level of improvement after intervention from information obtained from the patient or caregivers, utilising objective measures or patient reported outcomes (Cmte.5B).

Once the type of Urinary Incontinence (UI) with associated lower urinary tract symptoms (LUTS) has been established, there can be consideration of a differential diagnosis , and further investigations may be requested , and an eventual treatment plan can be formulated to address or modify the effects of the underlying cause(s). The success of the treatment plan can be measured by patient-reported outcomes (from a simple "yes" or "no" to more complex questionnaires), and/or other objective measures of urinary leakage events (including bladder diaries, pad tests, or urodynamics studies).

The initial assessment must consider the degree of bother, and the cost of further evaluation, balanced against the consequences of failure to diagnose an underlying condition, the risks and benefits of empirical conservative management or pharmacological therapy, and the need for an accurate diagnosis before more complex intervention or empirical therapy. The burden of these conditions and the availability of resources for individual patients, caregivers, physicians, and health care systems requires that primary intervention strategies be formulated from evidence-based findings and decisions emanating from the initial evaluation.

Of note, LUTS cannot be utilised with confidence to make a definitive diagnosis of a specific lower urinary tract condition or lower urinary tract disease (LUTD), as these symptoms may suggest and indicate pathologies such as urinary tract infection (UTI) or more

serious underlying conditions. Basic laboratory tests, such as testing for UTI or blood (haematuria), and appropriate screening for malignancy should be considered before the decision is made to choose therapy for incontinence. Urinary retention with overflow may present as urinary urgency, frequency, and nocturia with urinary loss mimicking OAB.

Concomitant pathology may affect urine production as a co-morbid contributory factor, by affecting fluid balance or renal function (fluid intake and output regulation) and may need to be addressed prior to or in combination with LUT or bladder outlet therapy. A thorough review of medications which alter fluid production or lower urinary tract function should be addressed. The physician should also seek a history of pelvic pathology or surgery and neurological symptoms and signs that may indicate alterations in the control of the lower urinary tract function or be responsible for the cognitive, motivational, or physical factors that determine the ability to perform toileting functions effectively. The physical examination and the appropriate laboratory tests are necessary to refine the differential diagnosis and therapeutic options.

The recent ICS report on the terminology for pelvic floor muscle (PFM) assessment lists symptoms a patient may use to describe a sensation which could be related to a disorder of PFM structure or function (11). Recognising the symptoms of possible PFM disorder can direct further assessment and guide intervention. PFM sensory symptoms may include numbness, reduced feeling, decreased sensation, tingling, pins and needles, sensitivity/hypersensitivity, or increased or unusual sensation in the region the patient perceives to be related to the PFM. Terms used to describe painful symptoms may include pain, tender, ache, burning or discomfort in the region the patient perceives to be related to the PFM. Further assessment of PFM function may be considered in patients describing these sensations (8).

2. INITIAL ASSESSMENT – GENERAL RECOMMEDATIONS

1. Lower Urinary Tract Symptoms (LUTS) cannot be used to make a definitive diagnosis; they may also indicate pathologies other than LUTD. Specific to this report, LUTS includes Overactive Bladder (OAB) a syndrome which may be associated with urgency incontinence (OAB-wet) or without incontinence (OAB-dry) (Level 4 - Grade D).
2. Urinary incontinence should be described by specifying relevant factors such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and quality of life as well as the measures used to contain the leakage and whether or not the individual desires help (Level 4 - Grade D).
3. Urinary incontinence should be categorised by symptoms into urgency incontinence, stress incontinence or mixed incontinence and conservative (non-invasive) therapies may then be started based on this classification to treat the most troublesome component, or both components of the incontinence. More sophisticated testing (e.g., urodynamic studies) is not required prior to conservative therapy (see indications for urodynamics in the Committee Report on Dynamic Testing Committee 6) (Level 3 - Grade C).
4. Both objective (bladder diary) and subjective (patient reported outcomes – PROs) are recommended for assessment and measurement of the degree of symptoms and bother of UI at baseline, and for the assessment of the impact of therapy (Level 3 – Grade D).
5. Normal lower urinary tract function requires the ability of the bladder to adequately store urine at low pressure while the bladder outlet remains competent, and the bladder to contract until completely empty while the bladder outlet remains open. In addition to an evaluation of LUT function, a thorough evaluation for co-morbid conditions which affect fluid intake and output should be undertaken. Diseases of the nervous system and pelvic disorders, as well as medications which may affect the LUT should be addressed (Level 4 - Grade D).
6. Referral to a specialist is recommended for haematuria (visible or microscopic), urinary tract infection (persistent or recurrent), prolapse (symptomatic or below the introitus) , obstruction or retention (symptoms or findings of palpable bladder, hydronephrosis or obstructive renal insufficiency), suspected neurological disease, mass (urethral, bladder or pelvic - benign or malignant), fistula (urinary or bowel), faecal incontinence, a history of prior pelvic surgery or radiation (incontinence, oncologic), symptoms suggestive of possible PFM disorder (Level 4 - Grade D).

3. INITIAL ASSESSMENT – GENERAL RESEARCH RECOMMENDATIONS

1. Standardisation of the ‘definition of symptoms’ and the ‘measurements of symptom frequency, severity and bother’ are essential for patient care and research. Continued research into the appropriate scales and metrics should be accompanied by a significant attempt to establish best practice guidelines for their use and a consensus on the adoption of universal standards.
2. Recognition and resolution of the differences in common language usage and scientific utilisation of terms should continue. Resolution of the differences in definitions and metrics between recognised societies and organisations is essential for communicating data with respect to patient care, research, and treatment outcomes.
3. Research into the development of accurate measures to objectify subjective symptoms such as “urgency” and other bladder sensory symptoms.
4. Development, standardisation, and universal adoption of symptom assessment tools (questionnaires) to improve the diagnostic accuracy of lower urinary tract symptoms (Refer to section 5B of this committee’s report).
5. Validation of the accuracy of specific components of the history and physical findings to establish an accurate diagnosis and to initiate non-invasive conservative or pharmacological therapy. In addition, to further identify components that would indicate the need for more invasive testing, complex therapeutic interventions, and indications prior to / or as a result of referral.
6. Creation and institution of evidence-based guidelines for the referral of patients to a specialist are needed to improve the efficiency of the healthcare system in treating the large burden of disease (See Epidemiology, Committee 1). The institution of conservative measures and pharmacology are in the domain of the primary caregiver. Further improvement in the ability to define the index patient, but more importantly the sub-groups of patients who will require more complex specialist therapy, will aid in counselling and referral at the primary level. In addition, refining the true risks for significant underlying disease noted while obtaining the history, or during the examination or laboratory findings will improve resource utilization.

IV. GENERAL POPULATIONS

1. INITIAL ASSESSMENT OF URINARY INCONTINENCE

Individuals with UI can be identified through routine screening, or the patient may initiate discussion about incontinence problems. The initial assessment of UI should help the health care provider to understand the type of incontinence, while identifying potentially modifiable contributing factors. Most primary treatment options, such as lifestyle modifications and behavioural treatments, do not vary by type of UI. However, it is important to determine the type of UI since some treatment options do vary . Equally important, establishing the type of UI will lead the health care provider to a list of possible underlying causes, or differential diagnosis of the urinary symptoms. Most causes of UI are non-life threatening. However, symptoms of incontinence may also herald life-threatening or more severe disease such as bladder cancer when associated with haematuria, when more specialized testing will be required immediately. Finally, assessing the level or bother and desire for intervention from information obtained from the patient or caregiver is essential for guiding the nature of the treatment plan.

1.1. History

Taking a careful clinical history is fundamental to the clinical process. Some studies have indicated that patient history alone is not completely accurate as the sole determinant of incontinence type (12, 13). However, Martin et al. (14) in a systematic review and meta-analyses on the methods for diagnostic assessment of urinary incontinence, suggested that women with urodynamic stress incontinence (USI) can be correctly identified in primary care from clinical history alone with a sensitivity of 0.92 (95% C.I.: 0.91- 0.93) and specificity of 0.56 (0.53- 0.60); symptoms of urge incontinence were found to be 0.61 (0.57- 0.65) sensitive and 0.87 (0.85-0.89) specific for the diagnosis of detrusor overactivity.

Despite the lack of formal evidence, there is universal agreement that taking a history should be the first step in the assessment of anyone with UI (1, 15).

The general history should include questions relevant to establish the type of UI, timing and severity of UI, and some attempt to quantify symptoms should also be made. The history should help to categorise LUTS as storage, voiding and post-void symptoms (16).

The incontinence first should be characterized subjectively. Does the leakage occur: With physical activity? With a sense of urgency? Without sensory awareness? If the nature of the incontinence is mixed, does one component cause more bother or occur more frequently than the other? Secondly, the leakage should be quantified if possible. Appraisal of the degree of leakage before therapy can be helpful during postoperative assessment of treatment impact. For the purposes of routine outpatient assessment, this quantification can be achieved based on the number of pads used per day or the frequency of clothing changes because of urinary leakage. Medical practitioners should also be aware of symptoms of PFM disorder listed above.

Acute symptoms can be defined by documenting patterns of fluid intake and output, acute infection, recent surgery or trauma. Chronic symptoms should prompt queries about a history of congenital abnormalities, neurological disease, relevant surgery or general health issues. History should also identify patients who need rapid referral to an appropriate specialist. These include patients with associated pain, haematuria, a history of recurrent urinary tract infection (UTI), pelvic surgery (particularly prostate surgery) or radiotherapy, constant leakage suggesting a fistula, voiding difficulty or suspected neurological disease (Red Flag Symptoms).

The voiding pattern should also be defined. What is the frequency of micturition during the day and during the night? Are there any voiding symptoms and/or storage symptoms? Previous surgery such as pelvic or back surgery and, in males, prostate or urethral surgery for benign or malignant disease should be investigated.

Information should be obtained concerning medications with known or possible effects on the lower urinary tract. The general history in women should also include assessment of menstrual, obstetric, sexual, gynaecological and bowel function. It is also helpful to determine the impact that the leakage has on the patient's daily life and activities if incontinence limits the individual's activity and if the patient made lifestyle changes because of the threat of leakage. Finally, it is important to emphasize the importance of establishing patient expectation of treatment and an understanding of the balance between the benefits and risks/burden of available treatment options (see Committee Report 5B).

The reader is referred to the report on Epidemiology (Committee. 1) for specific risk factors to be considered during the medical history, and to the report on Frail Elderly (Committee. 11) for a list of co-morbidities and medications that can cause or contribute to UI.

A later section of this Committee Report (5B) presents a complete review and evaluation of questionnaires that are applicable for clinical and research use in evaluating patient symptoms. Structured condition specific questionnaires may be utilised and may be either clinician or self-administered. Use of questionnaires may facilitate disclosure of embarrassing symptoms, ensure that symptoms are not omitted and standardise information for audit and research.

In the absence of questionnaire use, Table 1 summarises key questions for the initial assessment of urinary incontinence based on the expert opinion of this committee. Note that the committee strongly encourages the use of standardised questions.

Table 1: Key Questions in the Initial Assessment of Urinary Incontinence

Stress urinary incontinence: Do you sometimes leak urine when you cough or sneeze or when you exert yourself, such as when lifting a heavy object?
Urgency urinary incontinence: Do you sometimes feel an urge to void that is so sudden and strong that you sometimes don't make it to the bathroom on time?
How long have the symptoms been present?
How often do you leak urine and how much do you leak? (Do you need protections and how many during day and night?
Circumstances surrounding urine leakage e.g. sexual activity, change in position, provocation by running
water or 'key in the latch'?
Nocturnal symptoms or enuresis?
Association with other lower urinary tract or pelvic organ prolapse symptoms?

Impact on personal and social life?
Amount and type of fluid intake e.g. coffee, tea, alcohol?
Episodes of urinary tract infection or haematuria?
Previous treatment attempts (successful and unsuccessful)?
Mobility problems?
Cognitive deficits?
Neurological deficits?
Problems with constipation or faecal incontinence?
Number of pregnancies and the type of delivery, with complications?
Previous prostate, pelvic or abdominal surgeries or radiation treatment?
Coexisting diseases (diabetes, heart disease, neurological impairment)?
Types of medications consumed?

1.2. Bladder diaries

The micturition time chart records the timing of voids in 24 hours. The term frequency-volume chart is used to describe a chart that records the time of each micturition and the volume voided for at least 24 hours. The bladder diary may include fluid intake, incontinence episodes, pad usage, the degree of incontinence as well as a record of episodes of urgency and sensation and activities performed during or immediately preceding the involuntary loss of urine. Therefore, bladder diaries are most suited for the purpose of comprehensive evaluation of urinary incontinence. However, documentation of the frequency of an individual's lower urinary tract symptoms and the voided volume for at least 24 hours can be extremely helpful in the initial assessment of urinary incontinence, although 2-3 days of recording generally provide more useful clinical data. Moreover, a diary may be therapeutic as it provides insight into bladder behaviour and it can be utilised to monitor the effectiveness of treatment during follow-up.

A frequency-volume chart or bladder diary, if properly completed, can provide all of the following information.

a) Daytime urinary frequency: Number of voids by day (wakeful hours including last void before sleep and first void after waking and rising).

b) Nocturnal frequency/nocturia: Number of times sleep is interrupted by the need to micturate. Each void is preceded and followed by sleep.

c) Twenty-four-hour frequency: Total number of daytime voids and episodes of nocturia during a specified 24-hr period.

d) Twenty-four-hour urine production: Summation of all urine volumes voided in 24 hr.

e) Maximum voided volume: Highest voided volume recorded.

f) Average voided volume: Summation of volumes voided divided by the number of voids.

g) Median functional bladder capacity: Median maximum voided volume in everyday activities.

h) Polyuria: Excessive excretion of urine resulting in profuse and frequent micturition, defined as greater than 2.8 L of urine during 24 hours for an individual weighing 70 kg.

i) Nocturnal urine volume: Cumulative urine volume from voids after going to bed with the intention of sleeping to include the first void at the time of waking with the intention of rising (excludes last void before sleep).

j) Nocturnal polyuria: Excess (over 20–35% age dependent) proportion of urine excretion (nocturnal voided volume/total 24 hr voided volume x 100% = Nocturnal Polyuria Index [NPI]) occurring at night (or when the patient is sleeping). Nocturnal polyuria is most often diagnosed using the Nocturnal Polyuria Index >0.33) (17).

However, it should be noted that there are some limitations to the use of a frequency-volume chart or bladder diary. There is no evidence that the results of these charts provide a valid prediction of the type of urinary incontinence experienced by each patient (18,19). Some patients may have difficulty completing the diary in a reliable, meaningful or timely fashion, especially when increasing the complexity or the amount of time (days) required to complete the diary (20). The bladder diary may not yield information about the evolution of incontinence episodes that occur less frequently than once per day (20,21). Furthermore, for therapy monitoring, the use of the pre- and post-treatment voiding diary for 3-7 days is not always acceptable to by patients. However, previous research has identified several challenges with using bladder diaries in clinical trials, including inaccurate completion and a bladder self-monitoring effect (22). Alternative tools have been introduced for the follow up of patients with OAB. Chapple et al have validated an overactive bladder assessment tool (OAB-BAT) in multiple stages with input from OAB patients. The eight-item OAB- BAT v3.0 is a psychometrically sound measure for determining OAB patients' perspectives on symptom bother and the impacts of their condition. It could complement the assessment made with the voiding diary or even replace it (23).

Several studies have compared patients' preference for, and the accuracy of, electronic and paper voiding diaries in voiding dysfunction (24-28), but the utility of electronic diaries has not been fully clarified yet.

Due to intraindividual variation, FVC recordings differ on different days. The more days recorded, the more likely it will be that the recordings will capture the whole spectrum of variation. Few data have been reported on the intraindividual variation of FVC parameters (29-31). However, these variations have been used in statistical analysis leading to statements on the optimal duration of FVCs. Recommendations for diary duration vary considerably including 24 hours, 3 days or 7 days; this inconsistency is partially explained by differences among study populations, based on diagnosis, age, sex, and geography, and by differences in methods of analysis and in interpretation of the results.

In a mini-review on the reliability of FVCs, it was argued that using FVCs of 3 days or longer might be the most acceptable policy, but there was no evidence that compliance rates had been accounted for in the studies reviewed (32). The authors concluded that reliability was overestimated in some reports. Another review by Bright et al focusing on the validation of FVCs summarised that excessive duration reduces patient compliance, but also a short duration may produce unreliable measurements (19). Van Haarst and Bosch found that with each additional day, FVCs showed a decrease in compliance but an increase in reliability (33). At day 3, a reliability of 80% was achieved for all FVC parameters, but compliance dropped to 73%. Beyond 5 days, the yield of additional recorded days was limited. They therefore advocated an FVC duration of 3 days but

added that the duration could be shortened or extended depending on the goal of the FVC.

The choice of diary duration may not only be based upon better validity or reliability but also on the possible behavioural therapeutic effect of keeping a diary (34). Recently, Bright et al have described the development of the first validated bladder diary for the assessment of LUTS in both male and female adults, using a psychometric validation methodology. The resulting bladder diary is recommended for use over a 3-day period and has been accepted as the ICIQ bladder diary. Urinary incontinence is assessed by the recording of pad use. The ICIQ bladder diary has been validated using a British English-speaking population and as with all such tools, will require cultural adaptation and linguistic validation for other languages using the formal ICIQ protocol [35,36].

In conclusion, voiding diaries generally give reliable data on lower urinary tract function. However, there remains a lack of consensus on diary duration and how well diary data correlate with some symptoms.

1.2.1. Bladder Diary Recommendations

1. Ask patients with urinary incontinence to complete a bladder diary to evaluate co-existing storage and voiding dysfunction. A bladder diary is recommended in order to document and communicate both objective information and to objectify observations by the patient during the diary period. Although never completely diagnostic, diary patterns may characterise normal and abnormal states (Level 2, Grade A).
2. A 1-day frequency volume chart (FVC) which includes the first morning void on the following day is a reasonable tool to gain insight into voiding habits during normal daily routine. A 3-day FVC or diary is recommended for accurate assessment of LUTS and for confirming a consistent clinical pattern in day-to-day practice. For atypical clinical patterns or clinical research, a 7-day diary might be recommended, although it should be realized that compliance decreases. Most pharmacological studies now employ a 3-day diary as a standard to optimize patient compliance (Level 2, Grade A).
3. The validated ICIQ bladder diary is recommended for use over a 3-d period. The inclusion of the diary in research studies is recommended and will provide ongoing evidence of validation, as well as the external validity of the diary (Level 3,Grade A).

1.2.2. Future Research

a) The ideal duration of a bladder diary based on the utility of the diary for diagnosis, the selection of therapy, and improving the outcomes of therapy requires further investigation.

b) The utility of paper versus electronic methods of recording voiding patterns requires further research.

c) The ICIQ bladder diary should be culturally and linguistically validated for as many other languages as well as British English and be included in research studies for further validation as well as determining external validity.

In conclusion, voiding diaries generally give reliable data on lower urinary tract function. However, there remains a lack of consensus on diary duration and how well diary data correlate with some symptoms.

1.3. Urgency scale

According to the IUGA/ICS definition urgency is ": Complaint of a sudden, compelling desire to pass urine which is difficult to defer" (2). However, in clinical practice, urgency is often accompanied by other symptoms. Urgency, with or without urgency incontinence, usually with frequency and nocturia, is the cornerstone symptom of overactive bladder syndrome (OAB) (37); while together with bladder pain, frequency and urgency are typical symptoms of interstitial cystitis or bladder pain syndrome (38). However, sometimes patients with lower urinary tract symptoms may not be able to differentiate between normal urge (desire) to void and urgency (difficult to postpone) (4). Furthermore, with history only, it may be difficult to define the severity, duration and frequency of urgency (39,40). Thus, it is important to have appropriate tools that allow accurate diagnosis, to establish tailored therapy and to assess the effectiveness of treatment. Severity questionnaires and scales have been developed specifically to assess urinary urgency, to help the patient to define the symptoms and severity and the physician to establish the therapy and its effects. Table 2 and table 3 show the validated questionnaires and scales respectively, used to assess the urinary urgency.

Table 2: Questionnaires To Assess Urgency

Questionnaire	Aim of tool	Items	Population sample	Reliability	Content Validity	Construct Validity	Concurrent Validity	Discriminant Validity	Respon-siveness	GR
UPS (Urgency Perception Score) [35]	Grading the urgency to void and assessing the reason why individuals usually void	5	Men Women OAB + LUTS LUTS (without urgency) Healthy	Yes	Yes	Yes		Yes		B
UQ (Urgency Questionnaire) [36]	Severity of urgency and urge incon-tinence Impact of urgency and urge inconti-nence on the quality of life Discomfort of urgency with VAS scale	15 + 10 VAS	Women OAB	Yes	yes	Yes	Yes	Yes	Yes	A
USIQ-QoL (Urgency Severity and Life Impact Questionnaire-Quali-ty of life) [37]	Impact of urgency on the quality of life	8	Women Men OAB	Yes	Yes	Yes		Yes		B
USIQ-S (Urgency Severity and Life Impact Questionnaire: Se-verity Symptsoms QQQ) [37]	Severity of urgency	5	Women Men OAB	Yes	Yes	Yes		Yes		B
UU Scale [38]	Monitoring efficacy treatment	10	Women Man • OAB	Yes		Yes			Yes	A

Table 3: Scales to assess the urinary urgency (39-43)

Scale	Aim of tool	Degrees of urgency	Population sample	Reliability Test-re test	Content validity	Construct Validity	Concurrent Validity	Discriminant Validity	Respon-siveness	GR
UPS (Urgency Perception scale) [39]	Severity of urgency	3	Men Women OAB		Yes	Yes	Yes		Yes	B
IUSS (Indevus urgency Severity Scale) [40]	Severity of urgency per void The ability to complete actives	4	Men Women OAB with urge Incontinence	Yes	Yes	Yes	Yes	Yes	Yes	A

Scale	Aim of tool	Degrees of urgency	Population sample	Reliability Test-re test	Content validity	Construct Validity	Concurrent Validity	Discriminant Validity	Respon-siveness	GR
PPIUS (Patients' perception of intensity of urgency scale) [41]	Severity of urgency Urgency incontinence	4	Men Women Urgency Urge incontinence	Yes	Yes			Yes	Yes	A
USS (Urinary Sensation Scale) [42]	Severity of urgency	5	Men OAB+LUTS Women OAB		Yes	Yes	Yes	Yes	Yes	A
URS(Urgency Rating Scale) [43]	Severity of urgency	5	Men	Na	Na	Na	Na	Na		C

1.4. Urinalysis

A screening urinalysis is generally recommended as part of the testing for urinary incontinence. Although in many instances a reagent strip (dipstick) urinalysis provides the necessary information, a complete urinalysis includes both chemical and microscopic analysis (49). In relation to urinary incontinence, dipstick urinalysis is not a diagnostic test. Dipstick urinalysis may indicate proteinuria, haematuria, glycosuria, pyuria and/or bacteriuria requiring further assessment (50).

Even in the absence of controlled studies, there is general consensus that the benefits of urinalysis clearly outweigh the costs involved, although the use of urinalysis should always be associated with prognostic significance (51).

The importance of urinalysis in the basic assessment of patients with urinary incontinence and lower urinary tract symptoms (LUTS) is not dependent on gender, age or aetiology. Indeed, it has been recommended in the evaluation of geriatric patients including nursing home residents who are incontinent (52), in peri and postmenopausal women (53), and in older women reporting urinary incontinence (54).

Urine dipstick testing is a useful adjunct to clinical evaluation in patients in whom urinary symptoms are suspected to be due to (UTI). Urinalysis negative for nitrite and leucocyte esterase may exclude bacteriuria in women with lower urinary tract symptoms (LUTS) (55), and should be included, with urine culture when necessary, in the evaluation of all patients with LUTS.

Pyuria and bacteriuria, detected from urinary dipstick leukocyte esterase and nitrite tests respectively, are important signs of urinary tract infection. The specificity and sensitivity of these latter tests for UTI is increased when used together compared to either individual test (56).

A positive dipstick urinalysis will prompt formal urine microscopy and culture to detect UTI prior to antibiotic treatment and/or the use of additional tests such as endoscopy and urinary tract imaging. Urinalysis negative for nitrite and leucocyte esterase reliably excludes UTI in people with UI (55) and should be included, with urine culture when necessary, in the evaluation of all patients with UI (Level 4, Grade A, based on expert opinion). Urinary incontinence may occur during symptomatic UTI (level 3) (57) and existing UI may worsen during UTI (level 3) (58).

UTI can cause irritative voiding symptoms and urgency incontinence. UTI can cause or contribute to urinary incontinence disorders in several ways. Local inflammation can serve as a bladder irritant, causing uninhibited bladder contractions. Endotoxins produced by some bacterial strains can have an alpha-blocking effect on the urethral sphincter, thereby lowering intraurethral pressures.

The clinical relevance of asymptomatic bacteriuria (without pyuria) and pyuria (without bacteriuria) in the elderly is controversial as the rate and severity of UI was unchanged after eradication of asymptomatic bacteriuria in nursing home residents (level 2; Grade B) (59). In this context, it has been observed that clinically significant urine samples can even be obtained from disposable diapers in elderly incontinent women (60).

Haematuria can indicate important pathology such as urothelial carcinoma in situ, leading to lower urinary tract storage symptoms including incontinence (61).

Glycosuria is relevant, as a potential indicator of diabetes mellitus. This can cause symptoms via several mechanisms including polyuria secondary to osmotic diuresis. Diabetic peripheral autonomic neuropathy affecting bladder innervation may be associated with impaired bladder emptying. The clinician should note that a patient does not generally demonstrate glucose into the urine until the blood glycaemia is >180 mg/dl. Consequently, a dipstick urinalysis may fail to reveal intermittently high sugars or mild diabetics. If diabetes is suspected, then a random or fasting blood sugar is preferred (62,63,64).

For many years, urine has been considered sterile, grounded on the lack of bacteria cultivated in urine samples using standard culture protocols (65). Recently, bacterial commu-

nities (microbiota) have been discovered in the female bladder and consequently, the sterile urine paradigm is no longer valid. Emerging evidence suggests that the female urinary microbiota may contribute to symptoms of urinary incontinence in women (66).

At this time, clinical use of improved culture techniques that provide additional microbial information may be of particular relevance for patients with persisting LUTS, whose standard urine cultures show no growth. While improvements in urine culture techniques offer an alternative that can be implemented immediately in most clinical laboratories, sequencing is not practical for most current clinical settings. To investigate urinary microbiota, many research groups have performed DNA sequencing analysis, in particular, 16S rRNA gene sequencing (67).

Analysis by 16S rRNA sequence and expanded quantitative urine culture provided evidence for the presence of live bacteria in urine, non-detectable by standard culture protocols. Moreover, differences in the urinary microbiota between healthy individuals and patients with LUT dysfunction were demonstrated. In the near future, urologists must consider urinary dysbiosis as a possible cause of different functional LUT disorders, with potential clinical implications in their diagnosis and treatment (67).

1.4.1. Urinalysis -Recommendation

1. Perform urinalysis as a part of the initial assessment of a patient LUTS (Level 4- Grade D).
2. Dipstick test including haematuria, glucose, leukocyte esterase and nitrite tests are recommended (Level 4 - Grade D).
3. Additional tests available on dipstick strips, such a protein, bilirubin, ketones and pH, are not essential in LUTS or incontinence context (Level 4 - Grade D).
4. Dipstick is not as accurate as urine culture, being specific for infection but not sensitive (Level 2 - Grade C).
5. Urinalysis negative for nitrite and leucocyte esterase may exclude bacteriuria in women with LUTS (Level 3, Grade C).
6. Urinary incontinence may be a symptom during a UTI, and LUTS may deteriorate during a UTI (Level 3- Grade C).
7. If a urinary tract infection is present with LUTS, reassess the patient after treatment (Level 3, Grade C). The presence of a UTI worsens existing symptoms of UI (Level 3, Grade C).
8. Do not routinely treat asymptomatic bacteriuria in elderly patients to improve urinary incontinence (Level 1; Grade A). Elderly nursing home patients with UI do not benefit from treatment of asymptomatic bacteriuria (Level 2, Grade A).

1.4.2. Future Research

Emerging evidence challenges the long-held paradigm that the healthy bladder is sterile and evidence indicates that the human urinary tract contains microbial communities; however, the role of these communities in urinary health remains to be elucidated (68). Further research to clarify the role of urinary microbiota in maintaining urinary health and inducing LUT dysfunction will help refine treatment algorithms and prevention strategies (67).

Certain microbes have characteristics that protect against uropathogens by producing antibiotics, antimicrobial peptides, and/or other antimicrobial compounds that inhibit or kill other pathogenic microbes (69).

In addition, it is well known that the vaginal and gut microbiota are able to rapidly change microbial composition, and these changes may affect urinary microbiota. Finally, urinary microbiota-based biomarkers might represent new diagnostic, therapeutic, and prognostic tools for LUT functional disorders (67). New diagnostic tools are developing: expanded quantitative urine culture and 16S ribosomal RNA gene sequencing and could give allow a greater insight into many lower urinary tract disease including incontinence (70).

1.5. Post voiding residual in the female and male patient

Post-void residual (PVR) volume (also known as residual urine, bladder residual) is the amount of urine that remains in the bladder after representative voiding. It indicates poor voiding efficiency, which may result from a number of contributing factors. It is important because it may worsen symptoms and, more rarely, may be associated with upper urinary tract dilatation and renal insufficiency. Both bladder outlet obstruction and low bladder contractility contribute to the development of PVR. PVR measurement can be accomplished within a few minutes of voiding either by catheterisation or by calculation of bladder volume using a portable ultrasound scanner.

It is difficult to determine the value of post-void residual determination in the initial assessment of urinary incontinence since most studies with data on PVR have not been performed in patients with UI. However, the populations studied have included some women with UI, and incontinent patients with neurogenic bladder disease.

Several studies have compared volumes measured with portable ultrasound scanners versus catheterisation and found portable scanners to be 85-94% accurate (71-72). A study has imaged the bladder volume after catheterisation and found that the volume of urine remaining in the bladder after catheterisation accounted for most of the difference between the two measurements (71). Bimanual palpation cannot reliably estimate the post-void residual urine volume (73). Since PVR may vary, one measurement of PVR may not be sufficient (74). PVR should probably be measured several times to increase its reliability. In geriatric patients, Griffiths et al found a significant variability in PVR measurement depending on the time of the day, with the greatest volume occurring in the morning (75). A non-representative PVR is particularly common if the patient's bladder is not full enough to yield an urge to void. Special consideration is required in male patients with incontinence and bladder outlet obstruction, in incontinent neurogenic patients who may demonstrate combined disorders of storage and emptying (76), and preoperatively in female patients being considered for incontinence surgery.

An increased PVR alone is not necessarily a problem, but if combined with high pressures it can lead to upper tract problems. If related to UTI's, PVR needs to be treated since UTI's cannot be eradicated in the presence of an infected residual. A significant PVR also decreases the functional bladder capacity and thus contributes to urgency/frequency, urgency incontinence and nocturia. However, a Scandinavian study in nursing home residents found that an elevated PVR was not associated with bacteriuria and incontinence (77). Since recurrent UTI's, due to elevated PVR, can be associated with urinary incontinence it remains necessary to measure PVR in incontinent patients with UTI.

Review of the literature fails to show an evidence-based specific maximum PVR that is considered normal, nor is there a minimal PVR that is considered abnormal. The amount of residual urine that precludes treatment by various therapies has also not been determined. The AHCPR guidelines state that, in general, a PVR less than 50 ml is considered adequate bladder emptying and over 200 ml is considered inadequate emptying (expert opinion of the panel members) (78).

"Normal values" of PVR have been determined in several groups of non-incontinent and incontinent women. Gehrich et al studied 96 women (mean age 60 ± 11 yrs) that were seen in a well-women clinic. These women had no history of incontinence, retention, symptomatic prolapse or neurologic disorders. Most (97%) had a minor (asymptomatic) degree of prolapse, 80% were post-menopausal and 30% had had a hysterectomy. The median PVR was 19 ml (range 0-145 ml; mean 24 ± 29 ml); only 5% had PVR > 100 ml. Only, age > 65 yrs was associated with higher PVR. This study gives some indication of what might be considered normal or relatively normal (79).

Tseng et al studied 107 women with urodynamic stress incontinence. They found a mean PVR of 62.5 ml by bladder scan and 38.5 ml by catheterization. Only 15.9% had a PVR greater than 100 ml. The PVR determined by bladder scan offered a sensitivity of 64.7% and a specificity of 94.3% in detecting PVR greater than 100 ml (80). Haylen et al studying women with lower urinary tract dysfunction found that 81% had a PVR of less than 30 ml (81). Fitzgerald et al studied women with urgency, frequency and urge incontinence: 10% had an elevated PVR of > 100ml. In these women with OAB, the following independent risk factors of increased PVR were found: vaginal prolapse, symptoms of voiding difficulty and absence of stress-incontinence (82). Lukacz et al found that only 11% of women with pelvic floor disorders had an elevated PVR (83). Wu and Baguley studied 319 consecutive patients (196 women, 123 men) in a subacute general, but predominantly geriatric, rehabilitation unit. 22 had been admitted with a catheter and were excluded. Of the 297 "asymptomatic" patients, 21.5% had PVR volumes of 150 ml or more. Patients with elevated PVR (> 150 ml) were significantly more likely to have a urinary tract infection at admission and have urinary incontinence on discharge (84).

Milleman et al retrospectively reviewed 201 women (mean age 55; range 20-90) who presented with complaints of urinary frequency, urgency and /or urge incontinence. 19% had an elevated PVR of more than 100 ml (mean 211 ml; range 100-997 ml). On multivariate analysis the following independent predictors of raised PVR were identified: age > 55 yrs [OR 3.71], prior incontinence surgery [OR 4.32], a history of multiple sclerosis [OR 15.32] and pelvic organ prolapse grade 2 or greater [OR 3.61] (85).

In summary, an elevated PVR > 100 ml was found in 5% of women visiting a well-women clinic, in 10-19% of women with OAB, in 11% of women with pelvic floor disorders and in 15.9% of women with urodynamic SUI. Overall, incontinent women have a slightly higher risk of elevated PVR compared to asymptomatic subjects. Does a significant PVR have an impact on the outcome of treatment in patients with incontinence? Nager et al studied the predictive value of urodynamic measures on stress continence outcomes after surgery for stress urinary incontinence. They found that urodynamic measures do not predict outcomes. However, since women with PVR > 150 ml were excluded in this study, one can only conclude that PVR volumes < 150 ml did not have an adverse impact on stress continence outcomes (86).

Since there is no consensus on what constitutes a significant PVR in women; therefore, the Panel suggests the additional use of Bladder voiding efficiency (BVE) which is the proportion of the total bladder volume that is voided by the patient. The BVE can be defined as a percentage: BVE = (voided volume/[VV]+PVR) x 100. This may be a more reliable parameter to evaluate poor voiding (87)

A PVR measurement is recommended in men with symptoms suggestive of bladder outlet obstruction. It is a well know clinical principle that chronic urinary retention can be associated with overflow incontinence [ischuria paradoxa]. Apart from this there are unfortunately insufficient data on the role of PVR and its significance in male urinary incontinence. Therefore, there are insufficient data to draw conclusions about the association of PVR and urinary incontinence in men as well as the association of PVR and the outcome of incontinence treatment in men.

In the geriatric patient, a PVR should always be measured since it decreases functional bladder capacity and contributes to urgency/frequency, urgency incontinence and nocturia. PVR should probably be measured several times to increase its reliability. In elderly patients, Griffiths et al found a significant variability in PVR measurement depending on the time of the day; the greatest volume occurred in the morning (5). Counter-intuitively, a Scandinavian study in nursing home residents was unable to show an association between an elevated PVR and bacteriuria and incontinence (77).

1.5.1. Recommendations

1. Varying degrees of decreased bladder emptying, or urinary retention, may be a cause of LUTS that are associated with symptoms of decreased urinary storage. The decision to perform a PVR in disease specific sub-groups of incontinent patients should be based on an association of the condition with poor bladder emptying, whereas in individual patients this decision may be based on symptoms or physical findings (Level 2, Grade B).
2. Female patients who present with storage specific symptoms, with normal sensation and no complaints of decreased bladder emptying, and no anatomical, neurological, organ-specific, or comorbid risk factors for retention may be assessed for bladder emptying by history and physical examination alone (Level 4, Grade B).
3. Due to the increased possibility of bladder outlet obstruction due to prostatic obstruction in the male patient, the threshold for investigating residual urine in the male is significantly lower (Level 4,Grade D).
4. A PVR should be performed in incontinent patients when decreased bladder emptying is suspected, especially if treatments that decrease bladder contractility or increase outlet resistance are being considered (Level 4,Grade D).
5. Non-invasive ultrasound measurement of PVR is as accurate as measurement by catheterization and is therefore the preferred method (Level 4,Grade A)
6. A palpable bladder on physical examination is an indication for referral to a specialist (Level 3, Grade D)

1.5.2. Future Research

1. Development of more specific indications for PVR testing for diagnosis and prior to instituting therapy based on history, physical examination and disease specific findings.
2. Further development of low cost, minimally invasive, and accurate means of measurement of PVR that do not require catheterisation.

V. SPECIFIC POPULATIONS: EVALUATION OF THE FEMALE PATIENT

1. ESTABLISHING THE TYPE OF URINARY INCONTINENCE IN WOMEN

The aims of the assessment of women with urinary incontinence are the documentation and characterisation of type of incontinence, its timing and its severity, the differential diagnosis, prognosis evaluation and planning of treatment (88). The classification of subjective diagnosis of urinary incontinence into stress, urgency and mixed incontinence is basically clinical. Generalist physicians may identify a woman with incontinence through the review of systems during a routine visit or the patient may initiate discussion about incontinence problems. If a woman reports leaking urine, she is incontinent, and the symptoms should not be ignored. Assessment should include history, symptom assessment, and physical examination. A careful urological history may be helpful to make a first subjective differentiation between the types of incontinence. In fact, as shown in Holroyd-Leduc's meta-analysis (18), simple questions to diagnose stress or urgency urinary incontinence have high reliability in women, with the percent agreement between repeated questioning estimated at 90% for stress, urgency and mixed urinary incontinence sub-types (18).

Further questioning on the frequency, severity of leakage and degree of bother, is essential for planning treatment and counselling of the women. The leakage should also be quantified if possible, by using voiding diaries (89, 90), pad tests (the 1-hour pad test the most used) (91), and evaluation of the number of pads used per day. Finally, a general history and medication review are helpful to classify the different types of incontinence into uncomplicated and complicated. The definition of complicated or uncomplicated SUI is not widely agreed. According to FIGO's consensus uncomplicated stress urinary incontinence (SUI) is UI without further storage symptoms, absence of voiding symptoms and without history of recurrent urinary tract infections (RUTI), no prior extensive pelvic surgery or prior surgery for stress incontinence and no medical conditions that can affect the lower urinary tract (92)). Complicated SUI does not fulfil the uncomplicated SUI criteria (92).

In a multicentre single nation database (93) SUI has been defined as uncomplicated when the presenting history of SUI has been present for at least 3 months, the post-void residual urine volume is < 150 ml, urinalysis or urine culture is negative and clinical assessment of urethral mobility, with an expressed desire for surgery for SUI, and a positive provocative stress test. Conversely complicated SUI has been defined as incontinence in women with previous surgery for incontinence, history of pelvic irradiation, pelvic surgery within the previous 3 months, and anterior or apical pelvic organ prolapse (POP) of 1 cm or more distal to the hymen (88). Nevertheless, several studies (12, 93) have shown that patient history alone is not completely accurate in determining the type of incontinence. Symptom assessment by validated questionnaires can provide a very helpful complement to the patient history, to assess the impact of urinary incontinence on quality of life, and the symptoms (94-98). In the literature there are no studies that prove the usefulness of physical examination to typify the urinary incontinence. However, it is recommended to identify risk factors as well as significant associated or underlying pathology, such as significant prolapse, obstruction, neurological disease and malignancy (18).

2. GENERAL MEDICAL HISTORY

The history should include the nature and impact of incontinence symptoms, gynaecological and obstetric history, relevant coexisting diseases, current medications, functional status, review of environmental factors and lifestyle factors, previous treatment history, and current goals and expectations of treatment. In fact, the main goal of the general medical history in women with urinary incontinence is trying to identify all comorbidities that could initiate or worsen UI or even those which could negatively impact treatment success rates. The main factors associated with urinary incontinence are: obesity (99,100), diabetes and other metabolic conditions (101), neuropsychiatric disorders (102, 103,104), occupations involving heavy lifting, smoking, previous pelvic surgeries and constipation (105-106).

Neurological diseases, pelvic neoplasms (malignant or benign) and radiation therapy can also lead to incontinence. Therefore, a careful surgical history should be taken, and specific attention should be given to pain and other sensory disturbances, especially on sacral nerve dermatomes, which could imply a neurologic disease or an intrapelvic entrapment.

Pelvic pain can also be associated with apical support defects (107), endometriosis (108) or pelvic congestion syndrome (109). The latter two, can be associated with neurogenic urgency/urge-incontinence, when endometriotic lesions and/or varicosities entrap sacral nerves or involve the inferior hypogastric plexus (110,111).

Anorectal dysfunction, such as anal incontinence and obstructed defecation must also be carefully assessed and treated simultaneously, as these symptoms are strongly associated with urinary incontinence and share a common aetiology – pelvic support defect.

A careful surgical history must be taken, especially for pelvic reconstructive procedures, radical treatment of pelvic malignancies or endometriosis, as such procedures are associated with a high risk of intrapelvic nerve damage (112,113,114,115,116). Understanding the details of previous incontinence procedures is also important to plan treatment of recurrent/de novo/persistent SUI and/or urgency incontinence (117).

3. SYMPTOM ASSESSMENT

Determining if urine is involuntarily lost with effort or exertion, or on coughing or sneezing, is commonly used to help identify stress incontinence (118)

For example, a woman can be asked, "Do you lose urine during sudden physical exertion, lifting, coughing, or sneezing?". To diagnose urgency incontinence, the women is asked about the association between involuntary urinary leakage and feelings of urinary urgency. An example of such a question is "Do you experience such a strong and sudden urge to void that you leak before reaching the toilet?" (119).

As classification of Urinary incontinence is clinical, a careful symptom assessment is mandatory, and it is particularly important to plan the appropriate treatment. Furthermore, it is important to quantify the degree of leakage before and after therapy to evaluate the impact of the disease on quality of life, and to identify patients with

complicated incontinence that need to be referred for specialised management (92). To achieve these objectives there are several tools including history and clinical assessment together with validated questionnaires, voiding diaries and pad tests. Many validated questionnaires have been developed to assist in the evaluation of urinary symptoms and to help in diagnosing the type of urinary incontinence (94-98). They may be used in combination with history and clinical examination. The International Consultation on Incontinence (ICI) has developed an ICI questionnaire (ICIQ) to assess pelvic floor function in both clinical practice and research settings (120,121). It includes many modules about both female and male urinary symptoms or pelvic dysfunctions in particular urinary incontinence (ICIQ-UI). It has been shown that the short form (ICIQ-SF) correlates well with the 1-hour and 24-hour pad test for evaluation of the severity of SUI (122). The severity of SUI seems to be correlated with Intrinsic sphincter deficiency, although the diagnosis is possible only by urodynamic study (Urodynamic Valsalva leak point pressure (VLPP) < 60 cm water is believed to be diagnostic) (123).

The Modified Gaudenz-Incontinence questionnaire increases the likelihood of accurately diagnosing both stress and urgency incontinence, while the Bladder Instability Discrimination Index (96) and Versi's questionnaire (124), although useful to diagnose urgency and stress incontinence, are both complex and sometimes not easily used in the practical clinical setting. The patient-completed Questionnaire for Urinary Incontinence Diagnosis contains 6 questions, of which 3 are intended to predict stress incontinence and 3 are intended to predict urgency incontinence (125). It appears to increase the likelihood of correctly diagnosing urgency incontinence (positive LR, 3.7; 95% CI, 1.6-9.0; negative LR, 0.27; 95% CI, 0.17-0.42), but is not as helpful in the diagnosis of stress incontinence (positive LR, 2.8; 95% CI, 1.6-4.9; negative LR, 0.21; 95% CI, 0.12-0.37) (18). The Urogenital Distress Inventory, that is a widely used symptom tool, is a questionnaire helpful to assess LUTS bother, including incontinence, in women (126). The Questionnaire for Urinary Incontinence Diagnosis is a reliable 6-item questionnaire able to diagnose stress urinary incontinence and urgency urinary incontinence in a referral urogynaecology patient population with accuracy (98). Overactive bladder symptom scores are also very useful for women with storage symptoms including urgency incontinence (37) (39-47) (127).

4. PHYSICAL EXAMINATION (FEMALE)

The main objective of physical examination is to detect the signs, defined as any abnormality indicative of disease or a health problem, discoverable on examination of the patient; an objective indication of disease; or a health problem. No studies were found to support evidence that clinical examination improves care for diagnosing the type of urinary incontinence (UI) in women. Nonetheless, there is a wide consensus recommending clinical examination as an important part of assessment of women with UI, including: abdominal, neurological, gynaecological and pelvic examination with the purpose of detecting associated or underlying pathology that can explain the lower urinary tract symptoms (LUTS). Height and weight should be recorded so that the body mass index can be calculated (Kg/m2) as an important risk factor for UI in women of all ages (125,128, 129,130).

a) Abdominal examination. Observation of the abdomen may yield evidence of scars from previous surgeries or abdominal stretchmark. Increased abdominal stretchmarks may be found in association with other markers of abnormal collagen metabolism and are more likely in patients with prolapse and stress incontinence (131,132).

Bladder fullness or retention may be identified by abdominal palpation or by suprapubic percussion or bimanual vaginal examination. In one study designed to look at the clinical utility of basic assessment in elderly women, palpable enlargement indicated a post-void residual volume of at least 300ml (132). Other abdominal masses or distension can be also detected by abdominal examination. Tenderness or mass palpation in the renal area must be excluded by examination.

b) Neurological examination. Neurological signs related to S2-4 can suggest a possible neurogenic lower urinary tract or pelvic floor dysfunction. Saddle anaesthesia will occur with lesions affecting S2-S4. Assessment of gait, abduction and dorsiflexion of the toes (S3) and sensory innervation to the labia minora (L1-L2), sole and lateral aspect of the foot (S1), posterior aspects of the thigh (S2), cutaneous sacral reflexes, bulbocavernosus and anal reflexes are additional features of the neurological exam that may be assessed. A rectal examination will provide a subjective assessment of resting and voluntary anal tone (S2-S4). For patients with possible neurogenic lower urinary tract dysfunction, a more extensive neurological examination is indicated. In the elderly, full cognitive and mobility assessments are also recommended. An evaluation of hand dexterity should be performed when self-catheterization is being considered as a treatment option for incontinence associated with chronic urinary retention.

c) c)Gynaecological examination (vulva and vagina). At present there are few scientific data documenting the parameters of a normal pelvic examination in women of various ages and with various obstetric histories. The components of the examination have not been universally agreed upon. Gynaecological examination should include: inspection of the vulva, perineum and vagina, as well as vaginal palpation, with the evaluation of pelvic floor muscle resting tone, muscle mass and defects, ability to contract and relax. Full list of PFM assessment has been recently published and all medical practitioners should strive to use a standard assessment (133). The location of any vaginal pain should be noted and any tenderness over the course of the pudendal nerve. Bimanual pelvic examination is also part of gynaecological examination, with the assessment of the size, location, and mobility of the uterus, the adnexal structures. Palpation of any pelvic mass or unusual tenderness is possible by vaginal examination together with suprapubic palpation.

Vulval inspection allows a description of the skin and the presence of any abnormal anatomical features (atrophic changes, scars, erythema of the vulva, lichen sclerosis, cysts, other tumours). With the inspection of the external genitalia, we can also find an urethral caruncle (a small, soft, smooth friable red outgrowth along the edge of the urethra) or urethral mucosal prolapse, a small eversion of the urethral urothelium generally involving the posterior lip.

Another important part is the observation of the perineal movements when the patient is asked to contract, cough or bear down. This is a way to evaluate the pelvic floor muscles function. We can observe a perineal elevation as the inward (cephalad) movement of the vulva, perineum, and anus (expected during voluntary PFM contraction) and a perineal descent as an outward (caudal) movement of the vulva, perineum, and anus (small descent expected during bearing down). These movements may also be palpated

during vaginal and rectal PFM assessments. During cough the perineum should show no movement, or a ventral movement may occur due of the contraction of the pelvic floor muscles; a downward movement indicates a weak pelvic floor. Decreased ability to relax the PFM may also be associated with PFM disorders and may be related to UI or pain conditions. Due to the inherent subjective nature of visual and digital assessment, many of these characteristics and properties of the PFM are more accurately assessed using investigations and referral to a pelvic floor muscle specialist would be advised.

With the vaginal examination we obtain information about of the vaginal length and mobility, presence of scarring and/or pain, and level of oestrogenisation.

Vulval and vaginal atrophy (VVA) is a common condition, resulting from the effect of oestrogen deficiency on the female genitourinary tract including vagina, labia, urethra and bladder. A consensus conference panel introduced a new terminology for vulvovaginal atrophy: Genitourinary syndrome of menopause (GSM) (134). This syndrome includes symptoms of dryness, burning, and irritation and sexual symptoms of pain and dryness. Urinary symptoms and conditions of dysuria, urgency, and recurrent urinary tract infections (UTIs) are associated with vaginal atrophy (135). Pelvic examination helps to exclude other vulvovaginal conditions that can cause similar symptoms including vulvovaginal dermatoses, infection, or cancer.

Examination of the external genitalia shows a reduced mons pubis and labia majora bulk, reduced labia minora with a narrow introitus, a pale vestibular tissue and an erythema of the urethral meatus. Urethral caruncle, a benign outgrowth of inflammatory tissue arising from the posterior urethral meatus, is common finding related to hypoestrogenism. Vaginal examination shows an atrophic epithelium, shiny and dry with a loss of rugation. With progression of GSM, severe sings of atrophy can be observed as the attenuation of the vaginal fornices and also minimal blunt trauma from the speculum may result in petechiae or bleeding due to epithelial thinning and friability. With GSM, vaginal pH is typically greater than 5.0. History and examination are essential to make a correct diagnosis of GSM and the main goal of its treatment is to alleviate symptoms. Once other causes of these symptoms have been excluded, treatment can be approached in a stepwise fashion based on symptom severity: non-hormonal in women with mild symptoms and with more severe symptomatology hormonal therapies are indicated (low-dose vaginal oestrogens, vaginal DHEA inserts, and oral ospemifene) (136).

Urethral diverticulum presenting with a palpable suburethral mass, is another pathology that can be detected on vaginal examination. The most common finding is a tender anterior vaginal wall mass and if the diverticulum communicates with the urethra, it may be possible to express a purulent exudate from the urethra. Occasionally, a stone may develop within the diverticulum. Many patients with urethral diverticula are asymptomatic and need no treatment. Symptomatic patients report swelling of the urethra, recurrent cystitis, dyspareunia, urinary incontinence, urinary dribbling after passing urine and voiding difficulties (137-139). In a large cohort of women having urethral diverticulum excision, 29% had urodynamic stress urinary incontinence (USUI)at presentation and 38% had postoperative USUI (140).

d) d)Anorectal examination. The patient can be in left lateral position with hips flexed or in dorsal lithotomy. Digital rectal examination allows assessment of resting anal sphincter (AS) tone and voluntary squeeze. Strength can be classified as good or poor, in the absence of any quantitative assessment. Ano-rectal abnormalities can be found by a combination of inspection and digital examination. Painful examination may be associated with haemorrhoids, anal fissure, infection or pilonidal abscess, rectovaginal or anocutaneous fistula or tumour; and may confirm presence or absence of faecal impaction. Anal sphincter tear may be recognized as a palpable AS gap due to a previous obstetric or surgical damage (141).

e) Specialised test for diagnosis of UI in Women

Urinary incontinence as a sign, is the observation of involuntary loss of urine on examination, this may be urethral or extra-urethral (1). Urgency urinary incontinence is the observation of involuntary leakage from the urethra synchronous with the sensation of a sudden, compelling desire to void that is difficult to defer. The observation of leakage through the vaginal it is an extra-urethral incontinence (observation of urine leakage through channels other than the urethral meatus, e.g., fistula). Stress urinary incontinence (clinical stress leakage) is the observation of involuntary leakage from the urethra synchronous with effort or physical exertion, or on sneezing or coughing (1). Stress incontinence observed only after the co-existent prolapse reduction, is a sign of occult or latent stress incontinence (2).

Three special manoeuvres can be performed during the initial assessment of women with urinary incontinence: the stress test, the Q-tip test, and the pad test.

Stress Test. In women with the symptom of stress urinary incontinence (SUI), stress test it is important as an objective measure to confirm the diagnosis, particularly when surgical treatment is planned.

The stress test involves observation for urine loss when women, with a full bladder, are coughing forcefully or during a Valsalva manoeuvre. If the patient leaks with the onset of the cough and terminates with its cessation, the test is positive and likely to be a SUI. It is an easy test to perform in a single visit and the results are immediately available. The stress test performed with coughing appears to be a reliable test, reliability data are not available for tests performed using the Valsalva manoeuvre. This procedure can be performed while the patient is in the lithotomy position, if no leakage is observed, the test should be repeated in standing position (2). A negative supine cough stress test (CST) does not exclude incontinence. Rimstad et al. found that in the supine position only 49% of the women leaked during the stress test (142). Earlier studies have also found that the supine CST test has low sensitivity (143). A stress test is helpful for diagnosing the type of urinary incontinence. When SUI is suspected by the symptoms, the CST test is the most reliable clinical assessment for confirming the diagnosis (144). When compared with multichannel urodynamic studies, the CST test demonstrates good sensitivity and specificity for SUI (145-147). A detrusor contraction may occasionally cause leakage during a CST and we cannot exclude this possibility of a detrusor overactivity (DO).

Kulseng-Hanssen et al have demonstrated that only 5 of 100 stress and mixed incontinent women had a detrusor contraction simultaneously with stress leakage, and in none was DO the sole cause of leakage (148). Lagro-Janssen et al. noted that the presence of urge incontinence in the absence of leakage with coughing (negative CST) excluded the possibility of SUI and had a high specificity for the diagnosis of DO (149). Holroyd-Leduc et al. reviewed existing

evidence on the diagnostic accuracy of the stress test for stress urinary incontinence (18). Results from the meta-analysis revealed that a positive stress test increases the likelihood of a diagnosis of SUI (summary LR, 3.1; 95% CI, 1.7-5.5), while a negative test decreases the likelihood (summary LR, 0.36; 95% CI, 0.21-0.60).

The main limitations of this test are the variability of cough intensity and bladder volume. A working group of the International Continence Society (ICS) has developed an educational module, comprising a Powerpoint™ presentation and evidence base manuscript, to instruct on the performance, interpretation, and reporting of the CST in a standardized manner: the ICS-Uniform Cough Stress Test (ICS-UCST) (150).

Pad test. A pad test it is a non-invasive diagnostic tool, it involves the continuous wearing of continence pads for a set period of time. The objective of pad testing is to quantify the volume of urine lost by weighing a perineal pad before and after some type of leakage provocation. It is as an optional test for the evaluation of urinary incontinence, to distinguishing continent, from incontinent women, but it cannot contribute to distinguish the type of urinary incontinence (151,152). Holroyd-Leduc et al. reported that a positive pad test increases the likelihood of an incontinence problem (LR, 3.3; 95% CI, 2.0-5.4), while a negative pad test makes an incontinence problem much less likely (LR, 0.11; 95% CI, 0.05-0.27). (18). Price and Noblett have demonstrated that in women with symptoms of predominant stress urinary incontinence, the CST is more reliable than the pad test (147). Pad tests can be divided into short term tests, usually performed under standardized office conditions, and long-term tests, usually performed at home for 24–48 hours. Pad tests are generally performed with a full bladder or with a fixed known volume of saline instilled into the bladder before beginning the series of exercises.

The 1-hour pad test has been standardized by the International Continence Society (ICS-pad test) (152). This short test is appropriate in routine evaluation of patients during initial evaluation. However, it can be affected by many factors, if either the patient or physician have doubts about the accuracy of the initial test, evaluation should be extended by an additional hour or repeated. A 20-min test has been described by Hahn as a short-term pad test initially was carried out with water infusion into the bladder (153). Later it was demonstrated that when performed with a bladder volume of strong-desire to void, its sensitivity is better than the 1-hour pad test for women with stress urinary incontinence (154). The 24-hours test is more reproducible than a 1-hr test, but longer testing requires more preparation and a greater commitment on the part of the patient. A pad weight gain >1 g is considered positive for a 1-hour test, and a pad weight gain >4 g is positive for a 24-hour test. These values may increase in situations of increased perspiration (155). There is wide variation in the pad weight gain in incontinent women participating in clinical trials. Although some studies have found high test-retest correlations in pad tests (156,157) other studies have reported low inter-subject and intra-subject reliability (158,159). The correlation coefficient between total leakage during two long-term tests appears to exceed of standard 1-hour tests (160-161).

A pad test is a good instrument for evaluating the severity of urinary incontinence. However, it is not a perfect “gold standard” for UI severity. Pad test should always be interpreted in conjunction with standard self-assessment questionnaires including the bother index. In the analysis of 1-hour pad test, an increase of 1–10g is classified as representing mild incontinence, 11–50g moderate and >50g severe incontinence. Good correlation has been reported by Abdel-Fattah et al between the self-assessment questionnaires and the 1-hour pad test. The King’s Health Questionnaire showed a 96% sensitivity and 93% specificity of a 1-hour pad test in identifying incontinent patients (161). The good correlation between self-assessment questionnaires and 1-hour pad test, but not the 24-hour pad test supports the value in standardization. Good correlation with the 24-hour pad test and the International Consultation on Incontinence Questionnaire—Short Form (ICIQ-SF) has been documented (162). The values for 24-hour pad test are classified as follows: Mild (4–20g/24hour), moderate (21–74g/24h.), and severe (>75g/24hr) incontinence ([163). However, these values have to be considered with caution as they may change depending on the sample characteristics (age, proportion of women with more severe incontinence, etc). In another study comparing pad-weighing test with severity index (ISI), the mean pad-weighing (grams per 24 hours, 95% confidence intervals) , were : 7 for slight, 39 (26-51) for moderate, 102 (75-128) for severe, and 200 (131-268) for very severe UI. Spearman’s correlation coefficient for pad weighing results and severity index was 0.58 ($p < 0.01$), and bother increased significantly with increasing severity (164). A recently published study aimed to assess the correlation of a 20-min pad test, with the subjective urine leakage amount perceived by the patient and a moderate positive correlation was demonstrated (165). The main limitation of the pad test, as a diagnostic tool for UI, is the value for the cut off of a positive test and the inability to distinguish between types of incontinence. This limitation is especially important when this test is used as an outcome measure, when surgical treatment of stress urinary incontinence is evaluated, as these women can suffer “de novo” urgency urinary incontinence.

Q-tip test. Stress urinary incontinence (SUI) is classified based on urethral mobility. Urethral hypermobility is associated with greater surgical success after suburethral sling placement. Assessment of urethral mobility is an essential part of pelvic examination in women with symptoms of SUI, especially when surgery is the elected treatment. The Q-tip test has traditionally been used to assess mobility of the urethro-vesical junction. The test involves placement of a lubricated cotton swab or Q-tip in the urethra to the level of the bladder neck while the woman is in the lithotomy position. The degree of rotation of the free end of the swab is then measured while the woman performs a Valsalva manoeuvre. The free end should remain horizontal if no anatomical defect is present. If the free end moves above the horizontal, urethral hypermobility is suspected, this can occur in patients with stress urinary incontinence. A straining angle of 30º or greater relative to the horizontal during Valsalva or cough has been considered clinically relevant and defined as hypermobility (166,167). In a meta-analysis by Holroyd-Leduc et al. that examined the accuracy of the Q-tip test for diagnosing stress urinary incontinence, only two relevant studies met the inclusion criteria (18). Results of the analysis suggested that a positive Q-tip test does not accurately predict the diagnosis of stress urinary incontinence in women. Although the Q-tip test is a useful tool, it may be uncomfortable for many women due to the insertion of a rigid cotton tipped swab into the urethra. The identification of a visual examination tool to determine urethral hypermobility would help to eliminate this uncomfortable test. A study compared the diagnostic accuracy of Q-tip test with visual urethral mobility examination (VUME) and concludes that, VUME is a diagnostic alternative to Q-tip test for the initial assessment of urethral hypermobility when performed by an experienced provider and is preferred by women (168). With the intention of avoiding the insertion of the swab into the urethra, a study compared a vaginal swab test with the urethral Q-tip test for and demonstrated that a vaginal swab test with a cotton-tipped swab placed in the vagina 3 cm proximal to the external meatus in the midline at rest, is equivalent to the standard Q-tip

test in measuring urethral mobility with less discomfort for patients (169).

Another non-invasive method to identify women with urethral hypermobility is transperineal ultrasound with an excellent inter-rater reliability (170,171). This more specialised testing with pelvic floor ultrasound and other imaging techniques appears to be gradually replacing the Q-tip test for a more advanced assessment of bladder neck and urethral hypermobility, however they are limited by their cost, availability and requirement of special training.

5. PELVIC ASSESSMENT: PELVIC FLOOR STRENGTH AND PELVIC ORGAN PROLAPSE

5.1. Assessment of pelvic floor muscle strength

Pelvic floor muscles (PFM) play an important role in the continence and support of the pelvic organs. The tone, the strength with a voluntary contraction and their relaxation, should be evaluated during the initial pelvic examination of women with urinary incontinence and other pelvic floor dysfunctions. When assessing PFM strength, we ask the patient for voluntarily squeezing of the pelvic floor, while pulling upward and inward, consequently a maximum isometric voluntary contraction is generated. The IUGA/ICS Joint Report of Terminology for Female Pelvic Floor Dysfunction identifies visual inspection, digital palpation, EMG, dynamometry, and ultrasound as acceptable techniques for assessing PFM contraction and relaxation, although does not designate any method as a “gold standard” for quantifying PFM strength (172). The different PFM strength measures used clinically are moderately correlated (173).

Due to the location of the PFM inside the pelvis, the evaluation of the PFM function is limited when only observation is used. Vaginal palpation is accepted as subjective method to evaluate muscle function and is perhaps the most accessible and valid measure for PFM tone and strength (174,175). There is a number of published scales to assess PFM contractility measured although by digital vaginal palpation (176). Common scales include the ICS scale: absent, weak, normal, moderate, strong (177), modified Oxford grading scale 0-5(178) and the Brink scale which includes 3 components of pressure, displacement and time (179). There is no one best scale and assessors are encouraged to understand the limitation of each test.

Other PFM factors to assess include voluntary muscle relaxation (absent, partial, delayed, complete), sustained contraction endurance (the number of seconds the patient can sustain maximal or near maximal contraction), repeatability (the number of times a contraction to maximal or near maximal force can be repeated), coordination, and co-contraction. Resting tone is also important to assess using the scale increased tone, normal tone or decreased tone (without further gradations). The terms hypertonic and hypotonic are reserved for patients with neurological conditions. If possible, it is desirable to document findings for each side of the pelvic floor separately to allow for any unilateral defects and asymmetry (11).

The ICS report into the standardization of terminology of pelvic floor muscle function and dysfunction outlines 5 categories of PFM diagnosis:

a) Disorder of increased tone: PFM tension myalgia - a condition of pain and increased PFM tone

b) Disorder of PFM pain: PFM myalgia - a condition of PFM pain

c) Disorder of decreased tone - due to a decrease in either contractile tone (decrease in any contractile functions) or non-contractile tone (decrease in support of connective tissue)

d) Disorder of coordination: PFM dyssynergia - paradoxical PFM contractions during functional activities when relaxation is required for example vaginismus and obstructed defaecation syndrome.

e) Pudendal neuralgia: neuropathic pain syndrome caused by mechanical or non- mechanical injury of the pudendal nerve (11).

The morphology and integrity of the pelvic floor muscles may be also assessed by palpating its insertion on the inferior aspect of the pubic rami.

A discontinuity of the levator muscle at its attachment to the inferior pubic ramus is defined as levator injury / avulsion. This finding is more reliably assessed using 3D ultrasound imaging. Levator injury has been found to be associated with pelvic organ prolapse (180).

5.2. Assessment of Pelvic Organ Prolapse

Urinary incontinence and pelvic organ prolapse are separate clinical entities that often coexist. It is important to assess pelvic organ prolapse in a woman with symptoms of urinary incontinence, considering that the variants of the normal statics of the pelvic organs are not well established. Additionally, we must take into account that descent of a specific vaginal compartment, identified on pelvic examination, does not correlate well with the expected corresponding urinary symptoms (181). Assessment of pelvic organ prolapse described in this section is in accordance with the joint guidelines produced by IUGA/ICS in 2016 (182, 183). Pelvic organ prolapse (POP), as a sign, is the descent of one or more of the anterior vaginal wall, posterior vaginal wall, the uterus (cervix) or the apex of the vagina (vaginal vault or cuff scar after hysterectomy). The term stress incontinence on prolapse reduction (occult or latent stress incontinence) describes the development of stress urinary incontinence after the reduction of co-existent prolapse by surgical repair or pessary insertion (182,183). The presence of any sign of POP should be correlated with relevant POP symptoms, commonly this correlation would occur when the prolapsed organ reaches at the level of the hymen or beyond (184,185). All examinations for pelvic organ prolapse should be performed with the woman with an empty bladder and preferably an empty rectum. An increasing bladder volume has been shown to restrict the degree of descent of the prolapse (186). The choice of the woman’s position during examination, e.g. left lateral (Sims), supine, standing or lithotomy is that which can best demonstrate POP in that patient and which the woman can confirm as the maximal extent she has perceived e.g. by use of a mirror or digital palpation (187). When there is a discordance between symptoms and examination, we have to consider that the degree of prolapse may be worse after a lengthy time in the upright position as, in standing position, women with POP have more often symptoms and more severe discomfort. (188,189).

Pelvic organ prolapse staging. Each aspect of POP, uterine (cervical) prolapse, anterior vaginal wall (compartment), posterior vaginal wall (compartment), vaginal vault (cuff scar) prolapse can and should be subject to a clinical staging. The hymen always remains the fixed point of reference for prolapse description. To stage POP means identifying the lowest extent of any part of the vaginal wall

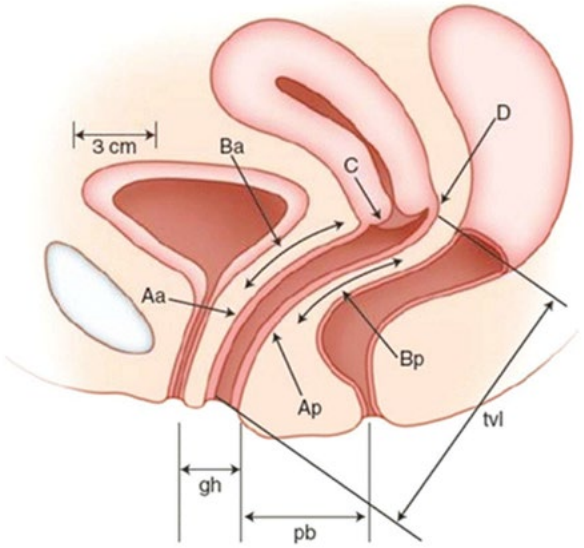

Figure 1: The six sites (Aa, Ba, C, D, Bp and Bp), the genital hiatus (gh), perineal body (pb) and total vaginal length (tvl) used cm above or proximal to the hymen (negative number) or cm below or distal to the hymen (positive number) with the plane of the hymen being defined as zero (0). Alternatively, a three by three grid can be used to organize concisely the measurements as noted in Fig. 2.

Anterior wall Aa	Anterior wall Ba	Cervix or Cuff C
Genital hiatus gH	Perineal Body pB	Total Vaginal Length TVL
Posterior wall Ap	Posterior wall Bp	Posterior Fornix D

Figure 2: Grid presentation of POP-Q measurements.

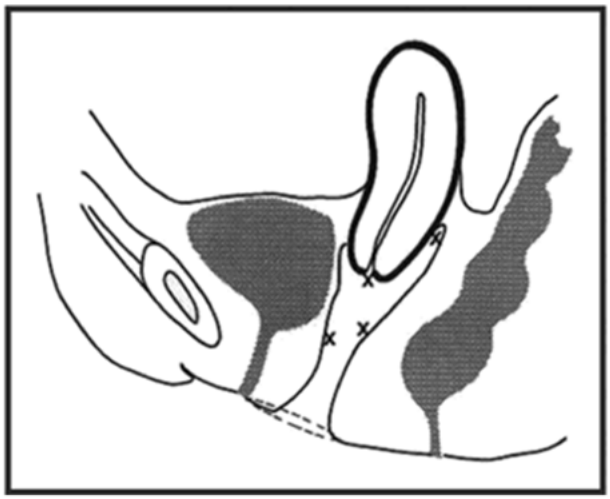

Figure 3: Simplified POP-Q.

or uterus. When this reaches close to the hymenal ring (at least stage 2), the prolapse is usually symptomatic. According with the IUGA/ICS guidelines for POP in 2016 (182,183), the following stages are considered:

Stage 0: No prolapse is demonstrated.

Stage I: Most distal portion of the prolapse is more than1 cm above the level of the hymen.

Stage II: Most distal portion of the prolapse is situated between 1 cm above the hymen and 1cm. below the hymen.

Stage III: The most distal portion of the prolapse is more than 1 cm below the plane of the hymen but everted at least 2 cm less than the total length.

Stage IV: Complete eversion or eversion at least within 2 cm of the total length of the lower genital tract is demonstrate.

Uterine/ cervical prolapse: Observation of descent of the uterus or uterine cervix.

Anterior vaginal wall (compartment) prolapse: Observation of descent of the anterior vaginal wall (compartment). Most commonly this might represent bladder prolapse (cystocele). Higher stage anterior vaginal wall prolapse will generally involve descent of uterus or vaginal vault (if uterus is absent). Occasionally, there might be an anterior enterocele (hernia of peritoneum and possibly abdominal contents), most commonly after prior reconstructive surgery.

Posterior vaginal wall (compartment) prolapse: Observation of descent of the posterior vaginal wall. Commonly, this would represent rectal protrusion into the vagina (rectocele). Higher stage posterior vaginal wall prolapse after prior hysterectomy will generally involve some vaginal vault (cuff scar) descent and possible enterocele formation. Enterocele formation can also occur in the presence of an intact uterus.

Vaginal vault (cuff scar) prolapse: Observation of descent of the vaginal vault (cuff scar after hysterectomy

Pelvic organ prolapse quantification (POP-Q). The need for an objective, site-specific method of quantifying and staging POP led to the design and validation of the POP-Q system. The original description of the POP-Q was by Bump et al in 1996 and is shown in figures 1 and 2 (190). This standard system, which represents a reliable and internationally accepted tool for describing the anatomical position of the pelvic organs, has been validated in the dorsal lithotomy, standing, upright and lateral position (191,192, 193).

The POP-Q records defects relative to the hymeneal remnants in centimetre gradients. These measurements are further staged according to the distal-most defect. The POP-Q system for POP considers the anatomical position of six defined points (two on the

anterior vaginal wall, two in the superior vagina, and two on the posterior vaginal wall) measurements are in centimetres (cm) above or proximal to the hymen (negative number) or cm below or distal to the hymen (positive number), with the plane of the hymen being defined as zero (O). For example, a cervix that protruded 3 cm distal to the hymen would be + 3 cm. All points are measured on maximal straining (except total vaginal length). The POP-Q as a system for quantitative prolapse description defines other landmarks and measurements: The genital hiatus (GH) is measured from the middle of the external urethral meatus to the posterior margin of the hymen. The total vaginal length (TVL) is the length of the vagina (cm) from posterior fornix to hymen when Point C or D is reduced to its full normal position. The perineal body (PB) is measured from the posterior margin of the hymen to the mid-anal opening.

Anterior vaginal wall prolapse is defined as descent of the anterior vagina so that the urethro-vesical junction (a point 3cm proximal to the external urinary meatus) or any anterior point proximal to this is less than 3cm above the plane of the hymen. On vaginal examination, we can observe a loss of the transverse crease between the lower and middle thirds of the anterior vaginal wall and descent of the anterior vaginal wall. Anterolateral protrusion into the vaginal canal may represent unilateral or bilateral detachment of the pubocervical fascia along the anterolateral vaginal sulcus from its attachment to the arcus tendinous fascia pelvis (white line). Central protrusions of the anterior vaginal wall may represent defects in the pubocervical fascia below the trigone and base of the bladder. Advanced prolapse of the upper anterior vaginal wall may obstruct a well-supported bladder neck. The two anterior vaginal wall points are as follows:

Point Aa located in the midline of the anterior vaginal wall three (3) cm proximal to the external urethral meatus. By definition, the range of position of Point Aa relative to the hymen is 3 to +3 cm.

A good correlation has been demonstrated between Point Aa and the straining Q-tip angle and suggested that Point Aa of the POP-Q system could be used to predict an abnormal straining urethral angle in women with Stage I anterior vaginal wall prolapse or greater. Point Aa of the POP-Q system could be a clinical tool that reflects urethral hypermobility in women with stress urinary incontinence in the initial evaluation of a patient and also before and after surgical treatment (194).

Point Ba that represents the most distal (i.e., most dependent) position of any part of the upper anterior vaginal wall from the vaginal cuff or anterior vaginal fornix to Point Aa. By definition, Point Ba is at 3 cm in the absence of prolapse and would have a positive value equal to the position of the cuff (Point C) in women with total uterine prolapse or post-hysterectomy vaginal eversion.

Prolapse of the apical segment of the vagina is defined as any descent of the vaginal cuff scar (after hysterectomy) or cervix, below a point that is 2cm less than the total vaginal length above the plane of the hymen. In some women, the intravaginal portion of the cervix may become elongated and cause the cervix to

extend into the lower vaginal canal, simulating prolapse, although the fundus may have good support. In other women, the uterus may prolapse fully outside the hymen as uterine procidentia. Following hysterectomy, the vaginal cuff may be well supported or may prolapse fully outside the hymen, along with other vaginal segments.

The two superior vaginal points are as follows:

Point C that represents either the most distal (i.e., most dependent) edge of the cervix or the leading edge of the vaginal cuff (hysterectomy scar) after total hysterectomy.

Point D that represents the location of the posterior fornix in a woman who still has a cervix. It is included as a point of measurement to differentiate suspensory failure of the uterosacral-cardinal ligament “complex” from cervical elongation. When the location of Point C is significantly more positive than the location of Point D, this is indicative of cervical elongation which may be symmetrical or asymmetrical. Point D is omitted in the absence of the cervix.

Posterior vaginal wall prolapse is defined as any descent of the posterior vaginal wall so that a midline point on the posterior vaginal wall 3cm above the level of the hymen or any posterior point proximal to this, less than 3cm above the plane of the hymen. Posterior protrusions into the vaginal canal are most commonly caused by defects in the recto-vaginal fascia allowing protrusions of the small bowel (enterocele) and/or rectum (rectocele). Normally, the anterior vaginal wall lies upon the posterior vaginal wall. Therefore, protrusions of the posterior vaginal wall can affect the function of the urethra and bladder that lie upon the anterior vaginal wall. For example, distal loss of support in the posterior segment may result in a bulge that compresses the urethra and affects voiding. The two posterior vaginal wall points are as follows:

Point Ap is located in the midline of the posterior vaginal wall three (3) cm proximal to the hymen. By definition, the range of position of Point Ap relative to the hymen is -3 to +3 cm.

Point Bp that represents the most distal (i.e., most dependent) position of any part of the upper posterior vaginal wall from the vaginal cuff or posterior vaginal fornix to Point Ap. By definition, Point Bp is at 3 cm in the absence of prolapse and would have a positive value equal to the position of the cuff in a women with total post-hysterectomy vaginal eversion.

The POP-Q system has not been widely adopted in clinical practice particularly by non-urogynaecologists; owing somewhat to difficulty in learning the assessment (195,196). Reasons for not using POP-Q include lack of training, the method is time consuming and the lack of an inexpensive and easily available ruler for the measurement. A study has demonstrated that digital assessment of POP-Q (DPOP-Q) is as accurate as measurement by a ruler type POPstix and additionally is better tolerated, faster, less expensive and can be conducted with the patient standing (197,198). A simplified version of the POP-Q was published by Swift in 2002, whereby the ordinal staging system of the original scale was retained (199). This is based on the POP-Q with similar ordinal staging but with only four points measured instead of nine. There is no Stage 0; it is combined with Stage 1. It is undertaken in the dorsal lithotomy position with the patient forcefully bearing down, performing Valsalva or coughing. Four points used: Point Ba in the anterior vaginal segment (estimated around 3 cm proximal to hymenal remnants). Point Bp in the posterior vaginal segment (estimated around 3 cm proximal to hymenal remnants). Point C (cervix). The apex / posterior fornix is Point D in non-hysterectomised women and point C in hysterectomized. (Fig.3). The inter-observer correlation of the simplified POP-Q was investigated in a secondary analysis of data from a large multicentre study. Weighted kappa statistics for the four POP-Q sites ranged from 0.53 (indicating poor agreement) to 1.0 (denoting excellent agreement) (200,201).

Despite the difficulties highlighted with the adoption of the POP-Q, reproducibility and reliability of the assessment system have been

demonstrated (202,203). Hall et al demonstrated that the examination could be completed within four minutes by new learners and two minutes by clinicians experienced with the assessment (197). With experienced practitioners, POP-Q staging performed using the measurement technique and estimation based on clinical examination are not significantly different (204). Parnell et al have described a POP-Q model in order to teach the POP-Q examination (205).

The relationship between anatomical defects measured by the Pelvic Organ Prolapse Quantification system (POP-Q) and lower urinary tract symptoms or other pelvic floor symptoms in women with pelvic floor disorders has been investigated and the symptom feeling of a bulge in the vagina is the only symptom that correlated with POP-Q in all vaginal compartments (206,207, 208,209). A study demonstrates that the sensitivity and specificity of this symptom were 60% and 83% when point Ba was 1 cm below the hymen. Whereas they were 55% and 83% when point C was 3 cm above the hymen (210).

The correlation between posterior compartment prolapse measured by POPQ and obstructed defaecation symptoms has been also investigated, the best-designed studies utilizing validated measures show a significant association between presence of posterior compartment prolapse and specific obstructed defecation symptoms, most significantly splinting, straining, and incomplete emptying (211,212). A retrospective study by Collins et al showed that a point Bp value of >-5 on the POP-Q, was found to be strongly correlated with defecatory dysfunction with symptoms of stool trapping and incomplete evacuation according with the CRADI-8 score (213).

The POP-Q has been used for the linguistic validation of condition specific health related quality of life questionnaires such as Prolapse Quality of life (P-QOL) (214,215), Pelvic Floor Distress Inventory (PFDI), (216,217), International Consultation on Incontinence Questionnaire Vaginal Symptoms (ICIQ-VS), Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ12) (218) and Pelvic Organ Prolapse/Incontinence Sexual Questionnaire, IUGA-Revised (PISQ-IR) (219-226).

The quantification of POP using the POP-Q was compared with dynamic MRI, the results showed that correlations of the anterior compartment were good to moderate, compared with central and posterior compartment that were poor to moderate. Correlations were independent of the POP-Q staging measurements. The agreement of MRI-based POP staging with the POP-Q is excellent, but the added clinical value is questionable due to poor association with clinical findings and pelvic floor symptoms (227-229). The relationship between clinical assessment of female pelvic organ prolapse using the POP-Q and dynamic 2D transperineal ultrasound (TPUS) has been also investigated and the accuracy of pelvic floor US staging was limited and that clinical assessment remains the gold standard (230). An observational study using POP-Q and pelvic ultrasound for the assessment of the type of cystocele, analyse the agreement between physical POP-Q and the Green radiological classification of cystocele. Kappa co-efficients ranged between 0.56-0.54 and 0.32-0.79 for clinical and ultrasound diagnosis respectively. The clinical utility of these findings has not been established (231). When clinical examination and imaging findings are compared, especially regarding cut-offs for the distinction between normal pelvic organ support and prolapse, conclusion is that the proposed cut-offs for 'significant prolapse' on ultrasound and POP-Q (Ba≥-0.5 and cystocele≥?10mm below the symphysis pubis, C≥-5 and uterine position of 15mm above the symphysis pubis, Bp≥-0.5 and rectocele≥15mm below the symphysis pubis) are plausible and mutually consistent. (232-235). According with the results of a recent systematic review about the value of the pelvic floor ultrasound for the evaluation of POP , it cannot replace the pelvic examination. However US, provides additional information that helps in treatment decisions (235).

An important advantage of the widespread adoption of the POP-Q system is the ability to compare surgical outcomes of different studies. The lack of standardised method to measure anatomical changes pre and postoperatively , has been one of the main difficulties in analying how different surgical procedures can correct anatomical defects in a different manner and their impact on function of the organs of the pelvic floor. The POP-Q has been used to define improvement in POP after surgical interventions in a number of studies; including native tissue repair (236-249), vaginal mesh (250-252) or abdominal mesh (253-257).

General recommendations in the female patient

A global evaluation for women is essential for effective treatment and prevention of relapse of UI, especially in patients with other comorbidities. Identifying and treating those symptoms are directly related of treatment success and resolution of symptoms, as well as their recurrence (Level 4, Grade A).

Pain and urgency must be carefully assessed, as they may indicate that incontinence can be secondary to a neurologic or other functional conditions (Level 3, Grade A).

Standardized PFM assessment can direct effective conservative management (Level 4, Grade A).

Urethral mobility can be assessed using the Q-Tip test weak evidence and predict success/failure of TOT(Level 4, Grade C).

Simulated operations, ring pessary test, VLPP and MUCP have been advocated to elucidate pelvic support-related incontinence/ symptoms and predict the outcome of a surgical procedure, but their predictive values still need to be demonstrated.

Future research is needed to establish the most reliable and valid techniques and tools to assess PFM function.

A careful assessment of associated pelvic support defects is essential for surgical planning and opportunistic resolution of all support-related symptoms in the same surgical procedure.

VI. SPECIFIC POPULATION: EVALUATION OF THE MALE PATIENT

1. CHARACTERISTICS OF MALE LUTS

In the male population, Lower Urinary Tract symptoms (LUTS) may present with dysfunction of the storage and emptying phase as well as with post micturition signs or symptoms. These symptoms can be non-specific in presentation and are multifactorial in origin. LUTS are progressive and age related but not sex or organ-specific. They cause significant bother and impair quality of life (258, 259). Traditionally LUTS were thought to be secondary to bladder outlet obstruction due to prostatic enlargement; however, recent scientific

evidence failed to show this relationship (259). Often, LUTS are unrelated to changes in prostatic size. Current research is aimed at understanding the impact of the bladder itself in LUTS. Bladder dysfunctions, such as Detrusor Underactivity, Detrusor Overactivity and other functional abnormalities can contribute significantly to LUTS (260).

In vitro as well as in vivo animal studies show a correlation between oxidative stress and ischemia with changes in bladder contractility in animals (261, 262).

LUTS are strongly associated with ageing and represent a major health burden for the patient and the society. Several epidemiological reports have demonstrated that storage symptoms (including urinary urgency and urgency urinary incontinence) defined as overactive bladder syndrome also increases with age in men. LUTS are often under-diagnosed and undertreated and still unfortunately often accepted as a normal part of ageing. Regarding urinary incontinence, epidemiological studies have shown that obesity is an independent risk factor for incontinence. Studies have shown that obesity is associated not only with a higher prevalence of incontinence (263) but also that obesity is a risk factor for postprostatectomy incontinence (264). There is a gender disparity as the correlation between obesity and urinary incontinence is higher in women, with 60 to 70% incidence of urinary incontinence among morbidly obese women. Although the incidence appears lower in men, is still quite relevant, as 24% of morbidly obese men have urinary incontinence (265). Obesity is a potentially modifiable condition. A recent meta-analysis confirmed that weight loss is associated with a reduction in incidence and severity of urinary incontinence among women and men. Specifically, in the male population, obesity appears to be more frequently associated with urgency incontinence (265).

Chronic prostatic pain syndromes (e.g. non-bacterial chronic prostatitis) and other pelvic floor dysfunctions can also present with a component of symptoms compatible with storage symptoms. In younger men, primary bladder neck dysfunction is a common cause of LUTS, with or without pelvic pain. Functional abnormalities of striated sphincter relaxation may also occur in young men. The complexity of the presenting symptoms and the various differential diagnoses mandate a thorough basic assessment of the lower urinary tract in men to plan optimal therapeutic intervention.

Epidemiological studies and meta-analyses confirm a high prevalence of LUTS in the community. There is an increased prevalence of LUTS with ageing (266). The incidence appears to be of 3.5% in men in the fourth decade of life, while in men over age of 85 the incidence is higher than 30%. These epidemiological data are confirmed by the finding that in the time period from 1992 to 2001 there was an increase of medical treatment for male LUTS from less than 2% to more than 10%. In the same time frame, there was also an increase in the time between the first diagnosis of LUTS and the time to surgery. The Multinational Survey of the Aging Male (MSAM-7) surveyed over 12 000 men age 50 to 80 in major countries of Western Europe and USA (266). Across all countries, prevalence increased from 22% in men aged 50–59 years to 45% in men aged 70–80 years. 31% of men reported moderate-to-severe LUTS (34% in the USA and 29% in Europe). Interestingly, despite the fact that 19% of men with LUTS present with complaints, only 10% received and appropriate medical treatment (267).

Based on the Integrated Health Care Information Solutions (IHCIS) database, LUTS are among the most frequent reasons for medical consultation among the male population older than 50. The fourth most common diagnosis in this population is BPH, after coronary artery disease, hyperlipidaemia, hypertension and diabetes mellitus (268).

LUTS have a significant impact on quality of life but also on potentially life-treating conditions such as falls in elderly population. As reported by Parsons et al. moderate and severe LUTS independently increase the 1-year risk of falls, particularly recurrent falls, in community-dwelling older men (269). In their study of 5,872 participants in the Osteoporotic Fractures in Men study were assessed for LUTS, using the AUA symptom score. Patients with moderate LUTS were found to have 11% higher risk of at least one fall, while the risk of fall increased to 33% in subjects with severe LUTS (269). Falls in the elderly population might have serious consequences and screening elderly patients for LUTS by primary care providers should be assessed routinely.

2. MALE INCONTINENCE

Improvement in early detection of prostate cancer has led to an increase of men treated for this condition. The rate of post-prostatectomy incontinence (PPI) is difficult to determine because of the varying definitions of incontinence, but approximately one in five men require the use of pads in the long term after radical prostatectomy (RP) (270). Incontinence has a significant negative impact on quality of life. This potential complication is also patients' greatest fear, especially in the youngest subset of patients (65 years or younger), requiring RP (271). Robot-assisted laparoscopic prostatectomy (RALP) was introduced with the aim of improving surgical outcomes, but controlled or randomized studies on the long-term effects are few and present knowledge of effectiveness is based mainly on case series or registry data (272).

The Swedish LAP PRO trial brings some very useful insights into answering the question of true incidence of PPI and whether there are any differences between techniques. In summary, this trial focused on the primary end point of urinary incontinence 12 months after RALP, as reported by the patients (to reduce the potential bias of Surgeon-Patient relationship) (273). Notably, this study recruited only patients of high volume surgeons, those with more than 100 procedures carried out to avoid the bias of the single surgeons learning curve. The study recruited 4000 patients and the final analysis included 2625 patients. 778 patients underwent an open retropubic radical prostatectomy (RRP) and 1847 underwent RALP. The study showed that patients classified as having urinary incontinence ranged from 20% to 56% after RRP and from 21% to 57% after RALP. The percentage of incontinence was even higher if a definition of dryness was combined with no use of pads and zero leaks (273).

Catalona et al. showed that incontinence after prostate surgery was primarily dependent on the age of patients (274). The older the patient, the more likely he is to be incontinent and to never regain urinary control. For 40-49 year olds only 3% (12/358) had long term incontinence but that increased to 8% (48/632) in 50-69 year olds 8% (48/632) and 13% (38/282) in men over age 70; for an overall prevalence of 7.7% (274).

Special consideration is needed for irradiated patients as the success rate and incidence of post prostatectomy incontinence surgery differ significantly from non-irradiated patients. The revision rate of Artificial Urinary Sphincter (AUS) surgery, a procedure done for PPI, was significantly higher in irradiated versus non irradiated men (mean 37.3 versus 19.8%; $p < 0.007$) after a mean follow-up of

38.4 months (275). Revision is typically performed for infection, erosion or urethral atrophy. Persistent urinary incontinence was also more than twice as likely in irradiated versus non-irradiated men (29.5 versus 12.1%; P = 0.003) with an odds ratio of 2.08 (275). Radiation induced changes involving the bladder neck and urethral tissue, such as fibrosis, are considered to be the primary aetiology for the development of incontinence. Surprisingly, the timing of radiation therapy does not seem to have any influence on the incidence of urinary incontinence. Similar rates of incontinence are reported in early and late radiation therapy after radical prostatectomy. Sowerby and colleagues reported the incidence of urinary incontinence to be 24.5% in men who underwent radiation less than 6 months from surgery and 23.3% in men with radiation greater than 6 months after prostatectomy (275).

Urgency incontinence is a failure of bladder storage usually due to the underlying pathology of detrusor overactivity (DO). Urgency incontinence commonly presents as part of the overactive bladder (OAB) syndrome. OAB is described as urinary urgency, with or without urgency incontinence, usually with frequency and nocturia, in the absence of infection or other obvious pathology (1). In men, OAB symptoms often coexist with emptying phase LUTS. Men with emptying phase LUTS such as poor flow and hesitancy are often assumed to have benign prostatic obstruction, although research has shown they may not.

3. SYMPTOM ASSESSMENT

Symptom assessment in men with incontinence should identify and exclude patients with complicated incontinence, who need to be referred for specialised management. Complicated incontinence comprises patients with recurrent incontinence after failed previous surgery, with total urinary incontinence, and/or with associated symptoms such as pain, haematuria, recurrent urinary tract infection, voiding symptoms, and/or a history of previous pelvic radiotherapy or radical pelvic surgery (276).

Because the occurrence of LUTS in men does not necessarily indicate concomitant prostate enlargement and/or obstruction, specific modalities should be used to ascertain the potential for the aetiological role of these entities. Underactive bladder (UAB) is the symptom-based correlate of detrusor underactivity (DU), as is the case with OAB and detrusor overactivity (DO).(277) The International Continence Society (ICS) consensus group has recently proposed a working definition of UAB as a symptom syndrome suggestive of DU (278). The definition is “Underactive bladder is a symptom syndrome suggestive of DU and characterized by a slow urinary stream, hesitancy and straining to void, with or without a feeling of incomplete bladder emptying and dribbling, often with storage symptoms.” Although patients with DU can present a variety of storage, voiding, and post-micturition symptoms, the voiding symptoms often predominate. However, a symptom complex of UAB is shared by LUTS attributable to bladder outlet obstruction (BOO) (277,278). Increased residual urine may cause the overflow incontinence.

A variety of symptom scores have been described to assess male patients with LUTS. It is important that symptom scores have a wide applicability across a number of different cultures and languages. Ideally, symptom scores should also help to determine the underlying aetiology of LUTS (for example, BOO, DO, impaired detrusor contractility); however, this is made difficult by the fact that different conditions can produce similar or even identical symptoms. Each symptom score has advantages and disadvantages, but it is clear that the worldwide use of such scores has helped in evaluating symptoms, treating patients, and communicating findings globally. Symptom scores have been used in male LUTS for a variety of purpose. 1) to assess symptom severity, 2) to examine the relationships between clinical measure/ test results and scores from symptom and quality of life (QOL) questionnaires, 3) to predict to treatment, 4) to assess the outcome of treatment.

The following symptom scores for male LUTS have been evaluated.

The IPSS: symptoms and QOL impact of LUTS
The International Consultation on Incontinence Modular Questionnaire-Male-LUTS (ICIQ-MLUTS): symptoms of LUTS and urinary incontinence
The Danish Prostatic Symptom Score (DAN-PSS): symptoms of LUTS and urinary incontinence
The OAB Symptom Score (OABSS)
The core LUTS Score (CLSS): symptoms of LUTS
The Urgency and Nocturia Scoring TOOL (UWIN): symptoms of LUTS

Three questionnaires with a high level of psychometric validity and reliability are the IPSS, the ICS’s ICS-male questionnaire (now known as the ICIQ-MLUTS), and the DAN-PSS. Although each was designed with the same purpose, only six symptoms are common to all three, including incomplete emptying, urgency, decreased stream, frequency and nocturia.

In men, the American Urological Association symptom score for BPH (AUA-7) is most commonly used in North America for assessment of subjective symptoms. However, equally reproducible data can be obtained from the International Prostate Symptom Score (IPSS)(279), the ICS male questionnaire (now renamed the ICIQM-LUTS, long and short forms, as part of the ICIQ modular questionnaire: www.iciq.net).

The IPSS has been the most widely used (in many countries and languages), but one of the major critiques of this questionnaire, is the fact that it is not disease or condition specific. In addition, it neglects the symptom of urgency incontinence, a symptom that produces significant bother. Urgency incontinence is an important symptom, particularly regarding the therapeutic outcome in BPO patients. The prevalence of this symptom was also reported as common by the ICS-“BPH” study group and was higher in men with BOO than in those without (280).

ICIQMLUTS (ICSmale-SF) is slightly longer but takes into account the symptom of urgency incontinence, and in fact may be divided into voiding (ICS-male-VS) and incontinence (ICS-male-IS) (281). As the concept of OAB has become widespread, as simple symptom questionnaire to quantitatively assess OAB symptoms, the OABSS, was developed and psychometrically validated. overactive bladder symptoms scores are also very useful for male patients with storage symptoms including urgency incontinence (282, 283). Other new symptom questionnaires to assess male-LUTS include UWIN and the CLSS.

Ten LUTS (increased daytime frequency, nocturia, urgency, urgency incontinence, stress incontinence, slow urinary stream, straining, a feeling of incomplete emptying, bladder pain, and urethral pain) were selected as core symptoms from 25 LUTS defined by the ICS committee, and symptom questionnaire to assess the core symptoms we developed as the CLSS (284). Symptoms were scored

according to their frequency and severity. The CLSS questionnaire was confirmed to show good test-retest reliability. The CLSS was compared with IPSS in men with LUTS, and the CLSS was shown to be more comprehensive than IPSS for symptom assessment of men various diseases and conditions (284). The CLSS provides overall assessment of relevant symptoms and may be useful for new patients, patients with multiple diseases, and patients without a definite diagnosis, as well as before and after intervention that may cause other symptoms. The CLSS was utilized for evaluation of longitudinal change of comprehensive LUTS and various types of urinary incontinence during robot-assisted radical prostatectomy (285)

Among LUTS, urgency, nocturia, and hesitancy are most bothersome, whereas weak stream, urgency, and frequency are the most prevalent in pooled populations being evaluated for BPH (286). Postmicturition dribble (PMD) is a term used to describe the involuntary loss of urine immediately after an individual finishes passing urine, usually after leaving the toilet in men or after rising from the toilet in women (1). PMD is classified as a postmicturition symptom according to the standardization of terminology. Although the exact pathophysiological mechanism of PMD has not been clarified to date, earlier studies suggest that PMD is secondary to a small amount of residual urine in either the bulbar or prostatic urethra that is normally “milked back” into the bladder at the end of micturition (287,288).

PMD is often provoked by an obstructing disease such as BPH or urethral stricture but can also be a symptom of a urethral diverticulum. As yet there is no validated symptom questionnaire that assesses post-micturition symptoms (post-micturition dribble and post-micturition incontinence).

PMD is one of the most prevalent LUTS (289-294) and is known to be one of the most common causes of bother (258,289,290). Jeong et al. (295) developed and validated the “Hallym Post Micturition Dribble Questionnaire” (HPMDQ) to assess PMD, which consists of 5 questions (frequency, severity, bother, quality of life and response to treatment for PMD) (295).

The International Consultation on Incontinence Questionnaire-underactive bladder (ICIQ-UAB) was developed as the first patient reported outcome measure for the assessment of the symptoms and impact on the health-related quality of life of UAB. (296)

To determine the cause of post-prostatectomy incontinence, many studies have stressed the lack of reliability of symptoms and emphasized the important role of urodynamic testing (297, 299). Recently, non-invasive standing cough test was utilized for evaluation of post-prostatectomy incontinence. (299,300) Nevertheless, valuable information can be gained from a careful history with regard to incontinence, especially when related to sphincter dysfunction. The symptom of stress incontinence is highly predictive of the presence of sphincter dysfunction. Chao and Mayo found that 67 of 71 men with post-prostatectomy incontinence secondary to sphincter dysfunction complained of the symptom of stress incontinence (301). Similarly, Ficazzola and Nitti found 95% positive predictive value and a 100 % negative predictive value for symptom of stress incontinence (302). Urgency incontinence as a predictor of bladder dysfunction does not seem to be as valuable, and the presence of bladder dysfunction cannot be determined accurately without urodynamic testing (301, 302).

An important aspect of the assessment of male incontinence should be a description of the type and severity of incontinence and precipitating events, Severity may be determined by the number of episodes per day, the need for protection (e.g., pads, penile clamp, external catheter), and the impact of incontinence on activities of daily living. Bladder diaries and pad tests can quantify severity. A bladder diary (or frequency volume chart) kept for 3 to 5 days may be useful in almost all male patients, especially in those with OAB. The time and voided volume are recorded for each micturition during several 24-hour periods.

Bladder diary completion by the patient provides useful evidence about the nor-mal urinary habits of the patient, including giving some estimate of bladder capacity and diurnal and nocturnal frequency, urgency and stress incontinence. It also helps to identify patients with nocturnal polyuria or excessive fluid intake which are common in the aging male. The data obtained from a frequency-volume chart provide a strong correlation with cystometric capacities and are reasonably immune to the effect of detrusor overactivity in men with LUTS (303).

The 24 hour pad test is an excellent test to quantify the amount of urine leakage in men. Since most patients use different size and type of pads, it is difficult to compare the number of pad/day per patient. Furthermore, some patients are very disturbed by any leakage at all and change the pad very frequently before they are saturated. The other distinction to be made is between a safety pad and true urinary incontinence. In general, the each 1g weight equals 1 ml urine loss. It is proposed to use a cut-off value of 250 g of urine to categorize minor from more troublesome or severe leakage (304). Recently, Machold et al. suggested that the technical feasibility of the 20-min pad test to evaluate post-prostatectomy incontinence was excellent. The results correlated significantly with both the self-assessment via questionnaire ($r = 0.63$; $p < 0.001$) and the 1-hour pad test (ICS; $r = 0.66$; $p < 0.001$). Moreover, it was highly reliable ($r = 0.74$; $p < 0.0005$) with excellent patient acceptance (305).

4. PHYSICAL EXAMINATION

The assessments focus on general physical examination, digital rectal examination (DRE) and neurological testing of the perineum and lower extremities.

In a general physical examination, specific attention should be placed on the evaluation of surgical scars, the presence or absence of a distended bladder and excoriation of the genitals, secondary to urinary incontinence. Abdominal palpation should be performed to evaluate bladder distension, especially in elderly incontinent men, who may have overflow leakage due to obstruction. In patients suspected of urinary retention, post-void residual volume should be measured. The examination should also include external genitalia, location of the urethral meatus, retractability of the foreskin and evidence of congenital malformation. The evidence of urethral discharge after abdominal straining (a Valsalva manoeuvre) or coughing in either the supine or upright position should be evaluated so that the presence of stress incontinence can be ascertained.

A focused neurological examination is also highly recommended. In a patient suspected of neurogenic bladder, evaluation of perineal sensation and lower extremity neuromuscular function, and anal sphincter tone, which is often decreased in neurogenic patients is important (306). A focused neurogenic examination should also assess the patient’s general mental status and ambulatory status.

DRE should include palpation of the prostate to assess size, symmetry and consistency of the gland and its relation to the pelvic

sidewall and the rectum. Enlarged, indurated and painful prostate may imply BPH, prostate cancer and prostatitis, respectively. The locally advanced prostatic cancer can also produce OAB-like symptoms including incontinence. DRE may exclude prostatic cancer, although its specificity and sensitivity is low (307). The DRE is 53% sensitive and 85% specific for identifying underlying prostate cancer when abnormalities (i.e. induration or nodule) are present (308). Furthermore, abnormal rectal tone can raise suspicion of an occult neurogenic disorder that may be contributing a patient`s symptoms. DRE tends to underestimate the true prostatic size: if the prostate feels large by DRE, it usually also is found to be enlarged by ultrasound or other measurement technique (309, 310). Prostate volume has been associated with the risk of BPH progression (311) and response to treatment (312). It has been reported that men with BPH with idiopathic detrusor overactivity showed a significantly higher incidence (54%) of intravesical protrusion of the prostate (313). This finding suggests that intravesical protrusion may in some way increase afferent impulses from the prostate and alter the stability status of the bladder. Occasionally tumours of the anal canal can be diagnosed while performing DRE of the prostate.

Assessment of the male PFM function should proceed using the same tests and diagnosis as the female including external observation, digital rectal palpation, EMG, and transperineal imaging ultrasound. External observation of correct male PFM contraction would result in closure and elevation of the anus, cephalad testicular lift and penile retraction. Anterior contraction of the male PFM (penile retraction) has been shown to be important in recovery of post prostatectomy UI (314). Although anterior PFM contractions may be visible externally, the best assessment is with imaging ultrasound. Skilled assessment and treatment of male PFM disorders is a valuable addition to the care of these patients

4.1. Urinalysis and Urine Cytology

All patients undergoing an evaluation for LUTS should have a urinalysis performed to evaluate for UTIs or other uropathology. The most significant findings would include evidence for pyuria, bacteriuria, and/or haematuria. Bladder cancer, carcinoma in situ of the bladder, urinary tract infections, urethral strictures, and bladder stones can cause OAB-like symptoms including incontinence in elderly men. Although haematuria or pyuria is not universally present in those conditions, urinalysis is important to rule out these conditions. Urinalysis is not a single test; complete urinalysis includes physical, chemical, and microscopic examinations. Dipstick urinalysis is certainly convenient but false-positive and false negative results may occur. It is considered an inexpensive diagnostic test able to identify patients with urinary tract infection as indicated by the presence of leucocyte esterase and nitrites. A substantial proportion of older patients with chronic OAB-like symptoms have significant bacteriuria, sometimes accompanied by pyuria. In men, recent urinary tract infections were associated with OAB without urgency incontinence (prevalence ration=2.9; 95% CI: 1.6-5.0) (315). However, infection may exist in the absence of pyuria and, in the elderly population, pyuria may develop in the absence of urinary tract infection.

Microscopic haematuria can be easily identified by dip sticks because of the presence of haemoglobin. The detection of haematuria is important because the condition is associated with a 4-5% risk of diagnosing urological disorder or malignancy within 3 years.

A systemic review and economic evaluation of diagnostic tests and algorithms used to investigate haematuria concluded that the evidence based on which to determine the ideal means of investigating haematuria was insufficient (316). However, because of the high prevalence of urinary tract infection and the increase of LUTS in the presence of urinary tract infection, various guidelines on the management of patients with LUTS suggestive of BPO, and urinary incontinence, endorse the use of urinalysis in primary care management (317,318).

Urine cytology is also recommended in male patients with haematuria and a predominance of storage symptoms, especially with a history of smoking or other factors, to aid in the diagnosis of bladder carcinoma in situ and bladder cancer.

4.2. Measurement of the Serum Creatinine

Epidemiological studies in community dwelling men have shown the absence of any association between BPO/BPE/BPO and chronic kidney disease (317, 319) suggesting that screening for renal function is not justified in male patients. Diabetes and arterial hypertension appear to be the most important causes of elevated serum creatinine in men with BPH and renal failure (315). Data from the MTOPS study showed that the risk of developing de novo renal failure in men with LUTS is low (less than 1 %) suggesting that is not necessary to monitor renal function in patients with LUTS / BPO (311). However, a study examining the association between LUTS and glomerular filtration rate (GFR) in men concluded that in older men without obvious enlargement of the prostate, as LUTS became more severe, GFR fell (320). In case of overflow incontinence accompanied with BOO, measurement of the serum creatinine might be necessary, because a significant residual urine may cause the bilateral hydronephrosis resulting in the renal dysfunction.

5. MEASUREMENT OF THE SERUM PROSTATE SPECIFIC ANTIGEN (PSA)

In most patients, a normal DRE may be sufficient to exclude locally advanced cancer as a cause of LUTS or OAB. There is no consensus as to the measurement of prostate specific antigen (PSA) in patients with LUTS. The rationale for measuring PSA is twofold: to screen for prostate cancer and to measure a parameter with prognostic value for the progression of BPH and the response to treatment. Because prostatic cancer is one of the potential causes of LUTS or OAB in men, PSA (together with DRE) is a relatively sensitive way to exclude prostatic cancer as a diagnosis (321,322). PSA measurement is recommended in men with LUTS and a life expectancy of over 10 years in whom the diagnosis of prostate cancer would change the management of patient's symptoms. Given the uncertainties surrounding prostate cancer detection physicians must use clinical judgment in determining which patients should or should not undergo transrectal ultrasonography and prostate biopsy in response to a particular PSA (323).

However, it is important to understand that about 25% of men with BPH have a serum PSA greater than 4 ng/ml. Because of the overlap between serum PSA values in men with BPH and those with clinically localised prostate cancer, other parameters (PSA velocity, free/total PSA ratio, complexed PSA and PSA density) will assist diagnostic specificity (324, 325). It has been suggested that a relationship between initial PSA level and subsequent prostate cancer detection with a stepwise increase in cancer detection rate (from <1% to 58%) in patients with <1.0 ng/ml, 1.1-2.5, 2.6-4.0, 4-1-10.0 and >10 ng/ml PSA value in over 26.000 patients enrolled in a screening program (326, 327). In addition, Thompson reported data on prostate cancer prevalence from the prostate cancer prevention trial (327) confirming a stepwise increase in the risk of having

a prostate cancer in patients with serum PSA from 0.5 to 4.0 ng/ml but showing the limitation of the current threshold of 4.0 ng/ml. Change of PSA threshold from 4.0 to 2.0 ng/ml has been proposed but currently no consensus exists (328).

In addition, serum PSA is a reasonable predictor of prostate volume in men with LUTS and can be used in this capacity in clinical decision making (323). It has been reported that the role of IPSS score in the assessment of BOO is questionable, and that the grade of obstruction is more related to prostate volume, PVR, and Qmax (329). It has been demonstrated that moderate-to-severe LUTS in men can result in urinary retention. The incidence of retention in men with untreated LUTS in community-based trials is 6.8 per 1000 during longitudinal follow-up of 4 years (330). If only patients with moderate-to-severe symptoms are considered, the rate of retention increases to 25 per 1000 (331). In a meta-analysis of predictors of retention in pooled groups of placebo patients from clinical trials of men with LUTS undergoing active interventions (4300 patients), Roehrborn et al. found PSA and prostate volume to be strong independent predictors of urinary retention and the need for surgery in men with LUTS followed up longitudinally in clinical trials (310, 332).

Laniado et al have also tested the hypothesis that PSA level could be used to predict the presence or absence of BOO, evaluated by pressure flow studies. In patients with LUTS, those with a PSA more than 4 ng/ml are significantly more likely to have some degree of BOO. Conversely patients with PSA less than 2 ng/ml have a 33% risk of BOO (333).

Recommendations

A variety of symptom scores have been described to assess patients with Male-LUTS. The IPSS, ICIQ-MLUTS, and DAN-PPS have been the most tested and were found to reproducible, valid, and sensitive for initial assessment. (Level 3, Grade A). However, the IPSS neglects of symptom of incontinence.

Urinalysis is recommended in patients with male-LUTS. There is currently insufficient evidence to recommend routine measurement of serum creatinine and post-void residual urine in male patients with incontinence (Level 3, Grade A).

In addition to DRE, PSA measurement is recommended in selected male patients with OAB (Level 3, Grade A).

Skilled assessment of the anterior PFM should be included in the assessment of patients with post prostatectomy UI.

Future research

1. Improve the understanding of the underlying pathophysiology and contributory clinical factors involved in the development and treatment of detrusor overactivity in the male patient, especially in differentiating the condition from female patients.
2. Development of simple, non-invasive, cost-effective methods to determine the contribution of bladder storage and bladder emptying abnormalities in male patients.

IX. QUESTIONNAIRES TO ASSESS SYMPTOMS AND HRQL IMPACT OF FAECAL INCONTINENCE **435**
1. Accidental Bowel Leakage Evaluation Questionnaire 436

X. QUESTIONNAIRES TO ASSESS SEXUAL FUNCTION/SEXUAL HEALTH AND URINARY SYMPTOMS **436**

XI. RECOMMENDATIONS FOR RESEARCH **437**

REFERENCES **438**

I. INTRODUCTION

This chapter updates the previous literature reviews of Patient Reported Outcomes (PROs), for lower urinary tract symptoms (LUTS), bowel incontinence, and sexual dysfunction outcome measures providing recommendations for questionnaire selection for use in clinical practice and research. This summary will review the purpose and content of the ICI questionnaire (ICIQ) modules. In addition this chapter reviews Patient Reported Outcome Measure (PROM) development and translation into different languages and cultures. There is also an expanded review of electronic Patient Reported Outcomes (ePRO) and questionnaire bias.

A PROs is defined as "any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else". A PROM is the tool or questionnaire used to collect the data. PROs measure different aspects of disease and therapeutic impact such as: symptom frequency or symptom bother, health-related quality of life (HRQoL), treatment satisfaction, adverse events, or work productivity measures (**Figure 1**). An essential component of selecting a PRO is to ensure that the selected PRO is consistent with the objective of the study or clinical purpose. For example, if the goal is to assess treatment satisfaction, then a treatment satisfaction measure should be incorporated into the study design or as a clinical outcome. Matching of appropriate PROs with desired outcomes is critical to success when assessing PROs and will be reviewed further in this chapter.

Ultimately, the last decade has been one of tremendous growth in the area of PROs with influences from scientific and regulatory communities. As such, the ICI will endeavour to continually update the recommendations it offers on the basis of emerging data and published evidence based on the recommendations of the prior reviews.

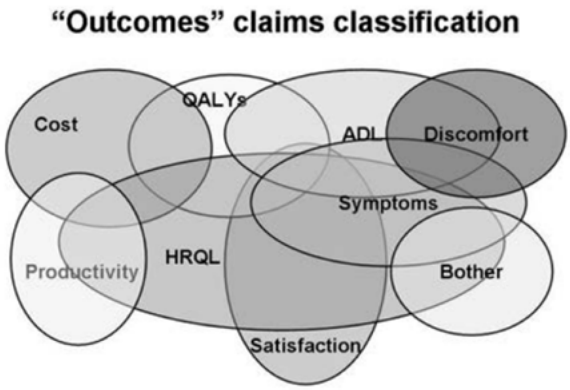

Figure 1: Patient Reported Outcome Assessment Areas

1. TERMINOLOGY AND DEFINITIONS

Symptom impact and treatment benefit can be assessed in several ways. The first line method is taking a detailed clinical history. In addition, PROMs are important and have proved their reliability in symptom and outcome assessment such as voiding diaries and validated questionnaires. They build the basis of the patient-centred healthcare system and represent the most important clinical review of symptom impact and treatment benefit from a patient perspective

. Patient reports are the best method for quantifying unobservable events such as pain and depression. Even when an event is observable, such as voiding or fluid intake, the patient is in the best position to report events over a period of time. PROMs provide a method for the standardised collection of data, or an objective assessment of subjective phenomena, from patients relating to the condition or treatment of incontinence, other LUTS, sexual function, and bowel problems. Clinicians' assessments of patients' outcomes have often been shown to underestimate the degree of bother perceived by patients, and to focus on issues of lesser importance to patients. Thus making PROMs more reliable and valid than Observer Reported Outcomes (ORO).

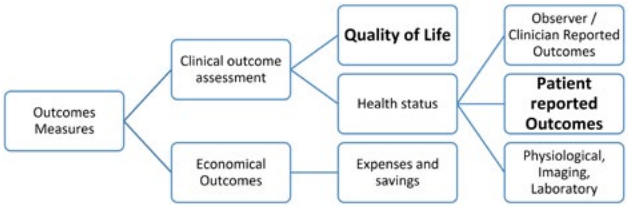

Figure 2: Types of outcomes measures

Outcome measures are categorized in 2 groups: clinical and economical (**Figure 2**). Economical outcomes report on cost of disease and treatment through expenses and saving. Clinical outcome assessment (COA) measures Health status and Quality of life. They can be further sub-classified into Observer / Clinician reported outcomes, Patient reported Outcomes and Physiological, Imaging, and Laboratory tests. If the patient is observed for the outcomes by a caregiver then the outcomes are termed observer reported outcomes (OROs). This chapter will focus on Patient Reported Outcomes (PROs) and Health Related Quality of Life Measures (HRQoL). **Table 1** provides further definitions of terms related to PROs.

Health related quality of life (HRQoL) measures are similar to PROs in that they are patient reported without interpretation by a clinician. However they differ from PROs in that they are a multidimensional measure which is indirectly related to a disease. Whereas a PRO symptom is a one-dimensional property directly related to disease and treatment effect. Thus, PROs concepts are simple whereas the concepts are complex in HRQoL.

2. TYPES OF PRO MEASURES

There are two types of PRO measures: generic and condition-specific. Generic measures are designed to assess outcomes in a broad range of populations (e.g., both healthy as well as ill individuals). These instruments are generally multidimensional, and assess at least the physical, social and emotional dimensions of life. An example of this type of instrument is the Medical Outcomes Study SF-36 Health Status Profile.

A second type of measure is condition-specific (e.g. instruments designed to assess the impact of specific diseases, conditions, age groups, or ethnic groups). Condition-specific measures can be similar to generic instruments in that they assess multiple outcome dimensions, but condition-specific measures also include items more specific to the particular condition or population being studied. Examples of condition specific instruments in urology and urogynae-

Table 1: Terminology of PRO

Clinical Outcome Assessment (COA)	A report of patient's health status. COAs can measure treatment benefit directly or indirectly. COAs include patient-reported, clinician-reported, and observer-reported outcome measures and are typically instruments that include a scale or score.
Patient Reported Outcome (PRO)	Any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else.
Patient Reported Outcome Measure (PROM)	The instrument or tool used to gather health status information directly from the patient, without amendment or interpretation by a clinician or anyone else.
Observer Reported Outcome (ORO)	A report of patient behaviour and symptoms given by an observer. An ORO measure does not include medical judgment or interpretation although it is subject to observer interpretation and is not a PRO. Generally, OROs are reported by a parent, caregiver, or someone who observes the patient in daily life. OROs are valuable in cases of cognitive limitation (ie an elderly patient with dementia or a child before the age of understanding).
Clinician Reported Outcome (CRO)	A report that comes from a trained health-care professional after observation of a patient's activities with a health condition. A CRO measure involves a clinical judgment or interpretation.
Performance Outcome Measures (PO)	A measurement based on a task(s) performed by a patient according to instructions that is administered by a health care professional. Performance outcomes require patient cooperation and motivation, e.g. measures of gait speed, memory recall, or other cognitive testing.
Health Related Quality of Life (HRQoL)	A multi-domain concept which represents the patient's general perception of the effect of illness and treatment on physical, psychological, and social aspects of life.
Electronic patient reported outcome (ePRO)	A PRO collected directly from the patient electronically without interpretation by the clinician or anyone else
Electronic patient reported outcome measure (ePROM)	The software or computer program used to collect PROs electronically
Interactive voice response system (IVRS)	Technology that uses pre-recorded voice questions and responses to complete the questionnaire usually administered over the phone
PRO domain	A sub-concept represented by a score of an instrument that measures a larger concept comprised of multiple domains. e.g. depression
PRO item	An individual question, statement, or task (and its standardized response options) that is evaluated by the patient to address a particular concept. e.g. Are you feeling depressed?
Conceptual framework	The conceptual framework explicitly defines the concepts measured by the instrument in a diagram that presents a description of the relationships between items, domain (sub-concepts) and concepts measured and the scores produced by a PROM.
Endpoint	The measurement that will be statistically compared among treatment groups to assess the effect of treatment and that corresponds with the clinical trial's objectives, design, and data analysis.
End point model	A diagram of the hierarchy of relationships among all endpoints, both PRO and non-PRO, that corresponds to the clinical trial's objectives, design, and data analysis plan.

Taken from several references including [7, 8, 9, 10]

cology include the Incontinence Impact Questionnaire, the King's Health Questionnaire, and the OAB-q.

In general, it is now common to include condition specific outcome measures in clinical trials due to their enhanced sensitivity to change and the need to minimise participant burden. Importantly, the type of instruments selected for inclusion in a research study will depend on the goals of the intervention and the specific research questions to be addressed. In practice, clinical trials that include PROs usually incorporate a combination of PRO measures most relevant to the study population and intervention, if applicable, being mindful of resource constraints and staff and participant burden.

II. SELECTING PRO MEASURES FOR RESEARCH STUDIES

a) Study Design

There are several protocol concerns that must be taken into account when using PRO measures in research studies, including the length of the study, the frequency of contact with the study participants, the timing of clinical assessments, the complexity of the study design, the number of participants enrolled, and participant and staff burden. The goal of the PRO assessment is to "fit" the PRO measures to the protocol without compromising either the study objective or design. For example, if the study design is complex with

frequent participant contacts and multiple clinical measures, it may be necessary to keep the PRO measures at a minimum or to reduce the number of times the PRO is assessed (e.g. baseline and end of study rather than during all participant contacts) to minimise participant and staff burden. At the same time, however, PROs must be viewed as an important variable in the overall trial design and should not be devalued in the data collection process. Consequently, PRO measures cannot be altered or reduced to accommodate study design as such alterations may yield less reliable measures or may seriously diminish the integrity of the overall study design and yield useless information. Having well developed research goals and questions regarding PROs will help to guide clinicians in the selection of measures for a study. The aim is to develop a conceptually adequate, yet practical PRO battery given the study population, the specific intervention, and the study design.

The frequency with which a PRO will need to be assessed in a research study will depend upon the nature of the condition or intervention being investigated and the expected effects (both positive and negative) of the treatment. At a minimum, as with all measurements collected in a research study, a baseline and end of study assessment should be completed. In addition, PRO assessments should be timed to match expected changes in functioning due to either the intervention, the condition or the disease itself. Timing follow-up assessments to coincide with typical patient follow-up visits, if appropriate, may also reduce the costs involved in the follow-up PRO assessments.

b) Study Population

It is critical to specify key population demographics that could influence the choice of instruments, the relevant dimensions of the PRO to be assessed, and the mode of administration. Thus, age, gender, educational level, language spoken, and cultural diversity should be carefully considered prior to selecting PRO measures. For example, a cohort of patients over the age of 70 may have more visual problems than middle-aged persons, making self-administered questionnaires potentially inadvisable. Ethnically diverse groups also require measures that have been validated across different cultures and/or languages.

In clinical trials, it is also important to consider how the disease or condition will progress and affect the outcomes of patients in the control group as it is to understand the effects of the study treatment. For example, in patients with incontinence assigned to a placebo-control arm of a study, one might expect a symptom to worsen and thus have an effect on daily functioning. The point is to select PRO measures that are sufficiently sensitive to detect changes in both the treatment and the control group patients. Use of the same measures for both groups will ensure an unbiased and comparable assessment.

c) Intervention

There are three major factors related to the intervention that are relevant to PRO assessment, and therefore require careful consideration: 1) the positive and adverse effects of treatment; 2) the time course of the effects; and 3) the possible synergism of the treatment with existing medications and conditions. It is crucial to understand how a proposed treatment can affect patient outcomes in both positive and negative ways. For example, some drug therapies may relieve LUTS but produce side effects like dry mouth or sexual dysfunction.

In addition, the time course of an intervention's effects on PROs is also critical both in terms of the selection of measures and the timing of when PRO measures are administered to study participants. For example, in a trial comparing coronary artery bypass graft (CABG) surgery to angioplasty, an assessment of PRO one week post-intervention might lead to an interpretation that the surgical arm had worse outcomes than angioplasty for PRO since the individuals in this arm of the trial would still be suffering the effects of the surgical procedure (for instance, sore muscles and surgical site discomfort) which could overwhelm any benefits associated with CABG. However, at six months post-intervention, the benefits of CABG surgery such as, relief from angina might be more profound than the benefits received from angioplasty. Thus the timing of when PROs are assessed could influence how one interprets the benefits (or negative effects) of the interventions.

Finally, it is important to have a clear understanding of the current medications the patient population is likely to be taking prior to randomisation to the study treatment, and how these medications might interact with the trial intervention, (either a pharmacological or behavioural intervention), to influence patient outcomes.

Quality-adjusted Life Year (QALY)

Increasingly HRQoL outcome measures are being used in the development of Quality Adjusted Life Year (QALY) measures. A QALY is a universal health outcome measure applicable to all individuals and all diseases, which combines gains or losses in both life quantity (mortality) and life quality (morbidity) and enables comparisons across diseases and programs. QALYs are widely used for cost-utility analysis. In the past decades, economic evaluation has been increasingly important for the decision maker to decide which treatment or intervention is more cost effective, in order to allocate limited healthcare resources soundly. Economic evaluation aims to compare interventions in terms of their costs and benefits, including their patient outcome impact. Health benefits can be quantified as QALYs which have become a standard measure and are now recommended in most of health economics guidelines as the method of choice. The economic chapter contains additional information regarding QALYs.

III. LITERATURE SEARCH STRATEGY

For the current version of this chapter the previous literature search was updated. A number of databases were accessed, electronically, with specific search criteria, such as validation work from the period January 2006 through August, 2021. Age and gender limits were not specified. Databases used included Pub-Med/MEDLINE, and websites accessed included oab.com, proqolid.com, ncbi.nlm.nih.gov and mapi-institute.com.

The following key words were used separately and/or in combination: "urinary incontinence", "urinary symptoms", "urgency", "overactive bladder", "stress incontinence," "incontinence," "questionnaire," "epidemiology," "prostate," "prolapse," "faecal," "bowel," "anal," "quality of life," "sexual," "geriatric," "paediatric," "satisfaction," "symptom bother," "goal attainment", "screener," and "gener-

ic." Questionnaires evaluated in this chapter were updated with any new information if new validation work was found. New questionnaires not in the previously updated resource tool were added to appropriate sections if they were validated and relevant with regard to the search terms specified above. Grades were evaluated for correctness, based on previous and new validation work, and modified if and when necessary to demonstrate any changes with respect to instrument validation.

Table 2: Ideal properties of PRO instrument (adapted from [19], [20])

Specific to the concept being measured
Based on end-point model
Good psychometric properties (reliability, validity, responsiveness, conceptual equivalence…)
As short as possible (minimum burden) but never too short
Wide use
Available in different languages and cultures
Easy scoring (the simpler the better)
Self-administered
Inexpensive

IV. PRO QUESTIONNAIRE DEVELOPMENT AND VALIDATION

PRO questionnaires can be used to record the presence and severity of urinary, bowel and sexual symptoms, as well as the impact of symptoms on everyday activities, health-related quality of life and satisfaction with treatment, etc. To ensure that the results obtained with PROs are clinically useful, data must be gathered using valid and reliable instruments. The characteristics of an ideal PRO instrument are shown in **Table 2**. Questionnaire design and development is not a simple process. Developing such instruments requires a multistep, structured process that incorporates cognitive psychology, psychometric theory, and patient and clinician input. The process begins by determining the intent and purpose of the PRO and culminates in studies that demonstrate the measure's validity, reliability, and responsiveness. The specific steps required for developing a PRO questionnaire are outlined in the following section and are shown in **Table 3**.

The development of a PRO is a rigorous, scientific process to provide confidence that the PRO is measuring what it is intended to measure, that it does this reliably, and is appropriate for use in the patient or population group under investigation. The final instrument must have demonstrated validity and reliability in the intended target population. PROs need to be developed with patient and clinician input and have the psychometric, or measurement, properties of the PRO evaluated to determine that it is a valid outcome measure. To be a useful measurement tool, a PRO instrument must also be easy to administer, reliable, and valid. Only PROs that have undergone this process and have published validation data are discussed in this chapter.

Table 3: A detailed description of PRO development phases (Adapted from ICI 2013 and Berger et al, [21])

Theorization of a conceptual framework	Outline hypothesized concepts and potential claims Determine intended population Determine intended application/characteristics (type of scores, mode and frequency of administration) Perform literature expert review Develop hypothesized conceptual framework Place PROs within preliminary endpoint model Document preliminary instrument development
Adjustment of the conceptual framework and outlining instrument	Obtain patient input Generate new Items Select recall period, response options and format Select mode/method of administration/data collection Conduct patient cognitive interviewing Pilot test draft instrument Document content validity
Authentication of the framework and evaluation of further measurement properties	Confirm conceptual framework with scoring rule Assess score reliability, construct validity, and ability to detect change Finalize instrument content, formats, scoring, procedures and training materials Document measurement development
Collect, examine and interpret data	Prepare protocol and statistical analysis plan {final endpoint model and responder model) Collect and analyze data Evaluate treatment response using cumulative distribution and responder definition Document interpretation of treatment benefit in relation to claim
Adapt the PRO instrument	Change wording of items, populations, response options, recall period, or mode/method of administration/data collection Translate and culturally adopt to other languages Evaluate modifications as appropriate Document all changes

De Vellis has proposed an eight-step process of scale development:

- "Determine clearly what it is what you want to measure": it is necessary to clarify exactly what it is that is going to be measured, including the different aspects (domains or dimensions) and what the purpose of that measurement is.
- "Generate an item pool"
- "Determine the format for measurement": Likert, pictorial, rating, anchored VAS or VAS, scales, multiple response, check lists, etc.
- "Have initial item pool reviewed by experts"
- "Consider inclusion of validation items"
- "Administer the items to a development sample": to pilot the new instrument with a small group of patients drawn from the target population.
- "Evaluate the items": this is the process to analyze the psychometric properties of the items of the scale.
- "Optimize scale length": it is obtained by deletion of poorly performing or redundant items.

1. DETERMINING QUESTIONNAIRE INTENT AND PURPOSE

The first task in developing a PRO measure is to determine why the instrument is needed. Given the current number of disease-specific questionnaires available in the field of incontinence and related pelvic disorders, a new PRO measure must fill a need that has not already been met by an existing instrument. Once the need for the measure is recognized, its purpose and clinical usefulness need to be considered because the purpose dictates the validation design process. For example, a symptom and a treatment satisfaction measure would be developed and validated differently because the outcome is different.

The development stage would focus on the outcome of interest (e.g., symptoms patients experience and the significance of each symptom, or what issues patients consider when determining how satisfied they are with treatment) with the items derived from the patient perspective and relating to the outcome of interest. Validation efforts would include designing a study focused on the outcome of interest, with the appropriate patient inclusion/exclusion criteria to enhance generalizability, while maintaining internal consistency and providing opportunities to test—at a minimum—reliability and validity.

2. DEVELOPING THE ITEMS

Designing a clinically useful PROM involves more than just developing a series of questions. In addition to clinician input and literature review, questionnaire items must be generated from a patient perspective and include patient views. The type of population can help to generate item wording, evaluate the completeness of item coverage, and perform initial assessment of clarity and readability. This is obtained through focus groups or one-to-one interviews to provide qualitative data on issues pertinent to patients and to identify the words patients use to describe their symptoms or disease impact. Focus groups and one-to-one interviews should be carefully planned to address the goals of the questionnaire being developed. For example, if a measure is intended to assess symptom bother, interview questions should pertain to the patient's symptom experience. Importantly, rather than using clinical terminology which patients may not comprehend, the words used during the focus groups or interviews should be common to patients. The results of the qualitative patient interviews lead to item generation. The process is done until saturation. Saturation is reached at the point when no new relevant or important information emerges and collecting additional data will not likely add to the understanding of how patients perceive the concept of interest and the items in the questionnaire. After items are generated, the newly drafted questionnaire should be reviewed by other patients and experts to ensure its readability and content validity.

An alternative approach is to adapt an existing measure to meet the needs of a new patient population or a different condition. The adapted questionnaire must be newly validated in the target population as the validity of the original questionnaire does not apply to an adapted measure.

For newly developed and adapted questionnaires, think out loud interviews or cognitive interviews can be used to ascertain the correctness and validity of the revised questionnaire. In the first approach, patients think out loud about what the question means to them and how they think through their response. For a cognitive interview approach, patients review and respond to the questionnaire items, and then they are interviewed about what each item meant to them as they completed the questionnaire. Both approaches provide information about what patients are considering when answering each question.

3. HEALTHCARE LITERACY

Healthcare literacy is defined by the CDC as "the degree to which an individual has the capacity to obtain, communicate, process, and understand basic health information and services to make appropriate health decisions". It is generally recommended that healthcare information (including PROMs) should be written in language no higher than a sixth to eight grade reading level. Avoiding clinical terminology and making words easy to understand provides the best opportunity for PROMs to be answered accurately even by those with lower healthcare literacy.

4. DETERMINING THE MODE OF ADMINISTRATION OF A QUESTIONNAIRE

When generating the PRO items, the mode of administration must be considered. Will the measure be completed by the patient (i.e., self-administered) or administered by an interviewer (i.e., interviewer-administered)? How the questionnaire will be completed needs to be determined before the validation stage because mode of administration can affect patient responses. For highly personal or intimate questions, a self-administered questionnaire is recommended to avoid response bias. Questionnaires that are self-administered are preferable to interviewer-administered questionnaires because the data collection burden is reduced and patients are more likely to provide unbiased information on self-administered questionnaires. Importantly, if a questionnaire has been validated for a particular mode of administration (self-administered pen and paper), this does not make the questionnaire valid for all modes of administration (e.g. electronic administration via web or hand held device). Should the mode of administration change from the original validation, processes must be undertaken to ensure no change in meaning or content have occurred with the format change. Recommendations

for this type of adaptation (from PRO to ePRO) are clearly outlined by Coons et al.

5. QUESTIONNAIRES' PSYCHOMETRIC PROPERTIES

All PROMs must demonstrate reliability, validity, and responsiveness, which are described in detail below. This can be accomplished in several ways:

- Perform a stand-alone cross-sectional study to validate the questionnaire in the patient population for which it was designed;
- Administer the untested questionnaire in a clinical study and use the baseline data to perform psychometric validation (the end-of-study data can also be used to evaluate responsiveness); or
- Perform a stand-alone longitudinal study with an intervention to determine the instrument's psychometric performance and responsiveness in a non-clinical trial setting.

The following psychometric properties must be tested for and demonstrated in a validated questionnaire.

Reliability refers to the ability of a measure to produce similar results when assessments are repeated (i.e., is the measure reproducible?). Reliability is critical to ensure that change detected by the measure is due to the treatment or intervention and not due to measurement error. Reliability can be predicted in three ways: 1) internal consistency 2) test-retest reliability (reproducibility), 3) inter-rater reliability. Inter-rater reliability does not apply to PROs and will not be developed in this chapter.

Internal consistency indicates how well individual items within the same domain [or subscale) correlate. Cronbach's alpha coefficient is used to assess internal consistency reliability, with higher alphas indicating greater correlation. Typically, Cronbach's alpha should be greater than 0.70 to indicate adequate internal consistency reliability [26,,]. Alpha-coefficient values >0.90 suggest possible redundancy in the questionnaire items. If the item-to-total alpha is less than 0.20, the question should be removed or rewritten. Item-total correlation is yet another test that may be considered for internal consistency. It is the measure of the association between an item and the total score from the set of the items within the scale [22]. It can be measured by using Pearson correlation coefficient. If the value of the Pearson correlation coefficient is high then there is a stronger relationship between the items.

Test-retest reliability, or **reproducibility,** indicates how well results can be reproduced with repeated testing. To assess test-retest reliability, the same patient completes the questionnaire more than once, at baseline and again after a period of time during which the impact of symptoms is unlikely to change (e.g., a few days or weeks) [26, 27]. The Spearman's correlation coefficient and intraclass correlation coefficient (ICC) are used to demonstrate reproducibility. For group data, a Spearman's correlation coefficient or an ICC of at least 0.70 demonstrate good test-retest reliability [7,26, 27].

Validity is a qualitative assessment and refers to the ability of an instrument to measure what it was intended to measure [26, 27]. A PROM should be validated for each specific condition, patient population, and language for which it will be used. For example a measure designed to assess stress incontinence would not be valid for OAB unless it were specifically validated in patients with OAB symptoms. Validity includes content, criterion, and concurrent validity.

Content validity is a qualitative assessment of whether the questionnaire captures the range of the content it is intended to measure [26, 27]. For example, does a measure of symptom severity capture all the symptoms that patients with a particular condition have, and if so, is the measure capturing the items in a manner meaningful to patients in language patients can understand? Content validity can affect all other measurement properties. Irrelevant items and missing concepts may decrease internal consistency and responsiveness. Good reliability does not guarantee that the full construct of interest is being measured or that no important concepts are missing thus risking over- or underestimating outcome results[7]. FDA guidelines recommend establishing content validity before testing other psychometrics[1]. To obtain content validity, patients review the measure and provide feedback as to whether the questions are clear, unambiguous, and comprehensive. FDA recommends to document the development process and instrument attributes to support content validity, including: item generation, data collection method, instrument administration mode, recall period, response options, instrument format, patient understanding, scoring system and respondent-administrator burden[1].

Criterion validity reflects the correlation between the new questionnaire and an accepted reference, or gold standard [26,] . One difficulty in establishing criterion validity is that a gold-standard measure might not be available [22,29]. Correlations approaching 1.0 indicate that the new questionnaire is very similar to the gold-standard measure and might be redundant[22,29]. When criterion validity can be established with an existing measure, the correlation should be 0.40 to 0.70. Criterion validation is usually divided in two types: concurrent validity and predictive validity[26].

Concurrent validity is a type of Criterion Validity. Concurrent validity measures how well a new test compares to a well-established test administered at the same time. It can also refer to the practice of concurrently testing two groups at the same time, or asking two different groups of people to take the same test.

Predictive validity: if the test accurately predicts what it is supposed to predict. It can also refer to when scores from the predictor measure are taken first and then the criterion data is collected later.

Construct validity is a quantitative assessment of whether the questionnaire measures the theoretical construct it was intended to measure [26, 27]. It encompasses convergent and discriminant validity.

Convergent validity indicates whether a questionnaire has strong relationships with similar PROM of the same concepts or variables. For example strong correlations should be seen between the new PROM and an existing tool measuring the same constructs. And weaker correlations should be seen with PROMs of unrelated constructs [26, 27, 28].

Discriminant validity indicates whether the questionnaire can differentiate between known patient groups (e.g., those with mild, moderate, or severe disease) [26, 27]. Generally, measures that are highly discriminative are also highly responsive.

Responsiveness indicates whether the measure can detect change (for better or worse) in a patient's condition. An aspect of responsiveness is determining not only whether the measure detects change but whether the change is meaningful to the patient. This can be done by determining the minimal clinically important difference (MCID) of the measure.

Minimal clinically important difference (MCID) is the smallest change in a PROM score that would be considered meaningful or important to a patient. A second component of MCID is the smallest change which would be related to a change in patient management. A treatment that is statistically significantly better than another may not necessarily have made a meaningful difference to the patient; the MCID indicates whether the treatment made such a difference from a patient perspective.

Unfortunately, there is no scientific test for MCID as it is an iterative process that involves two methodologies to determine the MCID of a questionnaire: an anchor-based approach or a distribution-based approach. With the anchor-based approach, the MCID is determined by comparing the measure to other measures (or "anchors") that have clinical relevance [33]. With the distribution-based approach, the MCID can be determined by the statistical distributions of the data [33], using analyses such as effect size, one-half standard deviation, and standard error of measurement [33,34].

Another methodology to evaluate treatment benefit is to examine the cumulative distribution function (CDF) of responses between treatment groups. The CDF provides plots to examine the treatment effect and mean improvements by treatment group to see if the mean improvement varies by patient subsets [1, 35].

6. LINGUISTIC AND CULTURAL VALIDATION

Cross-cultural research has specific methodological problems, most related to translation quality and comparability of results in different cultural and ethnic groups. Increasingly, PROMs are required to be used in a number of different populations and settings, however, questionnaires and their psychometric properties are not necessarily transferable. It is not enough to translate a questionnaire literally. The challenge is to adapt it in a comprehensible and cultural form, maintaining the meaning and intention of the original questions. A measure that is valid and reliable for a particular language and culture may not prove to be so after translation. As most of the questionnaires have been developed and validated in English, there is a potential risk of cultural bias. Linguistic and cultural adaptation of a questionnaire can occur during the development phase before validation, or it can be done after the questionnaire is validated in the language in which it was initially developed, with the latter being the more common approach. Ensuring the linguistic and cultural validity of a questionnaire is especially important for measures used in multinational clinical trials [36,37]. Cultural validation is needed if the questionnaire is available in the target population language, but it was developed in a different cultural and social context (for example Spanish from Spain and Spanish from South America). Both linguistical and cultural validations are necessary if the language is not the same.

There are different approaches to the translation process. The simplest and most common (but less reliable) is the direct translation (made often by unqualified translators) to the new language without further validation measures. The second is the translation committee: 2 or more translators work together or separately to produce a consensus questionnaire. The third is the back translation method: one translates into the new language and a second independent translator comes back to the original language; then two versions are compared.

Producing high-quality translation is labour-intensive and time-consuming. Many different translation methods exist, and there is no scientific evidence than one is superior to another. Although, there is the lack of scientific evidence in favour of one specific method of translation, it is strongly recommendable to adopt a multistep approach to ensure quality[37].

The ISPOR (International Society for Pharmacoeconomics and Outcomes Research) Task Force for Translation and Cultural Adaptation recommends some principles of good practice for the translation and cultural adaptation process for PROMs, which can be summarized in 10 steps:

1. Preparation: obtain permission to use the instrument, recruit key researchers to the project, invite instrument developer to be involved, etc.
2. Forward translation: there is a general agreement that more than one forward translation is needed, and all forward translators should be native speakers of the target language with previous experience in the translation of PROMs.
3. Reconciliation: resolves discrepancies between translations, should be carried out by researches and translators.
4. Back translation: of the reconciled translated version into the original language. Back translators should be native speakers of the original language.
5. Back translation review: comparing with original version to ensure conceptual equivalence of the translation. Some methods using Likert scales for assessing comparability of the language (refers to the formal similarity of the words, phrases and sentences) and similarity of the interpretability (refers to the degree to which the two versions engender the same response even if the wording is not the same) have been developed[38].
6. Harmonization: of the new translations through panel expert meeting
7. Cognitive debriefing: the new translated questionnaire is tested in a focus group of patients[5,6,7,8] native speakers of the target language, assessing the level of comprehensibility and cognitive equivalence with original tool.
8. Review of cognitive debriefing results and finalization
9. Proofreading: it is a final control quality step to fix minor errors previously undetected,
10. Final report

Some check lists to ensure the translation process quality have been proposed[34]. (and to encourage investigators to publish detailed steps. Design: From a synthesis of existing guidelines, we propose important considerations for getting started, followed by six early steps: (1. However, if a backward translation of the measure does not produce a semantically equivalent instrument, then the instrument may need to be developed in the target language, rather than just translated [36]. Equivalence between original and target PRO versions need to be achieved at many levels (**Table 4**).

After cultural and linguistic validation, PROMs should also be psychometrically validated within the target language. Thus, reliability, validity, and responsiveness need to be assessed with each language translation to confirm the same measurement properties are present in the translated language(s) and to ensure psychometric equivalence. If psychometric equivalence is not present (e.g., not achieving similar or better results in new language translation), the cultural and linguistic translations need to be re-evaluated and perhaps a new instrument may need to be developed.

The ICIQ questionnaires and many of the other questionnaires discussed in this chapter have multiple linguistically validated versions making them useful for International implementation. It is also

Table 4: Terminology in linguistic and cultural validation [36]

Conceptual equivalence	It is the equivalence in relevance and meaning of the concepts and domains of health an QoL being measured in different languages and /or cultures.
Item equivalence	It exists when items estimate the same characteristics and they are equally relevant and equivalent in both languages and cultures
Semantic equivalence	The meaning and the level of the language have to obtain the same psychological and understanding effects on both populations
Operational equivalence	It refers to the possibility of using a similar PROM format, instructions, mode of administration and measurement method in both populations
Measurement equivalence	The comparability of the conceptual and psychometric properties of the data obtained in different languages or cultural versions It applies for data obtained from PRO via two administration modes[25]
Functional equivalence	It is defined as the extent to which an instrument does what is supposed to do equally well in two or more cultures (or modes of administration)

important to note that the step after linguistic validation, demonstrating psychometric equivalence, should also be demonstrated to ensure that the PROM performs equivalently in different languages and cultures.

7. BIASES IN RESPONDING TO QUESTIONNAIRES AND SCALES

We generally assume that patients will respond honestly to questionnaires, but this is not a reflection of the reality. A number of factors may influence the response. Many different biases have been identified and should be minimized as much as possible.

Cognitive requirements[26] Answering questions is a complex cognitive task that usually has 4 steps (each of them with potentially bias risk):

1. Understanding: it is important to avoid ambiguous items, to use simple language and to avoid the "time-frame" effect. If you give a patient a long time-frame ("over the last year"), they will be more likely to remember the one worst event over that time frame. This is less with a shorter time frame ("over the last week").
2. Recalling the relevant behavior, attitude or symptom: patients need to recall specific events to answer questions, and it is very common to forget them. Patient memories for events that occur over a period of one year are extremely poor. Patients with chronic conditions have difficulties recalling specific events. It may be even more difficult if the disorder shows fluctuating symptoms over time. Patients with pain disorders tend to recall the last and most painful event suffered just prior to completing the questionnaire.
3. Inference and estimation: patients tend to overestimate infrequent events and underestimate frequent ones. Very often numerical responses are given in multiples of 5 or 10.
4. Mapping the answer onto response alternatives: the patient's response has to adapt to the questionnaire format, and in the "translation" process some information may be lost.

Questionnaires (especially those with many items) require a cognitive effort, and patients tend to minimize it. This is called the "satisfying" strategy, and results when a patient accepts the available option as satisfactory. However, that option may not be truly representative of their symptoms.

The strategy has 6 forms:

1. Selecting the first option that seems reasonable: in written forms, patients tend to choose the first item on the list, and in verbal forms they more easily remember the most recent option.
2. Simply agreeing with every statement, or answering "true" or "false" to all items.
3. Endorsing the social "status quo"
4. Selecting one answer to the first question and using it for all the rest. This is a typical problem of Likert and analog scales.
5. Answering "I don't know" or a neutral position in Likert scales.
6. Choosing the options randomly.

Minimizing this "satisficing" bias requires the tool to be as simple as possible (few items, one thing per item, short recall period, few options but including all the possibilities and be appropriate). Motivating the patient is crucial for avoiding satisficing bias.

Social desirability This bias appears when patients want to give a socially desirable answer. When the patient is not aware of it, is also called *self-deception*. When the patient is aware of it and is intentionally attempting to give a positive impression, it is also called *faking good*. Many factors can influence social desirability bias (individual, gender, cultural background, etc.).

Deviance (faking bad) This is the opposite to social desirability, a tendency to respond with deviant responses, occurring specially in the context of personality assessment.

The hello-goodbye effect. This is a well-known phenomenon that occurs typically in interventional clinical studies. At the beginning the patient presents himself as bad as possible for ensuring the staff include him in the study, and at the end, he may want to thank the investigators showing an improvement better than the real one, minimizing the actual problem.

Acquiescence Also called *yes-saying* bias, is a tendency to give positive responses. There is an equivalent bias for *no-saying* responders.

End-aversion Also called *central tendency bias*, when patients avoid systematically extreme options in a scale. The effect of this bias is to reduce the range of possible responses (losing reliability and sensitivity). This bias is highly influenced by social and cultural factors (e.g. some Asian cultures are considered more collectivistic, and individuals do not like to be considered different from the group).

Positive skew The responses are clustered in a positive trend. The result is a ceiling effect, and as most of the responses are in one extreme, then it may be very difficult to detect improvements after any intervention.

Framing. The manner in which a question is posed affects the results obtained. For example, it is not the same to ask about preferences of taking a drug giving the information of 1% of morbidity, or 99% of no adverse events.

Biases related to measurement change. The *response shift phenomenon*: self-judgment of health or QoL may remain stable despite large objective changes or the reverse, may change without objective variations. This is due to tree cognitive process: recalibration, reconceptualization and reprioritization. The description of this process is out of the goals of this document.

An alternative point is that patients do not remember the previous state. They are only conscious of the actual state, and try to infer what the initial state must have been. This is the *implicit theory of change.*

Hawthorne effect. Patients enrolled in clinical studies tend to pay more attention to questionnaire items than they would do in daily clinical practice, because they think clinicians may require them some explanation for their answers.

8. REGULATORY OVERSIGHT

As clinicians and scientists have begun to appreciate and accept PROs as appropriate outcome measures, regulatory authorities have issued guidance documents on current best practices in the development and implementation of PROMs in the approval process of medical devices[1, ,]. For PROs to be acceptable outcome measures for regulatory authorities, documentation of measurement properties must be present as well as evidence of inclusion of the patient perspective and understanding of the PRO and a cohesive conceptual framework that stipulates how the PRO is related to the intervention. While PROs within this document may have a "recommended" status, they may not meet all of the required regulatory guidelines and may require additional validation work either from a qualitative or quantitative perspective. Researchers seeking approval for medical devices should contact regulatory authorities early in the process of selecting a PROM for clinical trials to ensure regulatory acceptance of the PROM. The FDA's Medical Device Development Tools (MDDT) program qualifies tools that can be used during the medical devise approval process[10]. This process includes many measurement tools including PROMs. Qualification of a PROM means that the FDA has evaluated the supporting evidence for the tool and found it to have good qualities. The Center for Devices and Radiological Health PRO document gives a few examples of qualified PROMs including the International Prostate Symptom Score (I-PSS).

9. ELECTRONIC PATIENT REPORTED OUTCOMES

The use of electronic PROs (ePROs) and studies comparing transfer from paper to electronic format date back to the late 1990s[4]. Today the use of ePROMs is well established in research and is increasingly seen in clinical practice. These tools can vary from simple pre and post treatment data collection to complex, multisystem programs which track patient information regularly (usually weekly) and send alerts to medical professionals when responses are out of range. Easy to use ePROMs have been shown to result in increased compliance and patient satisfaction[8]. Some medical professionals have expressed concern that only collecting patient symptoms on ePROMs may miss important symptoms. In the clinic, all PROMs should be reviewed with the patient during a one-on-one interview to ensure that all symptoms and concerns have been addressed. The majority of research in comprehensive ePROMs is in the treatment of cancer and has shown improvements in patient care and HRQoL,,. Electronic data collection (ie ePROMs) allows clinicians to longitudinally monitor response to therapy and advancement of disease without increased clinical time investment[49]. Standardized routine symptoms and QoL assessment is a key component of quality patient centered care. Privacy of ePROs must be secured and considered in creation, maintaining, archiving, retrieving, and transmitting clinical data[1].

There are benefits and negatives to the use of ePROs in research and clinical practice (**Table 5**). Overall the benefits far outweigh the negatives in research. It has been shown that electronic data collection yields more reliable and accurate data, allowing a stronger test of the study objectives and a better picture of the patient's experience (16). Studies show no significant variation of scores from paper to electronic tool in older patients or those with low computer literacy [4,8]. An area where ePROs can have a positive influence is in patient reported adverse events. Research shows adverse event symptoms are often under-reported by clinical researchers. The field of cancer treatment has led this research with large data bases

Table 5. Benefits and drawbacks of ePRO (taken from multiple sources including Brancato G et al 2006)[50]

Benefits of ePRO	Drawbacks of ePRO
• Reduce missing data by requiring an answer before advancing • Can include complex skip patterns • Easily captured in the electronic medical record reducing data entry error by medical professionals • Real time ePRO reduce recall-bias (avoid retrospective data entry by the patient) • Automatic scoring • Increased patient compliance • No out of range data • More accurate in recording sensitive topics such as sexual function, drug use, or adverse events • Multiple formats available (personal computer, tablet, smartphone) • Convenience for massive interviews (web based questionnaires)	• An electronic device is needed • Difficulties of some patients in interacting with computers (computer anxiety or computer illiteracy) • Space limitations requiring splitting of questions (questions and responses must be short) • Referring back to response of a previous question is more difficult (flow and navigation must be easy for patients) • Should be completed in less than 30 minutes • Inability of the patient to add information about symptoms or concerns not included in the tool

of ePROMs on adverse events in chemotherapy and other cancer related treatments[49] .

Measurement equivalence studies investigate the comparability of the conceptual and psychometric properties of the data obtained via two administration modes such as paper versus electronic questionnaires[25]. These studies have also looked at the comparability between ePROM types such as handheld device versus desk top or web based versus interactive voice response system (IVRS). Several large studies and meta-analysis have shown good measurement equivalence between paper and electronic PROMs [4,8,25,,]biological agents, and devices was underscored by the release of the US Food and Drug Administration's draft guidance for industry titled \"Patient-Reported Outcome Measures: Use in Medical Product Development to Support Labeling Claims.\" The intent of the guidance was to describe how the FDA will evaluate the appropriateness and adequacy of PRO measures used as effectiveness end points in clinical trials. In response to the expressed need of ISPOR members for further clarification of several aspects of the draft guidance, ISPOR's Health Science Policy Council created three task forces, one of which was charged with addressing the implications of the draft guidance for the collection of PRO data using electronic data capture modes of administration (ePRO. A recent meta-analysis shows ePROMs are quantitatively comparable to paper with a difference in absolute scores of less than 2% and a pooled correlation coefficient of 0.88 (95 % CI 0.87 to 0.88)[8]. This paper reviewed ePROMs used in 23 different patient populations including cancer, depression, orthopedic, pulmonary, neurological conditions, and more[8]. Types of ePROM, in order of their uses, include: desk top computers, handheld devices such as smart phones, tablet / touch screen devices, and interactive voice response system (IVRS). Studies comparing paper to tablet conversion show the greatest level of agreement. Studies comparing paper versus IVRS had the lowest level of agreement although it is still good (true agreement 0.82)[8].

Coons et al defined levels of changes in migrating PROMs from paper to electronic format as follows[25]. Minor changes are described as transferring a paper questionnaire into a text screen format without significantly altering item content, recall period or response options. Minor changes also include going from multiple items per page to one item per screen. Meta-analysis of measurement equivalence studies shows there is no need to perform quantitative migration studies for minor changes from paper to electronic format [4,8] evaluating 278 scales, provided sufficient detail to allow quantitative analysis. RESULTS Among 233 direct comparisons, the average mean difference between modes averaged 0.2% of the scale range (e.g., 0.02 points on a 10-point scale However there is a need to standardize migration practices.

Moderate changes include changing the order of the questions, requiring a scroll bar to view the full question or all the responses, or splitting an item into multiple screens (e.g., having a question and its responses on different screens). Moderate changes to a questionnaire would require formal measurement equivalency testing. This testing would be required to ensure comparability between scores in different formats but also to ensure usability of the electronic format. Transfer to IVRS is the most common moderate change as it requires the transfer from visual to auditory testing. Significant changes and substantial modifications to a tool (including changes in wording or options) can fundamentally change the properties of an instrument and thus require a new full psychometric testing.

10. EPRO RELATED TO PFM DYSFUNCTION

In general, electronic versions of sexual, prolapse and digestive PROMs show good correlations with paper versions, and a high proportion of patients prefer ePROMs because they are easier to use[,,].

Some studies have not found differences in pain description between electronic a paper PROM versions,. Interestingly, Marceau et al[57] found that patients prefer electronic diaries and consider them easier to use; moreover, patients reported that the diary enabled them and their doctor to make care adjustments according to changes in pain status.

11. QUESTIONNAIRE DEVELOPMENT CONCLUSION

PROs are the most suitable method for assessing the patient's perspective of their lower urinary tract, sexual and bowel symptoms[34]. Questionnaires may be long and detailed for use in research, but need to be short and easy to use to be relevant for clinical practice. In addition to being valid and reliable, they need to be easy to complete and score, and, if they are being used to measure outcome, sensitive to change. Developing a new questionnaire and testing it thoroughly takes a great deal of time and is only necessary if there is not an existing instrument available.

There are many questionnaires currently available for use and these have been reviewed and described with recommendations from the Committee for their use in the last six ICI reports.

The major purpose of the ICI has been to provide a definitive international review and consultative opinion regarding the recommended measures to assess patient reported outcomes within the area of urinary incontinence and LUTS. To this end since the First Consultation, the ICI has worked to develop a modular format for the various patient reported outcomes allowing clinicians and researchers to select internationally recommended questionnaires for the assessment of their patients in both clinical practice and clinical trials. In this seventh ICI review, the ICIQ modular questionnaires (supported by the International Consultation) are presented in detail and their use evaluated. Whilst some of the modular questionnaires are still currently under full evaluation their content and format are presented within this chapter.

12. RECOMMENDED PRO QUESTIONNAIRES

Grades of Recommendation for Questionnaires 2021
As with previous Consultations, the Committee continues to use three grades of recommendation. However, we have added a + sign to indicate when published content validity is available for an instrument:

- Questionnaires were 'highly recommended' and given a **Grade A** if the Committee found "Published data indicating that the questionnaire is valid, reliable and responsive to change following standard psychometric testing. Evidence must be published on all three aspects and questionnaires must be relevant for use with

persons with incontinence. **Grade A + indicates there is additional evidence of *published* content validity."**

- Questionnaires were "recommended" and given a **Grade B** if the Committee found "Published data indicating that the questionnaire is valid and reliable following standard psychometric testing. Evidence must be published on two of the three main aspects (usually validity and reliability). **Grade B + indicates there is additional evidence of *published* content validity."**
- Questionnaires were considered to have "potential" and given **Grade C** if the Committee found "Published data (including abstracts) indicating that the questionnaire is valid or reliable or responsive to change following standard psychometric testing. **Grade C + indicates there is additional evidence of *published* content validity."**

The Committee decided that evidence published in abstracts or posters could be used to indicate a developing questionnaire's potential, but was not sufficiently peer-reviewed to provide the basis for a stronger recommendation.

As decided in the Fourth Consultation the recommendation will be to preferably utilize questionnaires from the ICIQ modules described in detail below. Many, but not all, of these questionnaires are Grade A or A+ questionnaires by previously stipulated criteria. Within the description of the ICIQ modules below the grade assigned to each module is indicated.

Should none of the modular questionnaires be deemed appropriate for specific research or clinical purposes, ICI's recommendation is to use a Grade A+ or A questionnaire as previously recommended. When no suitable instrument exists a Grade B or C questionnaire, performing additional validation as indicated prior to use if feasible, should be used.

For UI and UI/LUTS, the Committee examined the quality of the psychometric evidence. Only where published data were scientifically sound was the label 'with rigor' allowed. Where the Committee had concerns about the quality of evidence, this is noted in the descriptions of the questionnaires below. The Committee considered that the number of high quality questionnaires means that there are now sufficient questionnaires for most purposes and it is not necessary to encourage the development of new questionnaires, except for particular patient groups.

V. INTERNATIONAL CONSULTATION ON INCONTINENCE MODULAR QUESTIONNAIRE (ICIQ): WHAT IS THE ICIQ?

The ICI Questionnaire project was started in 1998, to meet the need for universally applicable questionnaires for use in clinical practice and research[1]. It was recognised that there was a proliferation of validated questionnaires each developed for a specific purpose and each subtly different. Although developers of the questionnaires were familiar with their content and use, the increasing number of questionnaires made appropriate selection difficult and limited the ability to compare similar clinical and research data due to different data collection methods.

The decision to develop standard questionnaire modules was taken by the Committee after the first ICI meeting in 1998, and resulted in the development of the ICIQ core questionnaires discussed in this section. The first questionnaire as a result of this initiative was the ICIQ-Urinary Incontinence Short form (ICIQ-UI-SF) for the assessment of urinary incontinence and its impact on quality of life. This remains the most widely used and requested questionnaire and has now been translated into over sixty languages.

An international advisory board was established to continue the development of the modular ICI questionnaire and to expand the scope of the modules to evaluate symptoms and impact of dysfunction of the lower urinary tract, lower bowel and pelvic organ prolapse. The advisory board consisted of clinicians and researchers with experience in the design and use of questionnaires representing the major societies involved in the assessment and research of lower genital tract, lower urinary tract and bowel function. The ICIQ recognised that many high quality published questionnaires already existed and, with permission from the authors, those instruments were adopted into the modular project. It was not possible to adopt all available questionnaires and where more than one option existed, the most appropriate questionnaire for the purpose was included. Where high quality questionnaires were not available, the need to develop a new questionnaire was acknowledged Researchers who have developed questionnaires that they would like to be reviewed by the advisory board for inclusion are encouraged to contact the ICIQ group through the website www.iciq.net. The ICIQ research group is based in the Bristol Urological Institute, at Southmead Hospital, Bristol, in the United Kingdom.

1. AIMS AND OBJECTIVES

The ICIQ's objective is to provide international consensus on the use of patient completed questionnaires for the assessment of lower pelvic symptoms and their impact on patient's lives. Four aims underpin the ICIQ in order to achieve clarity over questionnaire use:

1. To develop psychometrically validated questionnaires to evaluate symptoms and impact of dysfunction of the lower urinary tract, lower bowel and pelvic organ prolapse.
2. The adoption of existing questionnaires, that are psychometrically valid and complement the existing ICIQ questionnaires
3. To increase the use of patient reported questionnaires to standardise the assessment of lower urinary tract, lower bowel and pelvic organ prolapse and their impact on patients' lives.
4. To use the questionnaires to facilitate communication in different patient settings and different patient groups both in clinical practice and wider clinical research

The ICIQ Questionnaires are developed according to rigorous methodology which complies with industry-standard guidance for PRO development[1]. The ICIQ continues to update its methodology to maintain pace with the current advances in PROM development. Questionnaires that are newly developed and adopted as part of the ICIQ modules must meet current regulatory guidance and standards of documentation. As part of this, the development should include patients at each stage, and be published in scientific journals, to allow the quality of development to be publically available for the assessment of quality. The ICIQ's international nature requires that linguistically validated translations are available. More than 300 language versions of various modules have been validated to date and conducted according to an established protocol[62].

Table 6. The ICIQ Modular Structure

CONDITION	RECOMMENDED MODULES	OPTIONAL MODULES	RECOMMENDED ADD-ON MODULES		
	A) Core modules		**QoL**	**Sexual Matters**	**Post-Treatment**
Urinary Symptoms	Males: ICIQ-MLUTS Females: ICIQ-FLUTS	Males: ICIQ-MLUTS LF Females: ICIQ-FLUTS LF	ICIQ-LUTSqol	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	ICIQ-S* (satisfaction)
	ICIQ-Bladder diary				
Vaginal Symptoms	ICIQ-VS		ICIQ-VSqol*		
Bowel Symptoms	ICIQ-B	ICIQ-IBD			
Urinary Incontinence	ICIQ-UI SF	ICIQ-UI LF*	ICIQ-LUTSqol	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
CONDITION	B) Specific Patient Groups		QoL	Sexual Matters	
Nocturia	ICIQ-N		ICIQ-Nqol	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
Overactive Bladder	ICIQ-OAB		ICIQ-OABqol	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
Underactive Bladder	ICIQ-UAB/UAB PRO*				
Neurogenic	ICIQ-Neuro Bowel		ICIQ-Neuro bowel*		
Long term catheter	ICIQ-LTCqol				
Children	ICIQ-CLUTS*		ICIQ-CLUTSqol*		
Absorbent pads			ICIQ-Padprom*		
Cognitively impaired elderly	ICIQ-Qoldem*				
Inflammatory bowel disease incontinence	ICIQ-IBD				

2. ICIQ MODULES

In this chapter, questionnaires forming part of the ICIQ modular format are referred to as those **recommended** for use. Although many of the modules are Grade A or A+ questionnaires, others are still under various phases of development and are graded appropriately. Questionnaires that are in early stages of development are described as “in development”.

Nineteen ICIQ modules/questionnaires are currently available for use, with further modules in development (discussed in detail below). Clinicians or researchers can select module(s) to meet the requirements of their study or clinical practice. To simplify this selection process, modules have been categorised as shown in **Table 6**.

2.1. Core Modules

Questionnaires recommended to assess the core symptoms and impact on health related quality of life (HRQL) of lower pelvic dysfunction are contained in this section, in addition to impact on sexual matters. Core modules (**Table 6**) provide evaluation of:

- Lower urinary tract symptoms (Male and Female separately)
- Urinary incontinence
- Vaginal symptoms
- Bowel symptoms

Each symptom module is intended for the comprehensive yet succinct measurement of symptoms and associated ‘bother’. The bother item attached to symptom items, where applicable, enables the individual to indicate areas that cause the greatest negative impact on HRQL as perceived by them. This can be a more sensitive indicator of treatment goals than frequency of symptoms alone. The associated HRQL questionnaires cover specific issues that are a consequence of symptoms, such as life limitations and emotional impact. Sexual matters modules specifically evaluate the impact of lower urinary tract symptoms on this aspect from the male and female perspective.

A further core module has been added that moves away from the retrospective questionnaire format in the form of a bladder diary. This is a fully validated prospective tool for the measurement of bladder events as they occur.

2.1.1. Specific Patient Group Modules

Questionnaires to assess specific conditions or symptom complexes such as nocturia, overactive bladder and underactive bladder, in addition to management strategies such as long term catheter and pad usage are contained in this section along with HRQL modules for these specific symptom complexes where available. This category also includes specific patient groups, for example, children. These instruments contain only question items characteristic of the symptom complex or have been developed specifically for use in a diverse group This defines their context of use making the items/questionnaire only utilisable in this population.

- Nocturia
- Overactive bladder
- Underactive bladder
- Inflammatory bowel disease
- Lower urinary tract symptoms in children
- Individuals using long term catheters
- Individuals using absorbent pads

2.2. Optional Modules

This category lies within the core symptoms and includes lengthier questionnaires for more in- depth evaluation of lower pelvic dysfunction. There is the long form for the assessment of LUTS in men (ICIQ-MLUTS LF) and the long form for the assessment of LUTS in women (ICIQ-FLUTS LF). Whilst these questionnaires are suitable for use in clinical practice, they have not been shortened for clinical efficiency and are therefore more widely used in research studies where exploration of broader associated symptoms may be desired.

2.3. Post-treatment Module

The ICIQ-S assesses patient satisfaction experience, expectations and outcomes after urological surgery. The ICIQ-S is intended to be applicable to other urological patient populations after any urological or gynaecological procedure. A further questionnaire to assess patient satisfaction after urodynamic investigation is also under development.

3. GUIDANCE FOR USE OF THE ICIQ

The ICIQ recommends the use of a symptom and HRQL module that match the intended purpose of a study in order to provide a comprehensive evaluation of these two perspectives. The extent of burden placed on the respondent and the study or clinical outcomes must be considered however and ultimately guide questionnaire selection. The updated website, launched in 2019 www.iciq.net has the information required for permission for use, including licensing requirements if necessary. More information about the modules can be found here, including scoring instructions, sample copies and information on the associated validation publications. After registration through the website, access is given to the online library of the modules and translations where they may be downloaded freely. Additional information on any modules that are under development are also detailed here, and any announcements or developments are updated regularly through the ICIQ twitter account: @ICIQ_PROMs.

4. ICIQ QUESTIONNAIRE IMPLEMENTATION

The ICIQ modular questionnaire has attracted considerable attention from both clinicians and researchers worldwide since its structure was finalised in 2004. As of October 2019 there have been over 3700 publications that mention the 'ICIQ' or the modules[62]. The ICIQ is widely applied to clinical and general practice settings, alongside its considerable uptake for research purposes. The ICIQ has also been adopted in national guidelines for the management of urinary incontinence

The ICIQ is widely applied to clinical and general practice settings, alongside it's considerable uptake for research purposes. The ICIQ has also been adopted in national guidelines for the management of urinary incontinence in:

- women (NICE clinical guideline 171)
- primary care (SIGN 79)(www.sign.ac.uk/pdf/ sign79.pdf)

Table 7. The ICIQ modular structure (adapted from (Uren et al., 2020a)). The following modules were adopted as ICIQ modules with author's permission: ICIQ-Nqol, ICIQ-OABqol, ICIQ-LUTSqol. *These questionnaires are currently in development.

Condition	Core questionnaires				Post-Treatment
	Symptoms	**Optional**	**HRQoL**	**Sexual Matters**	
Urinary Symptoms	Males: ICIQ-MLUTS[53] Females: ICIQ-FLUTS[54]	Males: ICIQ-MLUTS Long Form Females: ICIQ-FLUTS Long Form	ICIQ-LUTSqol [13]	Males: ICIQ-MLUTSsex Female: ICIQ-FLUTSsex	ICIQ-Satisfaction[55]
Vaginal Symptoms	ICIQ-VS[56]		ICIQ-VS	ICIQ-VS	
Bowel Symptoms	ICIQ-B[57],[58]		ICIQ-B	ICIQ-B	
Urinary Incontinence	ICIQ-UI Short Form[61]		ICIQ-LUTSqol ICIQ-UI SF	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
Prospective bladder events	ICIQ-Bladder diary[59]				
Condition	**Specific patient groups**				
	Symptoms		**HRQoL**	**Sexual Matters**	
Nocturia	ICIQ-N		ICIQ-Nqol[70]	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
Overactive Bladder	ICIQ-OAB		ICIQ-OABqol[71]	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
Underactive Bladder	ICIQ-UAB*[72], [73]

Cognitively Impaired Adults	ICIQ-Cog*[75]				

- included in a primary care resource pack by the British Society of Urogynaecology.

There is an ongoing demand for innovative digital solutions that facilitate the administration of the ICIQ modules in electronic format, for both research and clinical practice. The advantages are automatic collection of PROM data, reducing the need for costly paper administration and data analysis. Evaluations of electronic ICIQ modules have been completed, indicating equivalence of their measurement properties and acceptability to the target audiences. In addition, the ICIQ has partnered with an existing eHealth platform provider to pilot test an electronic option for the routine clinical and research administration of the ICIQ questionnaires.

5. CONCLUSION

The ICIQ modular questionnaire project (www.iciq.net) provides a growing series of standardised questionnaires for the patient reported assessment of lower pelvic dysfunction symptoms and their impact on patients' lives. The ICIQ provides clarity over the selection of questionnaires by recommending only those with evidence of high quality and robust psychometric validation including validity, reliability and sensitivity to change. Increasing awareness of the ICIQ aims to promote increased use of standardised questionnaires and further evaluation of existing modules in order to advance the evidence base supporting use of these tools. These efforts aim to increase communication between clinicians and researchers and enable more wide- spread comparisons between different treatments and patient groups worldwide. The ICIQ continues to have international usage, and facilitates dissemination through its website, online library and a social media presence. In future, it is anticipated there will be a greater demand for their use in electronic format for both research and clinical practice.

VI. PATIENT-REPORTED OUTCOME (PRO) QUESTIONNAIRES TO ASSESS THE IMPACT OF URINARY INCONTINENCE, OAB AND LOWER

1. URINARY TRACT SYMPTOMS

There are a variety of PRO measures available for use in clinical practice and research that assess a range of concepts (e.g. HRQL, patient satisfaction, symptom bother, etc). Encouragingly, PROs awarded the highest ICI grade are being used widely in studies, with short forms that are easily accessible being preferred. This section provides an overview and assessment of these measures. Importantly, clinical practitioners and researchers need to clearly determine their clinical and research objectives before selecting a PRO as it is these objectives and the target patient population that will help determine which validated PRO is appropriate to use. **Tables 8 to 12** provide a brief overview of all current PRO measures for urinary incontinence and LUTS, their purpose, psychometric properties, translation availability, and recommended ICI grade.

Please note, as instrument development and validation is an ongoing process, the tables below contain publications through to November 2020. As additional work may have been performed on an instrument, it is always prudent to conduct a further literature search and/or contact the instrument developer prior to selecting an outcome measure for your clinical practice or study. This is particularly relevant for translation availability, which we have not included here due to the dynamic nature of translation production. Further study-specific testing should also be considered to ensure a tool's appropriateness for the intended purpose.

When using a questionnaire in a patient group other than the group for which it was initially developed, cognitive interviews with the new patient population should be held to review the applicability of the questionnaire to the new patient group. Several of the main questionnaires to be discussed below have now had modified versions published in the literature. The Committee's view is that although it may be appropriate to modify established questionnaires for use with some populations, it is advisable to keep such modifications to a minimum, and to use the original versions whenever possible. Any modifications of established questionnaires may result in changes (sometimes substantial) in the psychometric performance of the instrument, and thus all modified instruments should be subjected to the same psychometric testing as that employed in developing a completely new instrument. Specifically, modified instruments should report information regarding the instrument's construct validity, reliability, and test- retest reliability, at a minimum, and sensitivity to change, in intervention studies.

2. HEALTH-RELATED QUALITY OF LIFE MEASURES

Health-related quality of life (HRQL) measures help to assess the impact of disease and treatment on those aspects of quality of life related to health. UI is a symptomatic condition that has been shown to affect many aspects of a patient's life - physical, emotional, and social relations and cause concern and burden. As such, it is important to assess HRQL in clinical research and practice as this can aid identification of the most troubling aspect of the symptom experience and guide individualised management planning. **Table 6** provides a quick overview of the variety of HRQoL measures available and their validity and characteristics to determine which mea- sure is suitable for your objectives.

3. PATIENT SATISFACTION AND GOAL ATTAINMENT SCALING

Patient satisfaction and Goal Attainment Scaling are two important but separate types of PROs that allow for individualised assessment of disease impact and treatment. Patient satisfaction is the subjective, individual evaluation of treatment and includes a complex consideration of multiple components including treatment effectiveness, side effects, and/or the accessibility and quality of service provided by the healthcare system. Goal attainment scaling (GAS) is a method developed to ascertain individual patient treatment goals and using those to facilitate patient-provider interaction and tailor the treatment plan based on those individual's goals .

Measures of patient satisfaction can include evaluation of care provision, availability of resources, continuity of care, efficacy, finances, humaneness, information gathering and giving processes, pleasantness of surroundings and perceived quality/competence of health care personnel. At its most basic level, satisfaction is a comprehensive evaluation of several dimensions of health care based

on patient expectations and provider and treatment performance. As an outcomes measure, patient satisfaction allows health care providers to assess the appropriateness of treatment ac-cording to patient expectations. In chronic diseases, where patients must live with treatment, patient satisfaction may be the distinguishing out-come among treatments with comparable efficacy.

Table 7 presents a summary of satisfaction instruments identified in UI, OAB and other LUTS.

GAS has been used to measure clinically important change in several therapeutic areas. Although it was originally developed to assess health outcomes in mental health settings, it has recently been expanded to include evaluations in urogynaecology[79]. GAS has been linked to several possible benefits compared with traditional outcome measures, such as improved clarity concerning treatment objectives for both the healthcare provider and the patient, active involvement of the patient in problem-solving efforts, establishment of realistic patient and healthcare provider expectations of treatment, and increased motivation of patients toward improving their health condition[80]. The end result of GAS is to clarify patients' expectations for their treatment, document goal achievement, and eventually increase patient satisfaction and improve therapeutic outcomes. The overwhelming distinction between GAS and other PROMs is the individualised nature of expectations are accounted for and the opportunity to address unrealistic goals can be actively managed.

One GAS instrument for lower urinary tract symptoms has been well developed, the Self-Assessment Goal Attainment (SAGA) questionnaire. Numerous linguistically validated translations are available at: http://www.pfizerpatientreportedoutcomes.com .

4. SCREENING TOOLS

In order to improve the detection of incontinence, OAB and other LUTS, several screening tools have been developed (**Table 8**). These tools help patients self-describe symptoms and facilitate diagnosis of LUTS by the clinician. Only the B-SAQ has been designed to screen for general lower urinary tract symptoms (LUTS) rather than solely symptoms of one condition. The majority of patients with LUTS have mixed urinary symptoms, and therefore a questionnaire which can detect more than one symptom complex may be more functional as a screening tool in clinical practice than a highly specific questionnaire. The Leicester Impact Scale (LIS), OAB-V8, OAB-SS and QUID are all Grade A, short, simple to understand and complete, and easy to interpret. However the LIS is interviewer, not patient administered. Importantly, with screeners, responsiveness is not assessed, however the sensitivity and specificity of each tool is critical.

5. ASSESSING SYMPTOM BOTHER AND OVERALL BOTHER

Measures to assess this are included in **Table 9**. The Patient Perception of Bladder Condition (PPBC) [65][65] and the Urogenital Distress Inventory are the only Grade A recommend instruments. However, there are several Grade B and C measures which assess bother for incontinence and LUTS.

Symptom bother questionnaires provide insights into the experience of urinary incontinence symptoms by comparison with presence or absence. Measures to assess this are included in **Table 9**. It is highlighted that a number of symptom scores include bother ratings and therefore important to review all potentially relevant assessment tools when selecting the instrument of choice. The Patient Perception of Bladder Condition and the Urogenital Distress Inventory are the only Grade A recommend instruments. However, there are several Grade B and C measures which assess bother for incontinence and LUTS.

6. ASSESSING THE IMPACT OF URGENCY

Several instruments have been developed specifically to assess urinary urgency, which is defined by the International Continence Society as "the complaint of a sudden compelling desire to pass urine which is difficult to defer". Urgency is the driving symptom of OAB, thus assessing the effect of treatment on this symptom and its impact on HRQL is important. With any measure designed to evaluate urgency, patients must be able to distinguish between the normal desire to urinate (urge) and the difficult-to-postpone need to urinate (urgency),. Wording thus becomes critical in the development of urgency assessment measures. Chapple and Wein make a case for describing urgency as a "compelling desire to void in which patients fear leakage of urine" as a means of distinguishing this abnormal sensation from the normal need to void. However, some patients may have a sensation of urgency without fear of leakage, further complicating attempts to define urgency. Importantly, with some of these scales, patients have the option of indicating that they experienced UUI (an event) rather than the strongest feeling of urgency (a sensation) itself. Several instruments have been developed to assess urinary urgency these are summarised in **Table 10**.

VII. QUESTIONNAIRES FOR SPECIFIC PATIENT GROUPS

Most studies and questionnaires have been developed for use with members of the general population or urology/gynaecology patients with incontinence or POP. However, some specific patient groups may experience particular problems with incontinence (for example, children, frail elderly or those who are severely disabled), which may require independent investigation and potentially the development of more specific measures or the addition of a new subset of items on already developed instruments. This is an important consideration during questionnaire selection as determining the context of use for the tool and its appropriateness to the population in question is essential. The Committee advises that researchers should use existing highly recommended or recommended questionnaires if possible as this aids comparison and to reduce the increasing proliferation of questionnaires. Many of the questionnaires developed below for particular conditions (e.g. prostate cancer) pre-dated the development of highly recommended questionnaires, and highly recommended questionnaires should be used preferentially.

1. OLDER PEOPLE

Urinary incontinence symptoms play an influential role on the overall HRQL in older people (>65) and causes a significant decrease in HRQL, as severe as that of many chronic disease states. Since

the elderly commonly have a number of associated co-morbid conditions, it may be difficult to measure the impact of urinary incontinence with generic HRQL measures. The use of incontinence specific tools to measure patient-reported outcomes in the elderly, therefore, is of considerable importance. Validated incontinence-specific PRO questionnaires, such as IIQ, I-QOL or KHQ, are used for clinical trials or research on urinary incontinence including elderly people, but their validity has not been specifically assessed in this age group. Okamura assessed symptoms and HRQL in older people (men and women) with lower urinary tract symptoms including incontinence, using the KHQ and IPSS. They demonstrated that symptoms and HRQL in the elderly with LUTS could be assessed by IPSS and KHQ and that urinary incontinence appeared to be more associated with a decreased HRQL in elderly women.

On the other hand, there are a variety of factors affecting older people, including physical, social, mental, economic or environmental conditions, which are different from those of the young. In frail elderly people with dementia or physical impairment, it may be difficult to assess the impact of urinary incontinence alone. Questionnaires specifically developed for the elderly may be of great importance in this respect. However, there is little relating to the development or validation of particular questionnaires for older people with urinary incontinence and this has not progressed since the previous update. Three questionnaires dealing with older people were found and are described below. No questionnaires dealing with patient outcomes specifically for frail older incontinent people were found.

1.1. The Urge Impact Scale (URIS) [Grade B]

The Urge Impact Scale (URIS) was designed and tested specifically for older persons with urgency incontinence. The URIS was developed and validated by DuBeau et al. [72] and included 32 items, reduced to 24 items (URIS-24). The URIS-24 was psychometrically assessed for validity and reliability in community-dwelling older (>65y) men and women with urgency incontinence. Cronbach's alpha was 0.84 for the URIS-32 and 0.94 for the URIS-24. In assessment of test-retest reliability, interclass co- efficient (ICC) was 0.88. The URIS-24 had modest but nearly significant correlation with the number of urgency incontinence episodes (rho=-0.39, p=0.05). Factor analysis revealed 3 component structures corresponding to physiological burden, perception of personal control and self-concept. There was no analysis for responsiveness. They showed that the URIS-24 is an internally consistent, highly reproducible tool for the assessment of the QOL impact of urgency incontinence on older persons.

1.2. Geriatric Self-Efficacy Index for Urinary Incontinence (GSE-UI) [Grade A]

The GSE-UI was developed to provide measurement of a person's confidence in their ability to prevent urine loss and whether this is an important aspect contributing to improvements in UI. The questionnaire was developed by Tannenbaum et al and is intended for use in community dwelling adults aged 65 years and older. The developmental version of the questionnaire included 38 items, which was reduced to 20 following psychometric testing. This has since been further reduced to 12 items. Question items focus on confidence of the respondent to prevent urine loss in varied situations and produce a score where a higher score is indicative of a higher level of self-efficacy related to UI. During original testing, item responses were normally distributed with no ceiling effects. Positive correlations were observed with quality of life scores (r=0.7, P<.001), while negative correlations were evidenced for symptom severity (r=−0.4, P<.001). Initial test-retest reliability of the reduced 20 items using intraclass correlation coefficients, ranged from 0.50 to 0.86. Later evaluation of the reduced 12 item GSE-UI demonstrated responsiveness of the instrument and found it to be clinically useful.

1.3. Caregivers

The Overactive Bladder Family Impact (OAB-FIM) scale was developed to assess the impact of OAB on family members of patients with OAB. This 19-item tool consists of 6 subscales. Four subscales (Irritation, Activities, Travel, Concern) could be used for all family members; however 2 additional subscales (Sleep, Sex) should only be administered to spouses/ significant others. The OAB-FIM was highly discriminating between OAB and control family members, with all OAB family members indicating significant impact (all $p<0.0001$). Internal consistency reliability (Cronbach's alpha >0.71) and 2-week test-retest reliability (intra-class correlation coefficients >0.73) were high for all subscales. Concurrent validity of the OAB-FIM was demonstrated through statistically significant ($p < 0.001$) Spearman correlations with the OAB-q (coefficients ranging from 0.35 to 0.58) and the PPBC (0.31 to 0.56). No differences were noted on the OAB-FIM by patient incontinence status (none, urge vs. mixed). OAB-FIM scores also discriminated by family member perceptions of OAB severity, particularly among the Irritation, Activities and Travel subscales. Correlational analyses among the OAB-FIM and relationship quality measures suggest that greater OAB symptom impact on the family member was associated with increased problems in the patient–family member relationship. The responsiveness of the OAB-FIM is yet to be assessed. This measure can be found at www. pfizerpatientreportedoutcomes.com.

2. CHILDREN

Some questionnaires have been developed specifically to assess issues for children and can include parent and child versions of the questionnaire. Enuresis is a particular focus in addition to specific disorders such as Spina Bifida (ISI-P). A recent contribution in this area is a new Pictorial Urgency Scale for Children. Published evidence demonstrates robust correlations between standard verbal descriptors, bladder volumes and PUS images. This is an example of population-specific advances to improve communication of urgency sensation, which can be difficult to articulate for younger children. More comprehensive details of questionnaires for children are included in Chapter 9 (Children) and the section on the ICIQ modular questionnaire.

3. SPINAL CORD INJURED/ NEUROLOGICAL IMPAIRMENT

Individuals who have a spinal cord injury or are neurologically damaged can experience particular difficulties with incontinence and the use of various devices. It would be useful to investigate whether Grade A questionnaires, developed for people without neurological damage, can be used in this group, or whether additional modules or instruments are required. New instruments available in this area are detailed below.

3.1. ISI-P: Incontinence Symptom Index – Pediatric

The ISI-P was evaluated among a population 11-17 year olds with spina bifida to test its reliability and validity. The ISI-P is an 11 item, self-reported questionnaire and provides assessment of symptom severity and impairment. The response rate of 42.3% indicates ac-

ceptable validity although the sample size was small (n=33). Cronbach's alpha demonstrated internal consistency for both factors (0.936 and 0.792 respectively) with the two factor solution of 'symptom severity' and 'bother from incontinence' providing the best fit. The questionnaire would benefit from further testing but provides a brief, focused and clinically relevant tool for adolescents with Spina Bifida.

3.2. QUALAS-A: Quality of life assessment in Spina Bifida for Adults

The QUALAS-A was developed to evaluate quality of life associated with bladder and bowel disorders in adults with Spina Bifida. Items were generated through interviews and a focus group and refined to develop the 53 item pilot instrument. International recruitment achieved a sample of 532 participants to evaluate validity and reliability to assist item reduction. The resulting 15 item questionnaire provides a comprehensive assessment organized within three domains: Health and relationships, Esteem and sexuality, and bladder and bowel.

3.3. IUI: Incontinence Utility Index

The IUI is a condition-specific preference-based measure for urinary symptoms related to neurogenic detrusor overactivity that provides population based utility scores to value health states. The instrument was developed from the I-QoL and neurogenic module by applying Rasch modeling. 442 participants were interviewed to estimate social preferences and explanatory models identified that demonstrated adequate predictive validity.

3.4. Qualiveen: Quality of Life Related to Urinary Problems in Spinal Cord Injury [Grade A]

The Qualiveen was developed to evaluate the specific impact of urinary dysfunction on the quality of life of spinal cord injury patients in France. The initial items were developed following patient interviews, and were then assessed for validity and reliability in 281 spinal cord injury patients with urinary difficulties. The Qualiveen contains 30 items and has demonstrated good reliability and validity. Further validation of the Qualiveen has been performed in multiple sclerosis patients and it has been translated and validated into English, German, and Portuguese. The Qualiveen has demonstrated responsiveness in multiple sclerosis patients and has a suggested MID of 0.5.

4. PROSTATE/BLADDER CANCER

Many PRO questionnaires are available for assessment in this area: Post-radical prostatectomy questionnaire, Cancer Rehabilitation Evaluation System - Short Form (CARES-SF), Prostate Cancer Treatment Outcome Questionnaire (PCTO-Q),PROSQOLI, Modified South-west Oncology Group (SWOG), Functional Assessment of Cancer Therapy - (FACT-G), Bladder form (FACT-B) and Prostate form (FACT-P), Functional Assessment of Cancer Therapy Vanderviet Cystectomy Index (FACT-VCI), EORTC metastatic prostate cancer, Changes in Urinary Function, Prostate-targeted Health Related Quality of Life. More recently the C-PAT has been published for the assessment of the quality of care within the cystectomy pathway, providing insights to inform improved care across cancer centres. While it is beyond the scope of this chapter to review and recommend PROs in this area, the principles and guidelines discussed herein apply to selecting a PRO related to prostate and bladder cancer.

5. LOWER URINARY TRACT SYMPTOMS/BENIGN PROSTATE DISEASE

Many questionnaires have been developed to assess LUTS and benign prostate disease; however, most do not contain a full evaluation of UI. Perhaps the most widely known urology PROS are the AUA Symptom Index and the I-PSS (International Prostate Symptom Score). The IPSS has been utilitised internationally to assess symptoms of prostate disease with documented reliability, validity and responsiveness. More recently a Visual Prostate Symptom Score has been developed and an app version of the IPSS has been evaluated, providing alternative approaches to the assessment of symptoms associated with prostate disease. Additional PRO measures for BPH are as follows: Patient-completed modification of the Boyarsky, BPH Impact Index and BPH Health-related QoL survey.

6. PERINATAL WOMEN

Pregnancy and childbirth are associated with the onset, and aggravation of interrelated pelvic floor disorders (PFDs), such as urinary incontinence, faecal incontinence, pelvic organ prolapse and sexual dysfunction. Although many questionnaires have been developed to assess these disorders such as the ICIQ-UI SF for incontinence[61], ICIQ-B for anal incontinence[68], Accidental Bowel Leakage Evaluation (ABLE) questionnaire for bowel symptoms, the ICIQ-VS for vaginal symptoms[66], and the Pelvic organ prolapse-urinary Incontinence Sexual function Questionnaire-IUGA revised (PISQ-IR) for sexual symptoms, few have been validated specifically for use with women in the pre-natal or post-partum period (Madsen et al., 2021; Zuchelo et al., 2018)1,2 Italla Maria Pinheiro Bezerra,1,3 Adna Thaysa Marcial Da Silva,1,4 Jéssica Menezes Gomes,1,4 José Maria Soares Júnior,4 Edmund Chada Baracat,4 Luiz Carlos de Abreu,1,3 Isabel Cristina Esposito Sorpreso1,4 1Study Design and Scientific Writing Laboratory at ABC Medical School, Santo André, Brazil; 2Research Laboratory of Uninorte (Barão do Rio Branco Faculty. There are no tools specifically designed for screening of PFDs in pregnant women, however the Bulge, Bladder, Bowel questionnaire has been recommended as an initial screening tool before further in detail assessment of symptoms. Gray et al 2019 has recently reviewed in detail the PROMs for use in urogynaecology and female pelvic floor medicine. Although the list is likely to be comprehensive, the evaluative standards of assessing the psychometric robustness were not clear. Nevertheless, the ePAQ-Pelvic Floor and the Australian Pelvic Floor Questionnaire (APFQ) were recommended as the most comprehensive in scope and with sufficient evidence of validity. No questionnaire comes highly recommended by the ICI for the complete assessment of these issues in a complete and integrated way. The only questionnaire identified that has been developed specifically for women post-partum is the German pelvic floor questionnaire. This was derived from the German version of the APFQ and is yet to be available in other languages so its universal accessibility is yet to be determined in clinical practice.

Table 8: Health-related Quality of Life measures for Lower Urinary Tract Symptoms

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant	
ICIQ-FLUTS (ICIQ-Female Lower Urinary Tract Symptoms Formerly known as BFLUTS-SF (Bristol Female Lower Urinary Tract Symptoms Short Form) Grade A[64]	12-question tool used to assess female LUTS, particularly urinary incontinence, measure impact on quality of life and evaluate treatment outcome	Women incontinence	√	√	√		√		None
Contilife® (Quality of Life Assessment Questionnaire Concerning Urinary Inconti- nence); Grade B[139]	28-intem tool used to assess the impact of urinary incontinence on HRQL. Originally developed in French and designed for women with UI (urge, stress and mixed UI)	Women, SUI	√	√ (ICC = 0.96)			√		√
DAN-PSS-1(Danish Prostatic Symptom Score); Grade A [140]	15-item tool used to evaluate males with LUTS suggestive of uncomplicated BPH	Men, BPH	√	√	√		√		
EPIQ (Epidemiology of Prolapse and Incontinence Questionnaire); Grade B [141]	49-item tool developed and validated in English and Spanish to assess the presence or absence of AI, OAB, SUI, and pelvic organ prolapse in female population	women, PFD	√	√	√	√	√	√	
ICIQ-UI Short Form (International Consultation on Incontinence Questionnaire - Urinary Incontinence Short Form (ICIQ-UI Short Form); Grade A [61]	4-item tool used to assess the symptoms and impact of urinary incontinence in clinical practice and research	men and women, Urinary symptoms	√	√	√		√	√	√ (8 weeks)
ICIQ-MLUTS ICIQ-Male Lower Urinary Tract Symptoms SF Grade A[142]	13-item tool used to provide an evaluation of the occurrence and bothersomeness of lower urinary tract symptoms and their impact on the lives of men with LUTS	men with LUTS	√	√	√		√		

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant	
IIQ (Incontinence Impact Questionnaire); Grade A[143]	30-item tool developed to describe the severity of incontinence in a population. It was validated in a group of women aged 45 and over attending two continence clinics for SUI primarily. Used to assess the impact of urinary incontinence on HRQL.	Women, UI		√	√		√		√ (12Weeks)
IIQ-7 (Incontinence Impact Questionnaire); Grade A[144]	7-item tool used to assess the impact of urinary incontinence on HRQL	*validationstudy on men after radical prostatec-tomy whohad UI	√ (Cronbach's Alpha = 0.93)	√ (Spearman's Rho = 0.99; ICC = 0.75)	√	√	√	√	
IOQ (Incontinence Outcome Questionnaire); Grade B [145]	27 question tool developed for assessing quality of life after surgery for stress urinary incontinence	Women SUI	√ (Cronbach's Alpha = 0.83)		√	√			√
I-QOL (Urinary Incontinence- Specific Quality of Life Instrument); Grade A [146],[147]	22-item tool used to assess quality of life of women with UI	women, UI	√	√	√			√	√
ISI (Incontinence Severity Index); Grade C [109], [148]	2-item severity measure recommended by the World Health Organization for studying the epidemiology of incontinence and other LUTS; Developed in an epidemiologic study of 28,000 women in Norway.	Women, SUI				√	√		
ISQ (Incontinence Stress Index: ISQ-P [Patient]; ISQ-SOPS [Staff Observation of Patient Stress]; ISQ-SR [Staff Reaction to UI]); Grade C [110, 149]	40-item tool (20-items in short form) used to assess psychological stress associated with urinary incontinence	Women	√	√					

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant	
ISS (Incontinence Symptom Severity Index); Grade A [111], [150]	8-item instrument used for the self-assessment of severity of female urinary storage and voiding symptoms, rather than symptom bother or effects of on quality of life	Females		√ (ICC = 0.62 - 0.91)			√		√ (Duration not specified)
KHQ (ICIQ-LUTSqol) (King's Health Questionnaire); Grade A+[13]	21-item tool used to assess the symptoms impact of LUTS including urinary incontinence on HRQL. Developed in a clinical perspective to evaluate incontinence in women.	UI, OAB, men and women	√ (all domains except severity measure (Cronbach's Alpha = 0.60) demonstrated excellent IC)	√	√	√	√	√	√ (12Weeks)
LIS (The Leicester Impact Scale); Grade A[151]	21-item tool used as a quality of life measure for males and females with urinary storage symptoms of urgency, frequency, nocturia and incontinence.	men and women, LUTS	√	√	√		√		√
LUTSS (Lower Urinary Tract Symptom Score) Grade A1[52]	14-item tool used as a symptom evaluation for urinary storage symptoms (9 items), voiding symptoms (4 items) and associated bother (1 item).	Men and women, LUTS	√	√		√		√	√
M-ISI (Michigan Incontinence Symptom Index)[153] Grade B	10-item tool used to measure urinary incontinence and its bother, including three sub-domains: stress and urge urinary incontinence, and pad use	Women, aged 35-64 UI	√		√		√	√	

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant	
MUDI (Male Urogenital Distress Inventory); Grade B+[154, 155]	27-item tool used to address the dimension of physical health, focusing on bother from multiple symptoms associated with UI in men. Created by eliminating four gender specific items from UDI and IIQ.	Men with LUTS following a radical prostatec- tomy for prostate cancer	√		√		√		
MUSIQ (Male Urinary Symptom Impact Question- naire); Grade B+ [156, 157]	32-item tool used to capture mental/psychological health, social health, and global perceptions of function and well-being in men with urinary incontinence. Created by eliminating four gender specific items from UDI and IIQ.	Men, UI	√		√		√		
Nocturia Impact Diary[158]	12-item, 3 day diary to evaluate the impact burden associated with nocturia and its treatment. To be completed in conjunction with a voiding diary.	Men and women with nocturia	√	√	√			√	√
ICIQ N-Qol (Nocturia Quality of Life Questionnaire) GradeA+[70]	13-item tool used to assess the impact of nocturia on the quality of life of patients	men and women	√	√	√		√	√	√
OAB – q SF (OAB-q Short Form) Grade A[159]	19-item tool (shortened version of the OAB-q) used to evaluate both continent and incontinent symptoms of OAB and their impact on HRQL	OAB, men and women	√	√	√		√	√	√ (12 Weeks)
OAB-q (ICIQ-OABqol) (Overactive Bladder Questionnaire); Grade A [160]	33-item tool used to evaluate both continent and incontinent symptoms of OAB and their impact on HRQL. Developed from focus groups of men and women, clinician opinion, and a literature review	Continent and incontinent OAB	√	√ (ICC = 0.93 for 4-week recall period)	√	√	√	√	√ (12 Weeks)
OABSS (Overactive Bladder Symptom Score) Grade B[161]	4 item tool to evaluate key symptoms of OAB	OAB Men Women		√		√			

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant	
PFDI (Pelvic Floor Distress Inventory); Grade A[162]	46-items to assess presence of symptoms and HRQL in women with POP; 3 Scales (Urinary-28; Colorectal-17 Prolapse-16)	Females with symptomatic POP, UI	√ (Cronbach' s Alpha = 0.88)	√ (ICC = 0.87)	√			√	√
PFDI-20 (Pelvic Floor Distress Inventory Short Form); Grade A[162]	20-item short form of the PFDI (Urinary-6; Colorectal-8; Prolapse-6)	Females with symptomatic POP, UI		√ (ICC = 0.93)	√			√	√
PFIQ (Pelvic Floor Impact Question- naire); Grade A [162]	93-item functional status tool used to assess presence of symptoms and HRQL in women with POP; 3 Scales (Urinary-31, Colorectal-31, Prolapse-31)	Females with symptomatic POP, UI	√ (Cronbach' s Alpha = 0.98)	√ (ICC = 0.86)	√			√	√
PFIQ-7 (Pelvic Floor Impact Questionnaire Short Form); Grade A [162]	21-item short form of the PFIQ used to assess presence of symptoms and QOL in women with POP; 3 Scales (Urinary-7, Colorectal-7, Prolapse-7)	Females with symptomatic POP, UI		√ (ICC = 0.77)	√			√	√
PRAFAB (Protection, Amount, Frequency, Adjustment, Body image); Grade A[163]	5 item questionnaire widely used in the Netherlands by physiotherapists and researchers used to evaluate treatment effects for UI in women	women with UI	√	√	√		√	√	√
UIHI (Urinary Incontinence Handicap Inventory); Grade C [164]	17-item tool used to identifydifficulties patients may be experiencing because of their incontinence	Elderlywomen, UI due to detrusor instability	√(Cronbach's Alpha = 0.87)	√				√	
UISS (Urinary Incontinence Severity Score); Grade A[165]	10-item tool to assess symptom severity and impact of urinary incontinence	Women, UI		√	√	√	√		√
Urolife (BPHQoL9) (Benign Prostatic Hypertrophy Health-Related Quality of Life Questionnaire);Grade A[166]	9-item tool used to assess the impact of BPH and its treatment on the quality of life of patients	Men, BPH	√	√	√		√		√
YIPS (York Incontinence Perceptions Scale); Grade B [167]	8-item tool used to measure the psychosocial aspects of urinary incontinence and its management	Women, UI	√	√	√		√		√

Table 9: Patient Satisfaction Measures for Lower Urinary Tract Symptoms

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant	
BSW (Benefit, Satisfaction with treatment, and Willingness); Grade B[168]	3 single-item tool used to capture patients' perceived benefit, satisfaction with treatment, and the willingness to continue treatment	Men and women, OAB					√	√	√
GPI (Global Patient Satisfaction and Perception of Improvement); Grade C[169]	Single-item tool used to assess patient's improvement	Women, UI, SUI, MUI						√	
OAB-S (Overactive Bladder Satisfac- tion measure); Grade B[170]	51-items to assess following domains: expectations, control impact on daily living, medication tolerability, satisfaction and 5 overall assessments	Men and women, OAB	√	√	√		√	√	
OAB-SAT-q OAB Satisfaction questionnaire; Grade B[171]	21 or 40 -item tool used to assess patients' satisfaction with overactive bladder treatment including medication or non-pharmaceutical options such as physical therapy or biofeedback. The pre-medication module is designed assess the patient's expectations with medication and impact on OAB on patient's day to day life	Men and women, OAB	√	√	√		√	√	
PSTB (Patient Satisfaction with Treatment Benefit Questionnaire (Grade B)[172]	24 item tool to a patient satisfaction with OAB treatment	Men and Women OAB	√		√		√		
PSQ (Patient Satisf- action Question- naire); Grade C[169]	Single-item tool used to measure how satisfied a subject was with a program	Women, UI, SUI, MUI						√	
SAGA (Self- Assessment Goal Achievement Questionnaire); GAS; Grade C[173]	9-item tool on Goal Attainment related to lower urinary tract symptoms and the establishment of patients' goals concerning treatment for lower urinary tract symptoms (LUTS),	Men and Women aged ≥18 years with OAB			√	√	√		

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)

VIII. QUESTIONNAIRES TO ASSESS SYMPTOMS AND HRQOL IMPACT OF PELVIC ORGAN PROLAPSE

Women complaining of lower urinary tract symptoms often also complain of concomitant symptoms associated with urogenital prolapse and there are now a number of validated questionnaires available to use in the subjective assessment of women with prolapse symptoms. These questionnaires should be used in conjunction with the clinical assessment and standardised measurement of urogenital prolapse which is reported elsewhere in this section. In addition, given the number of conservative and surgical management options available for women with symptomatic prolapse standardisation of subjective outcome measurement is increasingly important.

This section will review the standardised symptom assessment tools for pelvic organ prolapse and, whilst the questionnaires described do not allow the clinical staging or planning of prolapse treatment they should be used alongside more objective tools to measure the subjective outcome of treatment. Evidence from previously reported studies has shown the importance or patient reported outcome measures and subjective assessment may provide a more meaningful assessment tool when compared to more traditional objective measurements. The use of these subjective outcomes has been shown to be robust and correlated with objective assessments during long term follow up.

Although the number of HRQoL questionnaires available to assess impact of urogenital prolapse is not as great as those associated with lower urinary tract dysfunction there are now a number of recommended and validated questionnaires available. However, it is important to consider that where specific problems associated with urogenital prolapse need to be considered, such as lower urinary tract symptoms or sexual function, then it may be preferable to consider the use of one of the questionnaires designed specifically for that purpose. In addition, as prolapse is often multidimensional, selecting questionnaires in the modular format of the ICIQ may be more useful in clinical practice.

For this current report the previous literature search was updated using the Pubmed/Medline databases from August 2016 – December 2020. The following key words were used either separately or in combination; ‘questionnaire’, ‘prolapse’ and ‘quality of life’. The grading of questionnaires was also reviewed and updated if new information had become available.

1. HRQOL QUESTIONNAIRES: PELVIC ORGAN PROLAPSE

There are now a number of HRQoL questionnaires that have been validated for the assessment of pelvic organ prolapse and have been reported by the International Consultation on Incontinence **(Table 17)**.

Although HRQoL questionnaires remain the most commonly used form of patient related outcome measure that are used in patients with pelvic floor dysfunction other measures of outcome have also been developed and reported. The Patient Global Impression of Improvement (PGI-I) was initially developed for lower urinary tract symptoms and has more recently been validated for use in patients with urogenital prolapse. The use of a simple one-answer patient reported outcome measure has also been used in studies using composite endpoints (Subjective and Objective measures) with the validated HRQoL questionnaires.

Table 17: Recommended questionnaires for the evaluation of symptoms and HRQoL impact of Pelvic Organ Prolapse

Grade A (recommended)
Pelvic Floor Distress Inventory (PFDI)[253]
Pelvic Floor Impact Questionnaire (PFIQ) [15]
Prolapse Quality of Life Questionnaire (P-QoL) [254]
Pelvic Organ Prolapse Urinary Incontinence Sexual Questionnaire (PISQ) [255],(PISQ 12) [256]
Pelvic Organ Prolapse Urinary Incontinence Sexual Questionnaire – IUGA Revised (PISQ-IR) [257]
ICIQ vaginal symptoms questionnaire (ICIQ-VS) [258]
The Australian Pelvic Floor Questionnaire (AFPQ) [259]
Grade B
Pelvic Organ Prolapse Symptom Score (POP-SS) [260]
Pelvic Floor Symptom Bother Questionnaire (PFBQ) [261]
Electronic Personal Assessment Questionnaire-Pelvic Floor (ePAQ-PF) [262]
Grade C (with potential)
Pelvic Floor Dysfunction Questionnaire [263]
Danish Prolapse Questionnaire [264]

2. PROLAPSE QUALITY OF LIFE QUESTIONNAIRE (PQOL)

The Prolapse Quality of Life questionnaire (P-QoL)[254] is a validated questionnaire which has been shown to be reliable and responsive. HRQoL scores have been shown to strongly correlate with objective assessment of prolapse using the Pelvic Organ Prolapse Quantification Questionnaire (POPQ) and women with symptomatic prolapse had a significantly higher score in each domain.

Since the original validation PQoL has now been validated in a number of new linguistic validations including Spanish, French Persian, Polish and Mandarin although a recent systematic review of the psychometric properties and cross –cultural adaptations and translations has suggested that there is limited evidence to support the robustness of the original validations of the translated versions.

3. PELVIC FLOOR DISTRESS INVENTORY (PFDI) AND PELVIC FLOOR IMPACT QUESTIONNAIRE (PFIQ)

The PFDI and PFIQ are based on the structure and content of the Urinary Distress Inventory (UDI) and the Incontinence Impact Questionnaire (IIQ) and also include specific domains covering pelvic organ prolapse and colorectal dysfunction.

The PFDI assesses symptom distress in women with pelvic floor dysfunction and includes the Urinary Distress Inventory (UDI), Colorectal-anal Distress Inventory and Pelvic Organ Prolapse Distress Inventory.

The PFIQ assess HRQoL impact and includes the Incontinence Impact Questionnaire (IIQ), Colorectal-anal impact questionnaire and the Pelvic Organ Prolapse impact questionnaire.

The questionnaires have been shown to be internally consistent and reproducible. Both the UDI and IIQ were shown to correlate with the number of urinary incontinence episodes per week and pad usage. In addition the Pelvic Organ Prolapse distress inventory and Pelvic Organ Prolapse impact questionnaire correlated with POPQ objective prolapse assessment whilst the Colorectal-anal Distress Inventory and Colorectal-anal impact questionnaire significantly correlated with episodes of faecal incontinence and defaecatory dysfunction.

The Pelvic Floor Impact Questionnaire (PFIQ-7) [15] and Pelvic Floor Distress Inventory (PFDI-20)[15] have recently been validated in Brazilian Portuguese, Swedish Danish, Polish, Chinese, Trigrigna, Finnish and Norwegian

4. THE AUSTRALIAN PELVIC FLOOR QUESTIONNAIRE (AFPQ)

The Australian Pelvic Floor Questionnaire (AFPQ) is a validated interviewer administered questionnaire with four domains assessing bladder, bowel, prolapse and sexual function in women complaining of pelvic floor dysfunction [259]. The AFPQ has been demonstrated to be valid, reliable, and responsive to change. More recently the Minimally Reported Difference (MID) has been reported and the questionnaire has also been validated in patients folllowing surgery for colorectal cancer.

5. PELVIC ORGAN PROLAPSE SYMPTOM SCORE (POP-SS)

The POP-SS consists of seven items each with a 5-point Likert response and has been shown to have good construct validity, internal consistency and to be sensitive to change. It has been validated using data from three large studies of women with urogenital prolapse and has now been translated into Turkish and Amharic.

Women having surgery were found to have higher POP-SS scores compared to those managed with conservative measures and these women, in turn, had higher scores than those who were asymptomatic. In addition significant differences in POP-SS were detected following surgery and PFMT.

6. HRQOL QUESTIONNAIRES; PELVIC ORGAN PROLAPSE AND SEXUAL DYSFUNCTION

6.1. Pelvic Organ Prolapse Urinary Incontinence Sexual Questionnaire (PISQ)

Both urinary incontinence and pelvic organ prolapse are known to have an important impact on HRQoL although until relatively recently there was no disease specific questionnaire available.

The Pelvic Organ Prolapse Urinary Incontinence Sexual Questionnaire (PISQ)[238] has now been validated in women who complain of symptomatic prolapse in addition to asymtomatic controls. Those women who complained of prolapse were noted to have a greater impact on HRQoL related to sexual function when compared to asymptomatic women and the instrument was found to correlate well with the Incontinence Impact Questionnaire-7 (IIQ-7) and the Sexual History Form-12 (SHF-12).

Subsequently PISQ has been validated as a short form (PISQ-12) and has been validated in Turkish , French, Chinese, Swedish, Portuguese, Iranian and Dutch.

6.2. Pelvic Organ Prolapse Urinary Incontinence Sexual Questionnaire – IUGA Revised (PISQ-IR)

One of the difficulties with PISQ was that it was only applicable to women who were sexually active. More recently an International Urogynaecology Association (IUGA) revised version (PISQ-IR) [239], for both sexually active and inactive women, has been validated using the Incontinence Severity Index (ISI), Pelvic Floor Distress Inventory -20 (PFDI-20), Epidemiology of Prolapse and Incontinence Questionnaire (EPIQ) and the Female Sexual Function Index (FSFI). Urogenital prolapse was assessed objectively using the POPQ system. Overall both sexually active women and non-sexually active women with symptomatic prolapse were found to have greater bother and there was good correlation with other, previously validated questionnaires.

The PISQ-IR has now been validated in French,Japanese, Arabic, Mandarin Chinese, Hungarian, German, Polish, Czech and Spanish. In addition a single summary score, based on the ten individual subscale scores has now also been validated which may be easier to use in clinical practice and cutoff scores for sexual dysfunction have recently been reported.

IX. QUESTIONNAIRES TO ASSESS SYMPTOMS AND HRQL IMPACT OF FAECAL INCONTINENCE

There are now a number of patient reported outcome measures which have been developed for the assessment of patients with Anal Incontinence (AI) and Faecal Incontinence (FI). Due to the considerable overlap between faecal incontinence and other forms of pelvic floor dysfunction questionnaires used for urinary and prolapse symptoms may also contain domains for anal and faecal incontinence. Likewise, items relating to faecal incontinence may also be included in questionnaires used to evaluate colorectal disease. In addition, due to the wide variation in normal bowel function within, and between individuals, some of these questionnaires may lack sensitivity and specificity for more specific bowel disorders such as Irritable Bowel Syndrome (IBS), Irritable Bowel Disease (IBD) evacuation disorder and constipation.

Since anal incontinence, faecal incontinence and bowel evacuation are closely related to pelvic floor function it may be inappropriate to consider bowel function simply in terms of continence and constipation. Constipation and evacuation disorders may result from a number of different pathologies such as outlet obstruction and slow transit in addition to other mechanical, pharmacological, metabolic and neurogenic causes.

Anal incontinence is known to occur in both men and women with the prevalence depending on age and the symptom is known to be important in terms of the underlying pathophysiology. Faecal urgency and faecal urgency incontinence are thought to be associated

with the loss of voluntary control due to impaired external sphincter function whereas passive faecal incontinence is thought to be associated with impairment of the smooth muscle of the internal anal sphincter .

For this current report the previous literature search was updated using the Pubmed/Medline databases from August 2016 – December 2020. The following key words were used either separately or in combination; 'questionnaire', 'faecal', 'anal', 'bowel' and 'quality of life'. The grading of questionnaires was also reviewed and updated if new information had become available.

The updated search found one new validated HRQoL instrument for the assessment of anal or faecal incontinence although there were no further validation studies reported on those questionnaires which were ungraded. Consequently the recommendations of this report have been revised appropriately.

The grades of recommendation are as outlined in previous sections. **Table 18** summarises the questionnaires reviewed and grades of recommendation.

1. ACCIDENTAL BOWEL LEAKAGE EVALUATION QUESTIONNAIRE

The Accidental Bowel Leakage Evaluation questionnaire [308] is a patient completed instrument which has now been fully validated and found to have good internal consistency, and test rest reliability in addition to construct validity. The questionnaire deals with patient important domains including predictability, awareness, control, emptying and discomfort. More recently the responsiveness and minimally important difference have also been reported.

Tables 13, 14 and 15 provide details of the specific psychometric properties and development of each questionnaire

Table 18: Recommended questionnaires for the evaluation of symptoms and HRQoL impact of faecal incontinence

Grade A+
ICIQ-B [67, 68]
Grade A (recommended)
Faecal Incontinence Quality of Life Index [222]
Birmingham Bowel and Urinary Symptom Questionnaire [218,219]
Questionnaire for assessment of Faecal Incontinence and Constipation[307]
Accidental Bowel Leakage Evaluation[308]
Grade B
Colorectal Functional Outcome Questionnaire [309]
Manchester Health Questionnaire [223]
Bowel Control Self Assessment Questionnaire [224]
Pelvic Floor Bother Questionnaire [310]
Elderly Bowel Symptom Questionnaire [228]
Faecal Incontinence and Constipation Assessment [220]
Grade C
Faecal Incontinence Questionnaire [311]
Ungraded
Postpartum Flatal and Faecal Incontinence Quality of Life Scale [225]
Bowel Function Questionnaire [216]
Surgical Outcome Tool for Faecal Incontinence [226]

X. QUESTIONNAIRES TO ASSESS SEXUAL FUNCTION/ SEXUAL HEALTH AND URINARY SYMPTOMS

Sexual dysfunction affects many people and may be caused by psychological, emotional or physiological factors, often with multifactorial and interrelated aetiologies. Sexual function may be regarded as a dimension or aspect of overall HRQL, for which a number of dimension-specific measures have been developed and validated. There is a wide choice of available instruments, the selection of which will depend on the clinical or research setting where the instrument is to be employed. Established and widely used measures that have been shown to be valid, reliable and responsive are clearly desirable, however the feasibility and appropriateness of using a particular instrument in a particular setting must also be considered. A large number of different instruments exist in this field, which aim to evaluate specific aspects of sexual function and sexual health.

While the importance of investigating male sexuality as part of a normal male urological assessment is established, this has not been established for female evaluation. Many physicians underestimate the prevalence of female sexual dysfunctions and do not routinely perform an assessment of sexual wellness as a part of their practice, despite evidence that many women with LUTS have sexual problems

In a comprehensive assessment of women with pelvic dysfunction sexual function should be investigated. However it is may be a difficult issue to discuss during a consultation because of discomfort or embarrassment. Female discomfort may stem from personal embarrassment, a sense that sexual dysfunction is not a medical problem and this may be compounded by a lack of time during health care visits.

In addition many physicians report a lack of training in how to appropriately address sexual function with patients. Clinicians who treat sexual problems often prefer to use unstructured rather than structured interviews or questionnaires in clinical practice as an unstructured approach allows the tailoring of questions to suit the couple or the individual being assessed. Unstructured interviews enable the clinician to support patients who feel vulnerable and encourage discussion. In this setting, vocabulary can be modified, as can the level of assertiveness and the depth of questioning to suit the needs of the individual. This flexibility is not readily achievable with questionnaires which individuals may also find difficult to complete due their impersonal nature or because of physical or mental impairment, cultural or language differences. However, some patients find the discussion of intimate issues with clinicians very difficult and questionnaires may allow these issues to be measured in private, at ease and more effectively before subsequently exploring questionnaire responses in the clinical interview itself. Therefore there is a wide choice of available instruments, which could help the physician during history taking and the selection of an instrument will depend on the clinical or research setting where the instrument is to be employed.

Table 16 outlines sexual health measures with a Grade A, B, C rating based on the criteria provided above, and the linguistic validations of each questionnaire are also documented.

This table includes the questionnaires useful to assess female and male sexual function in patients with any pelvic dysfunction and uri-

nary symptoms. Questionnaires obtaining an A+ rating demonstrate reliability and validity and also that content was derived with patient input and responsiveness to treatment has been shown.

A Rated group: the Female Sexual Function Index (FSFI) [229], the Female Sexual Distress Scale (FSDS) [234], the International Consultation on Incontinence Questionnaire-Vaginal Symptoms (ICIQ-VS)[66] and the Derogatis Sexual Functioning Inventory (DISFI) [232]. These questionnaires assess female sexual function and measure the quality of a patients current sexual functioning. The Menopausal Sexual Interest Questionnaire (MSIQ)[233] is also included in this group but only two domains. For male patients the International Index of Erectile Function (IIEF) [237] is recommended to assess men with erectile dysfunction. Most of the identified measures are self-reported, easy and quick to administer and many have various language versions available. The majority have also been previously used in incontinence populations

***B Rated group*:** the Daily Log of Sexual Activities (DLSA)[232] the Female sexual distress scale-revised (FSDSr)[235], the Index of Sexual Functioning for women (BISF-W)[243] the Change in Sexual Functioning Questionnaire (CSFQ) [244,245],and the Sexual Interest and Desire Inventory Female (SIDI-F)[247]. They assess the sexual dysfunctions in women with sexual desire disorder and functional sexual arousal disorder. The Pelvic Organ Prolapse Urinary Incontinence Sexual Question (PISQ-12) assesses sexual function after surgery in women with Pelvic Floor Dysfunction and has been validated in women with urinary incontinence and pelvic organ prolapse. The Sexual Quality of Life–Female (SQoL-F)[241] is useful to assess the impact of female sexual dysfunction on quality of life, while the Sexual Satisfaction Scale for Women (SSS-W) [242] measures the women's sexual satisfaction and distress in patients with pelvic floor dysfunction. The Sexual Function Questionnaire (SFQ)[240] is an instrument for both partners. This questionnaire also addresses some of the consequences of female sexual dysfunction for the woman, her partner and their relationship. Both the physical and the cognitive aspects of sexual response are evaluated within the SFQ items. The Male Sexual Health Questionnaire (MSHQ) [236] assesses sexual function and satisfaction in older men with urogenital symptoms of LUTS and sexual dysfunctions.

***C Rated group*:** The Women's Sexual Interest Diagnostic Interview--Short Form (WSID-SF) is used to assess sexual function in adult women with hypoactive sexual desire disorder, The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire, IUGA-Revised (PISQ-IR) [239], and the Sexual Health Outcomes in Women Questionnaire (SHOW-Q)[248] to assess the impact of pelvic problems on sexual desire, frequency, satisfaction, orgasm, and discomfort.

The choice of which tool to use will be dependent on the type of patient, age, type of pelvic dysfunction and on research hypothesis. For instance, if you wanted to assess impact of OAB on sexual function e.g. arousal in women then the FSFI should be used rather than the SQOL-F because the FSFI has a specific arousal domain whereas the SQOL-F assesses sexual quality of life.

XI. RECOMMENDATIONS FOR RESEARCH

1. The selection of a PRO questionnaire must reflect study purpose and objectives.
2. Grade A recommended questionnaires should be used in all clinical trials evaluating treatments
3. The inclusion of the ICIQ modules is preferred in all studies in order to standardize outcome assessment
4. Continued PRO development, refinement, and usage should accurately and adequately report on the methods, samples, statistical analyses and psychometric properties of questionnaires in scientific journals. This includes documentation of validity, reliability and responsiveness and consequently the quality of each study can be assessed.
5. Researchers are encouraged to use existing questionnaires and refine for specific populations when required; such as frail elderly and children.
6. Researchers are also encouraged to participate in collaborative work with the ICIQ project allowing the development and refinement of modules and translations.
7. Further work is required to establish the validity and utility of electronic patient reported outcome measures.

I. WHAT ARE URODYNAMIC STUDIES AND WHAT SHOULD, IN GENERAL BE THE ROLE OF URODYNAMIC STUDIES IN CLINICAL PRACTICE?

1. OVERVIEW

1.1. Introduction

Urodynamic testing (urodynamic studies - UDS) should be performed to objectively measure, document and diagnose the entirety of lower urinary tract (LUT) function and/or dysfunction. UDS should be done when it can have consequences for the patient's management, including pretreatment patient counselling(1)the role of urodynamics (UDS and/or when part of a surveillance or a research program. For this, the individual patient's symptoms, including their impact in terms of bother and degree of hindrance they cause, as well as the impact of other relevant circumstances (e.g. comorbidity and or use of other medication, or operability), should be kept in mind.

UDS can demonstrate signs not otherwise elucidated at presentation, such as an elevated postvoid residual urine (PVR) or detrusor underactivity (DU), which may be relatively unnoticed by the patient, even when neurologically intact. Upper urinary tract (UUT) signs (e.g. dilatation) can exist or develop without any symptoms, especially, but not uniquely in patients with relevant neurological abnormalities. Furthermore, the patient can present with complaints such as 'urinary frequency', 'nocturia' or 'recurrent UTIs', which are difficult or impossible to reproduce in the usual UDS laboratory. Therefore, UDS do not necessarily demonstrate or mimic the presenting symptoms of the patient but may reveal the underlying LUT dysfunction that may lead to lower urinary tract symptoms (LUTS).

Nevertheless, in the usual setting of a UDS study, a feature of LUT function or dysfunction may be observed/measured that is relevant to these unnoticed phenomena and may explain the patient's symptoms. Finally, UDS may provide a basis for the identification and prevention of conditions, signs or symptoms that may arise later and not present at the time of the testing; e.g. urinary retention or UUT dilatation or deterioration.

UDS allow direct assessment of LUT function by the measurement of relevant physiological parameters (2,3). Invasive UDS are defined as any test that involves insertion of one or more catheters or any other transducers into the bladder and/or other body cavities, or insertion of probes or needles, for example for needle EMG measurement(4)\" a new ICS Standard was developed in the period from December 2013 to December 2015. In July, a draft was posted on the ICS website for membership comments and discussed at the ICS 2015 annual meeting. The input of ICS membership was included in the final draft before ICS approval and subsequent peer review (for this journal.

The point of a clinical/biological test is that it will show a result on a continuum between what is considered normal and abnormal; UDS is no exception to this. The key to determining the cause of the signs and/or symptoms of lower urinary tract dysfunction (LUTD) will be to reproduce the function and the dysfunction of the LUT of the individual patient. In addition, concomitant UDS findings accompanying the main symptom or sign should be carefully assessed for the optimal management plan. For example, concomitant DU or detrusor overactivity (DO) or bladder outflow obstruction (BOO) in a female patient who presents with stress urinary incontinence may be important to diagnose and to optimize her treatment. The implicit consequence of this is also that ideally at least one complete filling (cystometry -storage) and pressure-flow study (PFS - voiding) cycle, that adequately represent the patient's problem (e.g. with regard to volumes) including post voiding features, (e.g. PVR or after contraction) should be tested, analysed, and documented, even if only storage or only voiding signs or symptoms have been expressed by the patient. Last but not least: when LUT sensation is altered, as it frequently is in patients with neurogenic LUTD, the symptoms are even less reliable than those of patients with intact sensation, making UDS as an objective evaluation to advise or justify a specific management even more important.

A definite indication for UDS is LUTD due to a demonstrable neurogenic deficit. Besides planning symptomatic treatment in such patients, UDS provides a risk assessment to predict UUT damage in all age groups and genders as mentioned and described by the relevant chapters in this consultation.

Thus, the role of UDS in broad clinical perspective can be:

a) To demonstrate all elements of LUT(patho)physiology of the patient presenting with signs or symptoms of dysfunction;

b) To identify all factors that contribute to the LUT dysfunction signs (e.g. urinary incontinence (UI)) and/or are the origin of the symptoms (e.g. frequent voiding) and assess their relative importance;

c) To obtain information about all other aspects of LUT function or dysfunction, whether or not expressed as a symptom or recognizable as a sign;

d) To allow a prediction of the possible consequences of LUTD for the UUT;

e) To allow a prediction of the outcome, including undesirable side effects, of a contemplated treatment, and include the possibility of additional treatment options in preoperative patient counselling (e.g. inform between-treatment options);

f) To confirm the effects of intervention or understand the mode of action of a particular type of treatment for a LUTD; especially a new and/or experimental one;

g) To understand the reasons for failure of previous treatments for UI, or for LUTD in general.

UDS is the gold standard to assess LUT function and dysfunction. Some studies have challenged the utility of UDS with a clinical diagnosis as the comparator. Specifically, the 'clinical diagnosis of SUI' was used as a predictor of outcome of suburethral tapes in a very select group of patients(5). When this clinical diagnosis (which is not standardized in general and was not for these trials) had been compared with one specific element of sometimes non-standard UDS diagnosis (and also including patients with DO(6)) neither method of diagnosis was superior for the patients recruited in this study with signs and/or symptoms of SUI. The question remains whether the overall outcome of the surgery (or alternatives for some of the patients) could have been better than the ±65% overall success rate (dry, without taking into account other symptoms e.g. frequent voiding), if a more structured clinical and UDS diagnosis

and/or analysis had been used in these studies(5,7). Furthermore, it was shown that even in the index or uncomplicated patients, preoperative UDS changed the clinical diagnosis in more than half of the patients, but this change was claimed not to affect the surgical outcome(5). However, the outcome of surgery in terms of DO and DU was not assessed in the long term. Last but not least, the definition of index or uncomplicated female patients with SUI is still not clear and they constitute only a minority of the whole patient pool(1) the role of urodynamics (UDS.

1.2. Conclusion

UDS in clinical practice evaluates a person's LUT function with at least one complete and representative filling, voiding and post-voiding cycle by testing with relevant pressures and flowmetry. UDS includes quality control, subsequent analysis, and systematic documentation.

2. UROFLOWMETRY

This is the non-invasive measurement of urine flow rate for both women and men, as well as for children. The general principles are universal, although voiding position is relevant(8), and a small series of young men voiding in the healthy range demonstrated that time after ejaculation may play a role(9). Uroflowmetry is also relevant for patients with neurological abnormalities, if they use a toilet in their daily life situation. The patient voids into a flowmeter in private, ideally with a normal to strong (but not uncomfortable) desire to empty their bladder(3,10).

Urine flow rate is continuously measured and displayed graphically. Various parameters from the trace are automatically calculated and printed out together with the trace. After adjustment for artefacts, the maximum flow rate, the volume voided and shape of the curve are usually the principal determinants of whether or not the patient is emptying their bladder in a normal way. Volume dependency on flow rate should be considered. If abnormal voiding occurs, it is good clinical practice to repeat the assessment to attempt to reproduce normal behaviour.

Several factors, such as patient apprehension, can give an abnormal recording in patients who normally have no voiding difficulty. Asking the patient about what she or he thinks about the voiding, whether the voiding was an adequate representation of their usual voiding, (if possible by comparison with the usual voiding diary volumes) must be regarded as good urodynamic practice. Repeating the assessment can remove such confounding factors. Unambiguous and careful instruction of the patient, privacy, appropriate leg/foot support and a short meatus to flowmeter distance are all inherently relevant(11).

The committee has not found any relevant technical changes or innovations to uroflowmetry equipment since 2013, but the committee notes with interest the current availability of home-based-uroflowmetry devices and recommends an evaluation of these technologies.

3. FILLING CYSTOMETRY

This is the measurement of the pressure inside the bladder to assess its storage capabilities. It is an invasive test which involves a catheter being placed into the bladder, usually transurethrally, and another catheter being placed rectally, vaginally or through an abdominal stoma to measure abdominal pressure.

Subtracting the indirectly measured abdominal pressure (p_{abd}) from the pressure measured inside the bladder (intravesical pressure, p_{ves}) gives a representation of pressure changes due to the action of the detrusor smooth muscle, the detrusor pressure, p_{det} (= p_{ves} – p_{abd}). During this assessment, the bladder is usually filled with normal saline solution, or x-ray contrast solution in the case of video UDS (VUDS), either through a separate catheter placed transurethrally or through the filling channel of a dual lumen catheter, if used.

Usually, the filling rate is much faster than physiological bladder filling (which is 1-2 mL/min) and therefore referred to as non-physiological in ICS terms. The bladder will become filled in about 10 minutes when 10% of estimated usual capacity (based on the voiding diary, taking into account the PVR whenever possible) is taken as the filling rate (mL/min)(4)\" a new ICS Standard was developed in the period from December 2013 to December 2015. In July, a draft was posted on the ICS website for membership comments and discussed at the ICS 2015 annual meeting. The input of ICS membership was included in the final draft before ICS approval and subsequent peer review (for this journal.

The intravesical, abdominal pressure and the calculated detrusor pressure are monitored as the bladder is filled and before the patient has been given 'permission to void'. The storage ability of the bladder is assessed in terms of the volumes required to elicit various sensations from the patient, its cystometric capacity, its compliance (passive muscle adaptation to volume increase and detrusor muscle relaxation), and the presence or the absence of phasic detrusor pressure rises. The filling (storage) phase of cystometry is when urodynamic SUI (USI) can be assessed by means of coughing, straining,or other provocative manuever on the request of the urodynamicist(12)four fellowship-trained urogynecologists reviewed 39 abstracted cases of urinary incontinence on two occasions: first without and subsequently with urodynamic data. Treatment recommendations were made for each case after each review. The probability of urodynamic data modifying treatment recommendations was estimated for each reader and for the population of readers using a random effects logistic regression to account for reader variability. The overall probability that urodynamic data would change treatment was 26.9% (95% confidence interval (CI. Good urodynamic practice demands that all three of abdominal, intravesical and detrusor pressures are evaluated to assess urinary bladder storage function.

The committee has not become aware of any changes since 2013 in technique of cystometry.

Pelvic muscle EMG during cystometry is not an ICS standard and not further discussed in this chapter (see chapter on imaging and neurophysiological testing for this). Alternatives for the ICS standard water (or saline) filled catheters and tubing are being evaluated and will be discussed in a separate paragraph. Specific attention to artefacts and errors merits attention and has been included in the update of the ICS Good Urodynamic Practices(13–15).

4. PRESSURE-FLOW STUDIES

Pressure-flow study (PFS) is the (ICS) term for measurement of the mechanics of micturition. When the filling phase of cystometry is complete, the patient is given 'permission to void' and asked to empty the bladder into a flowmeter whilst intravesical, abdominal and detrusor pressures are being recorded. The simultaneous measurement of flow rate and pressure enables voiding to be as-

sessed and PFS analysis can help determine whether a slow urine stream is due to BOO or to DU or to a combination of both. PFS can also assist the diagnosis of detrusor-sphincter dyssynergia (DSD) and a clearer description of dysfunctional voiding and/or quantification of outlet dynamics during voiding. Similar precautions as for uroflowmetry must be taken regarding representativeness, artefacts and patient apprehension.

Since 2013 no new studies have been published about the technique of PFS. Analysis of PFS regarding detrusor underactivity (DU) or 'poor contractility' during voiding has received increased attention and is suggested to be of future relevance(16,17).

5. URETHRAL PRESSURE PROFILOMETRY

This is a test to estimate the urethra's and the surrounding structures' ability to maintain a closed bladder outlet, allowing the body to contain urine within the bladder. A catheter is placed transurethrally into the bladder and then withdrawn along the urethra (usually by a mechanical puller at a constant rate). Catheters that use water perfusion but also catheters with microtip pressure sensors or catheters with air-filled ('charged') balloons are used to this aim. The pressure along the length of the urethra is measured and interpreted relative to the pressure inside the bladder or abdomen. The maximum pressure measured in the urethra is assumed to give an indication of the urethral closure function. The clinical relevance of the urethral pressure profile (UPP) is frequently discussed in the literature and alternative technical systems to measure urethral pressure or function have been published and will be discussed in following paragraphs.

6. ABDOMINAL LEAK POINT PRESSURE

This test estimates the urethra's ability to contain urine within the bladder when intra-abdominal pressure is increased. Intra-abdominal pressure is measured whilst the patient is asked to increase their abdominal pressure by Valsalva or by coughing. The abdominal pressure required to produce leakage from the bladder (leak point pressure or LPP) gives an indication of the closure function of the urethra and is termed the abdominal LPP. Diverse methods as well as reference pressures are used. New evidence (since ICI2013) for the relevance of LPP measurements and variants of LPP will be discussed in the specific paragraphs of this report. Detrusor leak point pressure (detrusor LPP) is conceptually very different from abdominal LPP and is discussed in detail later in this chapter.

II. TECHNOLOGICAL INNOVATIONS IN URODYNAMIC STUDIES

1. CATHETERS FOR PRESSURE MEASUREMENT

Traditionally, UDS is done with water-filled catheters and tubing and external pressure sensors. This is the ICS Standard.

Air-filled catheters have a small balloon on the tip and a lumen attached to a pressure transducer. After introduction, the balloon is 'charged' with air and measurement can take place. Air-filled catheters (T-Doc® Air charged™ catheters, Laborie, Mississauga, Canada) can be used for intravesical, intra-urethral as well as for abdominal pressure measurement in UDS and are CE (Conformité Européenne) marked and FDA (US – Food and Drug Administration) approved for their technical safety for use in humans.

1.1. Conclusions and Recommendations 2016

ICI2016 concluded that air-filled catheters may provide an acceptable alternative to other techniques for measuring the pressure closing the female urethra however normal values had not been established. Further, ICI2016 concluded that studies show that air-filled catheters record different pressure values to water-filled lines in UDS and are therefore not interchangeable(18) (19). The recommendations of the ICI2016 were that investigators planning to use air-filled catheters for intravesical and intra-abdominal pressure in UDS were advised to check for themselves that they have an equivalent performance to their current system for measuring pressure, and how their system compares to the standard reference values for clinically relevant limits of pressures obtained with the ICS standard water-filled systems.

1.2. New evidence 2021

Four further studies examining the performance of air-filled catheters have been published since ICI2016, two comparing air-filled and water-filled systems' readings during filling and voiding UDS(20) (21), one examining urethral pressure measurements(22), and one confined to usability and safety assessment(23). The first study(20) compared only intravesical pressure between the two systems, using the filling line of an air-filled catheter as a water column, and reported results in 50 women. The second(21) examined data from 25 patients (9 male, 16 female), comparing both intravesical and abdominal pressures by the same method. Significantly, though both studies report good correlation between the two methods of measurement, they also both report up to 20 cmH_2O spread in pressure differences between the two limits of agreement on Bland-Altman analysis, a result that agrees with previous studies(18) (19). Concern over this variation was raised in a subsequent letter to the editor(24), echoing concerns in a previous review(25). The reason for these differences, as well as the clinical significance is still not apparent, as these studies had all taken initial resting pressures into account, showing that some other unknown factor is causing the variations seen. Until this disparity is understood, the committee maintains the previous conclusion that the two pressure measurement systems are not interchangeable during filling and voiding cystometry. The study dealing with urethral pressure measurements(22) confirmed previous data that air-filled systems read higher urethral pressures than water-filled systems, while having a more reproducible reading. Given the small number of patients (33, all neurogenic), there is still a need for further investigation to ascertain normal values for air-filled urethral measurements. The fourth study(23) did not examine the pressure readings, but was limited to assessment of usability and safety of a new thinner catheter, which were positively reported.

1.3. Conclusions

- Air-filled catheters may provide an acceptable alternative to other techniques for measuring the pressure closing the female urethra, however reference values have not been established. (level 3)
- New studies confirm that air-filled catheters record different pressure values to water-filled lines in UDS and are therefore not interchangeable. (level 2)

- Air-filled catheters have not been widely tested in men or in children, or in patients with NLUTD.

1.4. Recommendation (Grade C)
- Investigators planning to use air-filled catheters for intravesical and intra-abdominal pressure in UDS are advised to check and reassure themselves that they have an equivalent performance to their current system for measuring pressure.
- Investigators planning to use air-filled catheters for intravesical and abdominal pressure in UDS are advised to check for themselves how the performance of their system compares to the standard reference values for clinically relevant limits (especially of resting pressures, obtained with the classical systems).
- Clinicians using UDS should be well aware of the technical demands of measuring with a water-filled system with external transducers and should be able to minimize, correct and recognize artefacts.

1.5. Topics for Research
- Studies to compare the performance of air-filled catheters with ICS standard water-filled pressure lines in the measurement of intravesical and abdominal pressure during filling and voiding cystometry in male, neurological and paediatric patients as well as analysis of test-retest reliability.
- Studies to determine the cause(s) of the observed differences in pressure readings between water-filled and air-filled systems.
- Studies to determine the clinical relevance of difference in pressure readings between water-filled and air-filled systems, including urethral pressures.
- Studies to establish standard values for urethral pressures, filling cystometry and pressure flow studies using air-filled catheters.

2. IMPLANTED TRANSDUCERS FOR PRESSURE MEASUREMENT

2.1. New evidence 2021

As an alternative to catheterised pressure measurement, interest has been shown in developing pressure sensors that can be implanted or placed within a body cavity and communicate readings wirelessly to a body-worn data receiver. Clearly better suited to long-term or post-operative monitoring, such devices would offer data sets longer than the most advanced ambulatory devices currently available and would allow monitoring without the intrusive effect of a catheter.

One such device(26), the ‘Bladder Pill’, was trialled in five Gottingen minipigs, being inserted into the bladder lumen. The pressure readings were validated by a comparison urethral pressure measurement catheter and demonstrated agreement. The same group reported data from a combined pressure and accelerometer system(27), again in pig models but within the bladder mucosa, adding another dimension to the potential for research. Another group has reported a device implanted in the mucosa first with wires connecting and then with telemetry connecting to the data receiver(28), followed by a new device ‘Uromonitor’, which was placed in the bladder lumen of human subjects(29).

Since these devices will only be monitoring one pressure, the intravesical, there may be limitations in that abdominal pressure variations will be present in this signal. However, the latter group above have also presented work that suggests that advanced signal processing can identify true bladder events from single channel data(30). Historic articles on the use of only one channel have urged caution or careful selection of patients. This work will need careful and convincing validation therefore if it is to be used in a diagnostic test.

2.2. Conclusions (Level 4) and Topics for Research
- Implanted devices hold promise for long term monitoring for research purposes or post-operative monitoring. Only animal studies have been done to date.
- Studies to investigate the use of these devices in humans will be needed before clinical applications can be targeted.
- Studies to validate and apply algorithms for event detection from single channel urodynamics are needed before use in routine clinical UDS.

3. OBJECTIVE ASSESSMENT OF BLADDER SENSATION

3.1. Conclusions and Recommendations 2016

Based on published results ICI2016 noted that there was a significant variation in clinical practice to determine bladder filling sensation landmarks and maximum cystometric capacity despite the standardisation of terms. The committee concluded that strategies to derive bladder filling sensation parameters in a more automated and objective way had been showing plausible and applicable results. ICI2016 stated that these were however not sufficiently tested with regard to reliability, relevance, investigator independency or test-retest robustness. Bladder filling sensation has received increasing attention since urinary urgency and early filling sensation remain clinically important and some treatments are believed to influence LUT sensation.(31) (32)

A patient-activated, keypad ‘urge score’ device to measure sensations during bladder filling was previously described in ICI2016 (33) (34) (35). Measuring of different bladder sensations has not been further investigated or adopted into standard practice.

In the development of the ICIQ bladder diary, the data from 264 patients’ diary recordings of urinary urgency showed weak agreement with questionnaire responses and UDS observations(36). Although cystometry is regarded as the gold standard to assess bladder filling sensation there is a paucity of evidence regarding its clinical relevance. Also, the question whether cystometry or alternative (diary–like) evaluations are more relevant remains unanswered.

Research has provided some *in vivo* evidence of the specific brain areas that are involved in LUT sensation, control and modulation, but this type of observation cannot yet be regarded as a replacement of cystometry, because up to now no brain pattern has been shown to correlate with a specific UDS abnormality.(37) (38).

Many studies consistently show that the correlation between objective and subjective features of detrusor adaptation to volume increment, bladder proprioception and the subjective interpretation of filling is weak.(39) (40) (41) (42) (43) (44) (45) In fact these observations also demonstrate that UDS is adding new and objective diagnostic information to what has been gathered with history, voiding diary and clinical investigation. Both UDS, as well as signs and symptoms, are relevant to select further treatment, for instance in the identification of DU.(46)

3.2. New evidence 2021

Two recent reviews have summarised developments to date in assessment of bladder sensation(47) (48). These again highlight the lack of consensus and the subjective nature of commonly used descriptions. One group reported(49) (21 participants) and validated(50) (10 participants) a sensation meter on a tablet computer that uses a combination of meter-style, slider bar and verbal summaries to record sensation. The meter produces a sensation–capacity curve, as used in another group's study(51), both of which demonstrated good repeatability. The filling rate and pressure on the abdomen were found to affect sensation, and further study will investigate clarifying objective description to take these factors into account.

3.3. Conclusions (Level 3-4)

- Based on published results, a significant variation exists in clinical practice to determine bladder filling sensation landmarks and maximum cystometric capacity, despite the standardisation of terms.
- Strategies to derive bladder filling sensation parameters in a more automated and objective way, have been published and show plausible and repeatable results. Assessment of confounding factors and larger studies are yet to be carried out.

3.4. Heart Rate Variability

Heart rate variability was evaluated to serve as a monitor of the autonomic nervous system as an objective measure for LUTD and/or bladder filling sensation, without arriving at a clinical application yet.(52) (53) (54). A recent study(55) in patients with myelopathy failed to show a significant rise in sympathetic or parasympathetic components of heart rate.

3.5. Conclusions (Level 3-4)

- None of the analysis or testing methods of the autonomic nervous system has, to date, shown any relevance for the objective diagnosis of LUT function.

4. NON-INVASIVE PRESSURE MEASUREMENTS

4.1. Conclusions and Recommendations 2016

Non-invasive measurements of bladder pressure during voiding in men by the penile cuff or condom catheter have been shown to correlate with traditional invasive measurement of bladder pressure. ICI2016 recommended (grade B) that non-invasive measurements of bladder or detrusor pressure can be considered in clinical experiments in order to evaluate voiding function when the male patient is not required to undergo an invasive assessment of the storage function of the LUT. The ICI2016 did not recommend condom or penile cuff pressure, nor near infrared detrusor spectroscopy, for the diagnosis of UI, nor of LUTD(56). Measurement of perineal noise during voiding as another way of non-invasively quantifying male BOO has been evaluated but has also not demonstrated relevance for the diagnosis of male UI(57). Transabdominal wall near-infrared spectroscopy (NIRS) was used to detect the haemodynamic changes that are associated with detrusor contractile activity (58) (59) (60).

4.2. New evidence 2021

Data has been published on a new version of a device (the 'urethral connector') to measure a proxy for isovolumic intravesical pressure during an interruption of voiding at the location of the fossa navicularis(61). The pressures obtained were similar to those obtained by conventional PFS and were significantly different between groups of obstructed and unobstructed men. No new data on perineal noise or NIRS have been presented.

Despite advances being made, both a systematic review(56) and a consideration of developments in 'less-invasive UDS'(62) concluded that since current technologies cannot yet replace invasive tests for pressure measurement, they are best placed for consideration as screening or triaging tools, to spare some patients from invasive UDS early in the treatment pathway.

4.3. Conclusions (Level 3)

- Non-invasive measurements of bladder pressure during voiding in men by the penile cuff, condom catheter and urethral connector have been shown to correlate with traditional invasive measurement of bladder pressure.
- Near-infrared detrusor spectroscopy has, in very selected recordings, shown a relation with detrusor activity but this could not be reproduced in an independent clinical follow up evaluation.

4.4. Recommendation (Grade B)

- The committee endorses that in clinical experiments non-invasive measurements of bladder pressure may be considered in order to evaluate voiding function, as screening tools for assessing male patients.
- The committee does not recommend condom, penile cuff or urethral connector pressure, nor near infrared detrusor spectroscopy, for the routine assessment of LUTD.

5. URETHRAL PRESSURE REFLECTOMETRY

5.1. Conclusions and Recommendations 2016

Urethral pressure reflectometry (UPR) is an alternative method of assessing urethral function that measures pressure and the cross-sectional area along the entire urethra continuously. This technology was evaluated in an *in vitro* study.(63) Subsequently UPR parameters of 30 SUI-S women and 30 volunteers (23 'continent' and 7 'nearly continent') were reported and compared with UPP(64). A feasibility study using the technique was also reported in 10 male patients(65). The committee recommended that urethral pressure reflectometry not be used in clinical practice for the diagnosis of UI

5.2. New evidence 2021

The group that developed the technique has since published several studies using UPR to monitor changes in urethral pressure in women before and after medical ((66), n=24), surgical ((67), n=28) and conservative ((68), n=31) treatment. Several of these studies showed that UPR can detect changes in urethral pressure that correspond to clinical indicators and relevant changes. Furthermore, in a study of 30 women(69), UPR was found to be highly reproducible in its measurements. These data suggest that larger studies are indicated in order to ascertain the utility of UPR within a diagnostic or prognostic framework.

5.3. Conclusion (Level 3)
- Clinical measurements of urethral pressure reflectometry opening pressure and cross-sectional area have provided some insight into urethral closure function, but, as yet have no clinical relevance in the diagnosis of UI.

5.4. Recommendation (Grade B)
- The committee recommends that urethral pressure reflectometry is not used in clinical practice for the diagnosis of UI before clinical relevance, non-inferiority and/or superiority over current UDS has been demonstrated.
- The committee considers that larger trials assessing the diagnostic and prognostic value of UPR would be justified.

6. ULTRASOUND IMAGING

6.1. Conclusions and Recommendations 2016

Imaging and ultrasound in relation to UI will be discussed in a separate chapter of this book. We will only give a short summary of ultrasound in relation to UDS observations.

The measurement of detrusor wall thickness has been used in several studies as a screening test for DO or for BOO with a variety of measurement techniques using transvaginal, transabdominal or transperineal ultrasound. Different protocols were used and measured different parts of the bladder. This has resulted in contradictory data. Some data showed a smaller cystometric capacity in patients with overactive bladder syndrome (OAB-s) or DO, and an association between increased detrusor wall thickness and DO on UDS. Also, observations of an association of ultrasound detrusor wall thickness and BOO have been reported. Most researchers conclude that overlap of the results and the relatively low predictive value should be improved before bladder wall thickness is used in clinical practice.(70) (71) Furthermore, the specificity of detrusor wall thickness for UI (or DO) has not been determined and is probably unlikely to be clinically meaningful. Studies of other specific patient groups have been reported. One, in SCI patients, concluded that detrusor wall thickness could not be used in such patients(72) and another in nocturnally enuretic children suggested that detrusor wall thickness could be applied as a screening tool to select children with DO(73).

Twenty men (mean ± SD age 66 ± 6 years) with LUTS were included in a study to evaluate radio frequency ultrasound imaging of detrusor wall strain. This bladder wall strain correlated positively with detrusor pressure in some patients with an isovolumetric and/or voiding detrusor contraction. It has however been difficult to continuously measure the bladder wall in a large proportion of the patients(74).

6.2. New evidence 2021

The latter group above have published data on the method of decorrelating sequential ultrasound images of voiding as a method of diagnosing BOO(75). Processing of transperineal ultrasound from 45 voiding male patients yielded a 95% specificity and 88% sensitivity for the diagnosis. Another group has been investigating the quantification of bladder wall biomechanics using ultrasound(76), as an adjunct to conventional UDS. The application of advanced image analysis could well offer non-invasive options for screening and potentially for diagnosis, as well as inform research into bladder physiology. This study also referred to a simpler assessment of bladder outline shape which has been explored by the group(77), and which is the subject of an ongoing research project elsewhere(78). Both groups report significant differences in measurable shape indices between patients with bladder contractions and patients with acontractile bladders, suggesting a non-invasive tool for the detection of DO.

Developments in the use of bladder wall thickness (BWT) measurements have also been reported, both in relation to the diagnosis of male BOO(79) (65% diagnostic accuracy for age>70y, n=196) and of male DU(80) (73% accuracy, n=448). Increased BWT in male patients has also been reported in patients with DO(81). Studies have also been reported in female patients(82), but a multicentre accuracy study reported that BWT is not a good replacement test for DO in women(83), where the lower urethral closure pressure in females may be a factor. The conclusion of the EAU systematic review(56) that BWT may have a multifactorial basis has been repeated in these more recent studies. Guidelines for reliable cut-offs in clinical practice for accurate diagnostics in place of invasive methods have yet to be developed, but researchers report that it may have a role in assisting patient management(79) (82).

6.3. Conclusion (Level 3)
- There is some evidence that detrusor wall thickness is related to BOO, DU and DO in men.
- There is no evidence that ultrasound detrusor wall thickness analysis can discriminate between DO (with or without UI) and BOO. Detrusor wall thickness has a relatively low predictive value to discriminate from normal LUT function.
- There is a large overlap between normal and abnormal values in detrusor wall thickness and a lack of standardisation in ultrasound detrusor wall thickness measurement.

6.4. Recommendation (Grade C)
- The committee recommends that ultrasound detrusor wall thickness not be used in routine clinical practice for the diagnosis of LUTD related to UI, but that guidelines for use in patient management be investigated.
- The committee recommends that studies into the analysis of bladder wall biomechanics and bladder shape using ultrasound be encouraged and supported.

III. URODYNAMIC STUDIES: NORMAL VALUES, RELIABILITY AND DIAGNOSTIC PERFORMANCE; REPRODUCIBILITY AND RELIABILITY OF URODYNAMIC STUDIES

1. CYSTOMETRY: NORMAL VALUES AND TEST-RETEST VARIATION

1.1. Introduction

Awareness of lower urinary tract （LUT） function and physiology is important when UDS is performed. Similarly, normal anatomy should be known when medical imaging is performed or evaluated. The function and physiology of the LUT is fairly simple by itself: the bladder should adapt to the increasing volume of urine produced by the kidneys as the bladder fills during the micturition cycle with only little or no pressure increment. The stretching bladder muscle should signal to the conscious brain to create awareness of fullness, and the necessity to empty, at adequate volumes and safe pressures. In humans the bladder should contract and empty quickly and effectively in tandem with voluntary pelvic floor striated muscle relaxation. The smooth muscle bladder outlet should be contracted during storage and relaxed and funnelled during voiding. Bladder muscle dome and base are antagonists and the pelvic floor muscle acts as the voluntary learned control, rather than these autonomic innervated smooth muscles. Any deviation from this is abnormal, may cause difficulty and may provoke the need for medical therapy. In neurologically normal persons signs and symptoms are sensitive but not specific for the dysfunctions, if measured with UDS. In neurologically affected persons, symptoms are, usually because sensation is affected, less sensitive and/or usually less specific. UDS is usually done for persons that present with symptoms and the result of the test can be used to explain all elements of function and can be used to put the presenting symptoms in the perspective of dysfunction and pathophysiology, in relation to what can be physiologically expected from the lower urinary tract. This description is qualitative, not quantitative; the ICI2021 working group and earlier ICI working groups have summarized the more quantitative evidence.

1.2. Summary of earlier conclusions and recommendations

Earlier ICI consultations(84) concluded that various studies have been helpful in giving normal values and test-retest variation of UDS parameters in healthy volunteers. But also, that there has been some evidence that evaluation of bladder filling sensation may be different between laboratories. These may be observer dependent, making data exchange as well as generalization and interpretation of published data difficult. It was advised that investigators and clinicians recognize ‘normal’ test-retest variation as well as the differences and/or variations between usual lower urinary tract behaviour and UDS, with a specific recommendation that investigators and clinicians assess the representativeness of the evaluation based on the patient’s perception as to how well the tests have reproduced their usual LUTS. UDS are showing test-retest variation of ±10-15% for various parameters (volume, pressure or flow) and observations, as well as a variation in evaluation(85–89)abstracted clinical and urodynamic information from 100 charts, selected for adequate completeness from a consecutive series of 135 women referred for urodynamic testing. For each of the 100 cases, the reviewers assigned International Continence Society filling and voiding phase diagnoses, and overall clinical diagnoses. Raw agreement proportions and weighted kappa chance-corrected agreement statistics (kappa. A test-re-test variation in clinical testing is expected and unavoidable(90) and UDS performs similarly to other clinical tests where cooperation between patient and clinician is relevant. Apart from the inherent physiological variation of UDS, clinically relevant practice variations and inter-observer interpretational variations were noted in earlier ICI reports(91,92). Further standardisation of UDS as well as education were recommended(84).

1.3. New Evidence 2021:

ICS has published a new practice standard for invasive UDS(4) that has included further standardisation of the evaluation of filling sensation. This standard has also included the recommendation of earlier ICI committees to include patient reported representativeness in the evaluation. The new standard was followed up and well explained in narrative reviews(93,94). One health care system has earlier proposed a national quality standard for UDS(95), that led to a renewed document(96). Recognition of artefacts and features, that may occur while performing or evaluating UDS, was substantiated and standardized with a manuscript as well as with an International Continence Society (ICS) teaching module(14,97) and software may become increasingly relevant in supporting measurement quality control(13). Standards of equipment performance are still valid(98). Further additional attention has been given to the reference to the surrounding atmospheric pressure(99) and the vulnerability of the ICS standard(4) water-filled system in this regard(100). The drawbacks of the traditional water-filled system were a driver for innovation(101) although sufficient evidence was deemed required in order to replace or adjoin the standard system(102,103). Comparative evidence is evolving *in vitro*(104) and in clinical measurements(105–108) and is enthusiastically discussed(109,110).

Normal LUT function is well defined and easy to understand, and two groups have found studies that represent normal lower urodynamic physiology (111–113). Some research again draws attention to continuous urethral pressure(114,115) but with unknown clinical relevance at present(116,117). Video (X-Ray/Fluoroscopy) and EMG as adjuncts to standard cystometry are discussed in an expert consensus meeting, concluding with recommendations(118,119) and also in a teaching module and a manuscript with the aim to improve practice(120,121).

1.4. Conclusions

The committee concludes that limits of normality in UDS are well established (Level 2). The committee also concludes that precise limits for abnormal (i.e.reduced) compliance are not exactly known (Level 3). The committee concludes that LPP has many variations (also without cystometry) and that standardization of technique is lacking (Level 3).

1.5. Discussion

Normal function and physiology of the LUT is the basis for diagnosis of abnormality and dysfunction. Based on the commonly accepted limits of normality a specific dysfunction can be diagnosed. Not every dysfunction needs treatment and treatment is selected on the basis of diagnosis, signs, symptoms, bother, prognosis and risk to the upper urinary tract, and patient preference.

There is a risk for urinary tract infection (UTI: <5%) after invasive UDS. A systematic review evaluated nine randomized controlled

trials and concluded that prophylactic antibiotics did reduce the risk of bacteriuria after UDS but there was not enough evidence to suggest that this effect reduced symptomatic UTI(122). The ICS standard(4) has recommended to advise the patient to drink extra amounts immediately after the test to prevent bacteriuria evolving into infection and inflammation.

1.6. Recommendations (Grade A):
Persons diagnosing LUT function and dysfunction should be sufficiently aware of normal LUT function and physiology, and its variability. They should also be familiar with the variability in the results of UDS. Persons performing UDS and persons interpreting the test results should have a thorough knowledge of normal physiology and its deviations, should be aware of the circumstances of the tests and their potential influence on LUT function and should be able to evaluate the tests with the reported representativeness in mind.

It is important that any new equipment used for UDS should have established reference values. It is particularly important to note that reference values between water-filled systems and air-filled systems are not interchangeable.

Antibiotic prophylaxis should not be routinely prescribed for UDS testing, The procedure should be performed with sterile catheters, tubes, fluids and aseptic technique as per good clinical practice. Local microbiological advice should be sought and protocols developed for the local UDS laboratory.

2. REPRODUCIBILITY OF AMBULATORY URODYNAMIC STUDIES

2.1. Summary of earlier conclusions and recommendations
Earlier consultations have not found published data on the reproducibility or test-retest differences of ambulatory UDS for patients with UI without relevant neurological abnormalities(84). A report on ambulatory UDS for patients with NLUTD was included in ICI2016 concluding fair reproducibility but with difficulties in zeroing of the pressures and balancing of the abdominal and vesical pressures(123). These technical difficulties may likely also occur in non-neurogenic dysfunction but it has not been studied or reported.

2.2. New evidence 2021
A single centre retrospective cohort study deemed ambulatory UDS to be useful for 430 patients out of 12,123 patients (3.5%) that underwent conventional UDS. In those patients ambulatory UDS changed the treatment plan in 75% of the cases (124).

2.3. Conclusion (Level 3)
The committee has not found studies that report reproducibility of ambulatory UDS for patients with non-neurogenic urinary incontinence. A reproducibility study in patients with neurogenic LUTD has observed difficulties in technical reliability of this test, though this has not adequately disproved ambulatory UDS for patients without neurogenic dysfunction. A new study has demonstrated that ambulatory UDS, when used for a sub-selection of patients, can change the treatment plan.

2.4. Discussion
Movement artefacts, pressure balancing and assessment of fill volume as well as prevention of urodynamic catheters from dislocating are challenging in ambulatory monitoring and standardization of the test is likely of relevance(125).

2.5. Recommendations (Grade B-C)
- The committee does not recommend ambulatory UDS as a routine first-line diagnostic test for patients with LUTD.
- The committee recommends greater attention to test-retest differences of ambulatory monitoring.
- The committee recommends standardization of the indication, the practice and the technical quality and analysis of ambulatory UDS.

3. INFLUENCE OF CATHETER ON VOIDING

3.1. Summary of earlier conclusions and recommendations
There is evidence that, in general, flow is reduced when voiding with a urodynamic catheter in the urethra and that this reduction is partially caused by the size of the catheter. It has been the opinion of earlier committees that single catheters 6-8 Fr incorporating both a filling channel and a pressure-sensing channel (i.e. double lumen catheters) should be used for intravesical pressure measurement during cystometry, as is also included in the ICS standard(4). PFS parameters and the subsequent PVR and Void % (voiding efficiency) should be interpreted together with the free flow voiding parameters.

3.2. New evidence 2021
A new study was published, confirming that the catheterized flow rate differs from the free flow in a cohort of patients(126) which in combination with an *in silico* analysis, again leads to the recommendation to always compare these two flow rates(127).

A study evaluated the test-retest reliability of uroflowmetry in a cohort of patients with various clinical incontinence syndromes. Test-retest differences were reported as insignificant in all groups apart from the patients with SUI and all uroflowmetry results were similar between the diverse syndrome groups. Although the number of abnormal, ineffective voiding, or reduced, intermittent or fluctuating flow rates was not provided, the authors have concluded that uroflowmetry with PVR requires further appraisal as a screening test for women with urinary incontinence(128).

3.3. Conclusion (Level 3)
Studies have confirmed that the transurethral urodynamic catheter causes an effect on voiding and flow rate that is proportional to the size of the catheter. Apart from these static effects, a dynamic effect is likely in a proportion of patients. The usefulness of uroflowmetry with PVR is not proven for women with isolated urinary incontinence. However, the pattern of flow on a flow curve may indicate straining and can be helpful.

3.4. Discussion
Both test-retest variation as well as variation in circumstances (e.g. position, privacy, bladder volume) play a role in 'dynamic differences' between two flow rates. The potential effects of position (for men and women) and privacy have not been reported in PFS. Also, differences may be large without clinical relevance in relatively high flow rates (especially when >15 mL/s). Double lumen 6 Fr catheters are ICS standard and PFS categories are based on measurements with catheters of this size, however only in male patients(4). Dysfunction of voiding has not been included in the scope of this

consultation however LUT function and dysfunction of storage and voiding are inextricably bound together.

3.5. Recommendations (Grade A-B)
- The committee recommends that investigators interpret pressure-flow study parameters and the subsequent PVR and voiding efficiency together with the free flow voiding parameters when relevant in the diagnosis of concurrent LUTD, together with the complaint of UI.
- Standard practice of dual lumen, as thin as possible catheters (8 Fr or less) for filling and pressure recording during UDS is recommended. If a dual lumen catheter is not possible, a two catheter technique can be an alternative during the filling phase, with removal of the filling catheter at the end of filling and prior to voiding.

4. URETHRAL PRESSURE MEASUREMENTS

4.1. Summary of earlier conclusions and recommendations
ICI committees have concluded that diverse studies have shown considerable test-retest variation and that urethral pressures depend on the pressure recording catheter used and its orientation within the urethra, and also depend on patient position, volume of fluid in the bladder and position of the patient. The clinical specificity of the results has never been demonstrated to be very high(84).

4.2. New evidence 2021
A pressure profile through the urethra has recently again been demonstrated with many sensors(129,130) or with an alternative to micro-tip sensors(131). There is no evidence that this solves the earlier problem of the lack of specificity for the type of urinary incontinence. Another recent study has again shown that there is a very substantial overlap in UPP results when a cohort of women was separated into diverse types of UI(132). Far more relevant, however, is the comment written in reaction to this research(133), which said that the pressure profile can never be an exact representation of the closure forces because technical limitations prohibit this, and measurement unavoidably affects function. An expert group has summarized many uncertainties around the assessment of urethral function and suggested areas for research(134) that should be scrutinized against the fundamental physics of intra-urethral assessment. That urethral closure function is not static *per se* was recently summarized by an expert group(116), as well as in a systematic analysis(115).

4.3. Conclusions and recommendations
Relatively high closure pressure in the bladder outlet can prevent incontinence in a normally functioning bladder. The premise of a UPP is not unjustified. The Committee concludes again that the very large overlap of urethral pressure values in clinical practice reduces the diagnostic value of the test due to low specificity. There is no evidence or plausibility that profilometry with more synchronous pressures or with alternative ways of pressure recording are of any potential advantage.
- The Committee discourages UPP as a single diagnostic test.
- The Committee recommends the use of standard UPP only in combination with cystometry and pressure–flow test, if deemed necessary, e.g. to confirm very low ‘urethral pressure’ or when leak point pressure has been very low during cystometry.
- Dual lumen catheters do not provide a precise measurement of urethral pressure profilometry as the eye holes are not opposite each other.

5. ABDOMINAL LEAK POINT PRESSURES

5.1. Summary of earlier conclusions and recommendations
ICI committees have concluded that diverse definitions and techniques to determine abdominal LPP exist and also that there is a variable association between abdominal LPP and the patient-experienced or measured severity of bother, or amount of UI. Studies have shown that different techniques and patient positions influence the results of abdominal LPP. Committees have not recommended abdominal LPP measurement as a sole test in female patients with UI. With regard to post RRP UI in men, Valsalva LPP was evaluated as a predictor before artificial urinary sphincter (AUS) insertion but did not show any relevance.

5.2. New evidence 2021
Apart from the above comments on UPP, a study has shown the plausible effect of an intra-urethral balloon catheter during the urodynamic stress testing(135). Cough stress testing with an air pressure balloon in the urethra results in higher LPP (or no leakage at all) compared to leak pressure testing without this. Also reconfirmed is that women with easier and larger amounts of leakage, more vaginal deliveries and older age have a larger chance of relatively low LPP(136).

5.3. Conclusion (Level 2-3)
Earlier and new studies showed no evidence that abdominal LPP is very specific to diagnose female patients with SUI or male patients with post RRP-I in subcategories.

5.4. Recommendation (Grade B)
• The committee does not recommend abdominal LPP measurement as a sole test in patients with UI without relevant neurological abnormalities.

6. PROVOCATIVE MANOEUVRES

6.1. Summary of earlier conclusions and recommendations
ICI committees have concluded that upright position, moving to a toilet, and hand washing are provocative of DO and recommended that the results of provocative cystometry are interpreted in the light of the patients’ symptoms, and to bear in mind whether the results obtained are representative. Also recommended earlier was that all circumstances and provocations during UDS should be reported. No standard for the diverse manners of provocation for patients with urinary incontinence is published, neither for the provocation of DO and nor for the provocation of stress urinary incontinence.

6.2. New Evidence 2021
The committee has not found new evidence regarding the position of the patient during cystometry although seated position is defined to be standard whenever possible(10). The latest ICS-GUP standard has introduced and defined the term ‘cough associated DO’ for one of the provocative tests during cystometry(4). A newly published evaluation has shown that this is applicable and relevant(137). Although clinical stress testing (as explained in the clinical assessment chapter of this consultation) is better standardized

at present(138) a standard for urodynamic stress testing and or leak point assessment is still lacking.

6.3. Recommendations (Grade C)

- The committee recommends that the results of provocative cystometry are interpreted in the light of the patient's symptoms and to bear in mind whether the results obtained are representative.
- The committee recommends the performance of UDS in the upright position (not supine); for females in the sitting position, and sitting or standing for males, whenever possible, because of the better sensitivity for filling phase abnormalities, but also because of the greater possibility of representative voiding and better patient comfort.
- The committee recommends that, when possible the filling position should be similar to the voiding position to avoid artefacts during recording of pressures.
- The committee recommends development of standards for provocations during UDS.

7. CLINICAL APPLICATIONS OF URODYNAMIC STUDIES; CORRELATION WITH SYMPTOMS AND SIGNS

7.1. Summary of earlier conclusions and recommendations

Numerous studies have demonstrated that symptoms and signs are not very predictive of the results of objective assessment. Objective assessment is the basis for almost every disease although symptom and signs may be helpful in initial management. Urinary incontinence is no exception; recognising the overactive bladder syndrome (OAB-S), SUI (and/or voiding dysfunction syndrome) may be helpful for initial conservative management(139), but good healthcare practice usually requires objective assessment when initial symptom or syndrome management fails. Earlier committees have always confirmed the guidelines that state that UDS is the gold standard to assess LUT function and dysfunction. All guidelines recommend UDS 'when necessary'. That UDS is fundamental in the objective assessment of urinary incontinence is never disputed although no guideline has ever been very specific in the indication for UDS. Earlier ICIs have recommended UDS as the gold standard assessment of patients with urinary incontinence.

7.2. New evidence 2021

A large study has confirmed that many patients with 'typical' SUI, as defined in earlier studies, did not have the 'typical' result on UDS. Even the most 'straightforward patients' with this syndrome could have diverse LUT dysfunctions(140,141). An *ad hoc* expert group has recently summarized the abundant evidence that confirms the mediocre specificity of symptoms, when resistant to initial management, for dysfunction and used this to underline another plea for objective assessment(142). Regrettably the ICI committee has found that no new studies have provided good guidance to define resistance to treatment or failure of pragmatic, syndrome-based management, neither for OAB-S(143), or for OAB-S incontinence or for SUI.

UDS may be help predict UI or delayed recovery of continence after radical retropubic prostatectomy (RRP) (144–146), which may be useful to counsel patients when they opt for surgical intervention. However, many confounders exist, especially the surgery and surgical technique itself. It is known and plausible that urodynamic parameters do not predict concomitant LUT problems when filling cystometry is done only up to leakage (e.g. (147)). The situation after intervention leads usually to larger capacity and to the need to void (without BOO and without PVR) as well. A balloon occlusion urodynamic technique, as was described in the earliest standards(148), is essential for many patients and occlusion (whether with a balloon catheter(149) or with manual closure of the urethra) should be applied as standard.

7.3. Discussion

Syndrome-based diagnosis of urinary incontinence has some diagnostic predictive value and is definitely of use in initial management. There is a lack of good prospective assessment of the diagnostic strategy after failure of initial management. It is plausible that objective UDS assessment may reduce the necessity of invasive second line management, and by reducing the number patients allocated to unnecessary invasive treatments would reduce failure rates, harm and costs, as well as increase success rates.

7.4. Conclusions and recommendation (Grade A)

- The committee recommends, in agreement with all guidelines, UDS as the gold standard test for patients with UI and LUTS.
- The committee recommends to precisely define 'failure' or 'treatment resistance' after initial (and syndrome-based) management.
- The committee recommends including red flags or alarms within the definition of the UI syndromes, potentially leading to a lower threshold for objective assessment of dysfunction, before any management.

8. QUALITY ASSURANCE IN URODYNAMICS

8.1. Evidence base

As in any medical test, monitoring and assurance of quality is vital. Urodynamic testing is frequently discussed with regard to its clinical quality and relevance. Technical quality has received attention for over 15 years.

In the UK health care system a single centre set of urodynamic traces were retrospectively evaluated for accuracy of baseline and cough pressures(150). Approximately 65% of the pressures were acceptable. An unexpected high rate of catheter loss around voiding was observed while using a separate single lumen filling catheter beside the pressure recording catheter. Initial resting pressures and cough responses, were also evaluated in other manuscripts reporting traces from different centers(151,152), with similar results, i.e. some imbalance in cough responses and errors in intravesical or abdominal initial resting pressures values, or both. Reviewing published traces and urodynamic traces found on the internet showed in addition to these errors lack of visible scales and other relevant elements of urodynamic testing(153,154). Another single centre retrospective study observed errors in interpretation and especially in flow rates, associated with insufficient voided volumes leading to unrepresentative results(155).

After publication of the 2016 ICS Good Urodynamic Practices and also after an ICS teaching module, helping to recognize errors and artefacts(15), a prospective multicenter study observed technical artefacts and errors, both in measuring quality as well as in clinical evaluation(156).

8.2. Conclusion
Evaluation of the technical quality of urodynamic testing shows that a relevant proportion of UDS has errors and artefacts.

8.3. Discussion
Technical artefacts occur, though do not always hinder diagnosis. It is demonstrably clear that many artefacts or errors seem not to be recognized, as becomes obvious when examining published tracings where urodynamic diagnoses are given based on obviously erroneous tracings, without discussing the reliability or validity of the measurement. Research questions to answer to help remedy this situation have been proposed(157).

8.4. Recommendation
Practical training of persons performing urodynamic testing (urodynamicists) is very relevant, including quality monitoring. However training and education of the persons establishing the diagnosis and management (the treating physicians) is even more important to prevent mis-interpretation, independent of technical measuring quality.

IV. PATIENT EVALUATION: WOMEN

1. STRESS URINARY INCONTINENCE IN WOMEN

1.1. Urethral Pressures and Severity of Stress Urinary Incontinence

1.1.1. Conclusions and Recommendations 2016
Various studies have shown a weak association between UI severity and urethral function tests (LPPs and urethral closure pressures) and cohort studies have shown that UI volume and intravesical volume at leakages are poorly associated with symptoms' severity and/or with patients' quality of life. In addition, studies have shown that urethral pressure and/or LPP did not have a predictive value towards outcome 6 months following TVT surgery, apart from the 6% patients with very low urethral pressures (<20 cmH_2O). However, it was also noted that there is a lack of evidence specifically for the management of patients with very low urethral pressures and that the many possible surgical solutions do not differ very much in outcome. In ICI2016, the committee recommended that LPP and urethral closure pressures not be used as a single factor to grade the severity of UI and did not recommend the use of urethral function tests for predicting the outcome of any surgical treatment for SUI (Grade C).

1.1.2. New Evidence for 2021
Two retrospective studies showed a correlation of SUI severity as determined by Stamey score with an abdominal LPP (ALPP) <60 cmH_2O which these studies defined as intrinsic sphincter deficiency (ISD)(136,158). In one study ALPP<60 cmH_20 was also associated with a positive empty bladder stress test. A large retrospective database study of women with urodynamically demonstrated SUI confirmed a lack of correlation of maximum urethral closure pressure (MUCP) and ALPP, showing only a weak association at 150 ml bladder volume that improved to a moderate association at bladder capacity(159).

1.1.3. Conclusions and Recommendations
- The committee considers that the term 'severity of incontinence' is not universally defined. Since it is not always clear whether severity refers to patient-reported bother or to physician-perceived therapeutic challenges (i.e. more difficult to treat), the committee suggests to better standardize the term.
- While there is increased evidence that higher degrees of subjective SUI and physical findings such as a positive empty bladder stress test are associated with ALPP<60 cmH_2O, the clinical relevance of this finding remains uncertain. The newer literature confirms the poor correlation of MUCP and ALPP, making it difficult to define ISD in a practical way by urodynamic parameters.
- The ICI2021 committee recommends assessing urethral function by at least one of the above methods, MUCP and ALPP if it will affect treatment. The committee reaffirms its recommendation that LPP and urethral closure pressures not be used as a single factor to grade the severity of UI. Furthermore, the committee does not recommend the use of urethral function tests for prediction the outcome of any surgical treatment for SUI. (Level of evidence 3, Grade of Recommendation C)

1.2. Aspects of Urodynamic Studies Relevant to Therapy for Stress Urinary Incontinence

1.2.1. Conclusions and Recommendations 2016
ICI2016 reported that prior ICIs concluded that UDS is not cost effective in the *primary* health care setting for women with symptoms that are likely associated with SUI ('SUI-predominant'). ICI2016 discussed the "VALUE" study that concluded that UDS does not influence the outcome of SUI treatment (7) and the "Investigate1" trial, a randomized controlled trial (RCT) designed to demonstrate the feasibility of a RCT into the role of UDS for patients with SUI(160). The investigators concluded such a trial was feasible and their pilot data indicated that there was a change in practice based on UDS with 80% versus 95% undergoing surgery. However, the study was not powered to demonstrate significance and the authors concluded that 450 patients would be needed in each arm to answer the question, which is more than the two prior prospective studies concluding that preoperative UDS was not necessary for uncomplicated SUI. Because a simplified accurate and reproducible system for anatomic changes and establishing the likelihood or presence of SUI was not in place, it was concluded that it is impossible to establish the need for UDS in a reliable manner in this setting. At present, the predictive value of a clinical diagnosis towards the selection and the outcome of management are unknown. UDS can only be disputed (or discarded) as the gold standard when prospectively compared to its alternative; a reproducible systematically derived clinical assessment or a well-defined 'stress urinary incontinence', and/or a precisely defined 'urgency urinary incontinence' (or 'overactive bladder – wet syndrome'). Thus, the committee recommended that UDS is kept in mind when discussing costs, risks, harm and benefit of the various methods (clinical or UDS) of diagnosis for LUTD and/or UI, in relation to the method of treatment.

1.2.2. New Evidence for 2021
There was minimal new information introduced to further support or oppose the use of preoperative UDS to predict outcomes of surgery in women with SUI. In a retrospective review of 71 women with DU and SUI undergoing retropubic synthetic sling, the authors found that successful treatment of SUI without the need for clean intermittent catheterization (CIC) was predicted by two independent variables: IIQ-7 score ≤6, and Q_{max} ≥6 mL/s(161). They also noted that Q_{max} ≤6 mL/s can predict needing CIC after surgery. However, their cohort included a mix of patients including those with neuro-

genic LUTD and procedures were modified based on UDS findings. However, in another larger retrospective study of 403 women the same senior author found that the presence of DO or DU did not affect continence rates at 5 and 10 years post-surgery versus patients with normal detrusor function(162). In a systematic review and meta-analysis of 4 randomized controlled studies with 150 women, the authors found that routine UDS prior to non-surgical management of UI or surgical management of SUI was not associated with improved treatment outcomes, when compared to clinical evaluation only(163). Data was limited and they suggested that well-designed clinical trials are needed to evaluate the clinical and cost-effectiveness of routine UDS prior to surgical management of SUI and OAB-S.

1.2.3. Conclusions and Recommendations

- The committee recommends that UDS be considered when discussing costs, risks, harm and benefit of the various methods (clinical or UDS) of diagnosis for LUTD and/or UI, in relation to the method of treatment. Care should be taken to determine if and how UDS will affect treatment and/or counselling. Recommendation Level of Evidence 2, Grade of Recommendation B.
- The committee suggests that in a patient with SUI symptoms and no other UDS cause for these symptoms failure to demonstrate urodynamic SUI does not exclude the diagnosis of SUI.

1.3. Prediction of Failure of Surgery

1.3.1. Conclusions and Recommendation 2016

ICI2016 did not find any new evidence for UDS predicting surgical failure. The committee, however, reviewed some studies that commented on the new onset or persistence of OAB-S in women with mixed symptoms of UI. An extensive review of the outcome of all minimally invasive surgical techniques after >=2 years showed that storage LUTS and voiding LUTS had an overall similar prevalence of about 15%.

1.3.2. New Evidence 2021

The committee did not find any new evidence that any specific urodynamic parameters can consistently predict surgical failure. Sections 1.1, 1.2, and 1.5 (above and below) which address specific areas do not add constistently and reliably to the evidence that specific UDS parameters do not predict surgical failure.

1.3.3. Recommendation

The committee recommends that studies evaluating the predictive value of UDS for failure of management include a strategy that is based on UDS results, including change of management and/or continuation of current management on the basis of UDS results, and include evaluation of an intention to treat principle.

1.4. Voiding Difficulties after Surgery

1.4.1. Conclusions and Recommendations 2016

ICI2016 confirmed the conclusions of ICI2013 that voiding dysfunction in women has been defined in many ways throughout many publications, but lacking consistency in UDS criteria and analysis. Also concluded was that test methods have been unable to reliably predict which patients will develop voiding difficulties after surgery for SUI. Normal UDS do not predict absence of voiding difficulties after sub-urethral tape. However, it was found that flow rates, if abnormal, may be useful in predicting post-operative voiding dysfunction and retention following retropubic and transobturator suburethral slings. It was recommended that patients are informed that it is difficult to predict who will develop voiding difficulty following surgery for SUI and recommended that patients with poor flow rates before intended surgery are informed that they have a higher likelihood of having voiding problems following suburethral tape placement for SUI. Also of importance, though not specifically mentioned in ICI2016, was that a large randomized, controlled trial of pubovaginal sling vs. Burch colposuspension showed that no preoperative UDS (including maximum urinary flow rate) was able to predict postoperative voiding dysfunction or the risk for surgical revision(164).

1.4.2. New Evidence 2021

A Cochrane review in 2017 found the presence of voiding dysfunction after transobturator and retropubic mid-urethral slings was 5.53% and was slightly higher in retropubic vs. transobturator slings(165). However, no specific predictors of voiding dysfunction were mentioned. There is no new evidence regarding other incontinence surgeries such as pubovaginal sling or Burch colposuspension.

1.4.3. Conclusions and Recommendations

The committee confirms the conclusions of the ICI2016 regarding definitions of voiding dysfunction after stress incontinence surgery and the lack of predictability of UDS in predicting voiding dysfunction after mid-urethral sling and furthermore extends these conclusions to other incontinence surgeries, specifically pubovaginal sling and Burch colposuspension.

The committee recommends that clinicians may use UDS to evaluate bladder contractility, bladder outflow obstruction, and bladder emptying prior to stress incontinence surgery, however there are no consistent predictors of postoperative voiding dysfunction for midurethral slings, pubovaginal slings and Burch colposuspension.

Level of Evidence 2, Grade of Recommendation B.

1.5. Urgency, Mixed Symptoms of Incontinence, or Overactive Bladder Syndrome after Surgery for SUI.

1.5.1. Conclusions and Recommendations 2016

The prospective studies that were available at ICI2013 indicated that OAB-S, mixed symptoms of UI (MUI) and/or DO at presentation have a negative effect on the outcome of all available surgical interventions for SUI. ICI2013 concluded that methods have been unable to reliably predict which patients will develop *de novo* urinary urgency (OAB-S) after surgery for SUI when the pre-intervention evaluation has been negative for DO (or for reduced compliance). *Post hoc* evidence suggests that procedures for the treatment of SUI which are more 'obstructing' produce a higher chance of *de novo* urinary urgency (OAB-S). The ICI2013 recommended (grade B) that patients with SUI are informed that the chance of developing urinary urgency (OAB-S) following surgery is unpredictable and recommended also that patients are counselled before surgical intervention regarding the possibility of a lesser success rate when OAB-S and/or UDS signs of DO (or reduced compliance and/or cystometric capacity) exist. For ICI2016, a study showed that also patients with 'obvious' symptoms of SUI may have DO, and that these patients are successfully managed without surgery and another study demonstrated that when TVT-O was done only in patients with USI without DO, the cure rate after 10 years was markedly higher (95%) than that usually reported ±75-80%(166). No new recommendations were given.

1.5.2. New Evidence for 2021

In a single retrospective study of 157 women with MUI undergoing mid-urethral sling surgery, authors noted an objective cure of 82.2%

in women with USI but no DO, versus an objective cure rate of 55.2% in those with USI plus DO/DOI(167). Subjective cures were 81.1% and 53.7% respectively. The type of incontinence surgery did not affect postoperative outcomes in either of the groups. The authors concluded that although there is evidence for a good cure of the stress component of MUI, urodynamic investigation with its findings prior to management of MUI could have greater implications for selective patient-centred counselling because the presence of DO or DOI resulted in poorer objective and subjective outcomes. The authors did not specifically report on other patient-reported outcomes. The ESTEEM trial, a randomized controlled trial to determine the effect of behavioural and pelvic floor muscle therapy combined with surgery vs surgery alone on incontinence symptoms among women with MUI in which UDS was not done, showed that patients in both arms had significant improvements in both stress and urgency incontinence after 1 year(168). Women with more severe urgency symptoms at baseline may benefit from perioperative behavioural and pelvic floor muscle therapy combined with mid-urethral sling(169). Among women with MUI, behavioural therapy and PFMT combined with mid-urethral sling (MUS) compared to MUS alone resulted in a small statistically significant difference in urinary continence symptoms at 12 months, but that difference did not meet a prespecified threshold for clinical importance. It should be noted that all women had moderate to severely bothersome SUI **and** UUI at least one episode of each on a 3-day diary.

1.5.3. Conclusions and Recommendations

- The committee recommends that patients with SUI are informed that the chance of developing urinary urgency (OAB-S) following surgery or the possibility of urinary urgency improving after surgery is unpredictable and recommends also that patients are counselled before surgical intervention regarding the possibility of a lesser success rate when OAB-S and/or UDS signs of DO (or reduced compliance and/or cystometric capacity) exist and also the possibility that pre existing overactive bladder symptoms may improve. Level of Evidence 2, Grade of Recommendation B
- The committee recommends invasive UDS after failure of initial non-invasive management of SUI. (Evidence Level 1 (guidelines). Grade of Recommendaition A.
- The committee recommends that UDS may be performed in patients with MUI prior to surgical treatment of SUI, if the results of the UDS will affect management or counselling. Level of Evidence 2, Grade of Recommendation B

1.6. The Role of Urodynamic Studies in Predicting Urinary Incontinence in Women after Surgical Management of Pelvic Organ Prolapse

1.6.1. Conclusions and Recommendations 2016

Various studies summarized for prior ICIs have shown that symptoms of SUI can appear after surgery for pelvic organ prolapse (POP). A variety of methods to uncover 'occult stress urinary incontinence' in women with POP have been reported and in prospective stud-ies it has been demonstrated that all have different sensitivities and specificities. Standardi-sation of these tests was considered necessary. The ICI2016 recommended that patients with POP be informed about the relatively unpredictable chance of developing SUI after surgery for POP. Also, noted was that although UDS is referred to as the gold standard for the diagnosis of LUTD in all teaching books (level 1), it is yet not precisely determined in which type of patients a UDS diagnosis (in addition to a clinical diagnosis) is needed for long term effective and safe management.

The following recommendations were made (Grade 2):

- Consider managing a patient with SUI without a UDS diagnosis, and to individually discuss the likelihood of success and/or the possibility of side effects or failure of surgical man-agement (with suburethral tape) based on the available clinical diagnosis.
- Considering UDS prior to surgical treatment in patients with SUI when clinical signs sug-gest atypical, not uncomplicated or complex SUI exists.
- Consider including the complete and systematically gathered results of UDS in the man-agement plan for patients with SUI when UDS is done.

1.6.2. New evidence 2021

One retrospective database review suggested that SUI may be more important than the demonstration of occult SUI (O-SUI) on invasive UDS. In a study of 274 women without O-SUI, de novo SUI developed at ≥6 months postoperatively in about 5% of women with no SUI and in 17% of those with SUI(170). Another retrospective observational study of 98 women without LUTS undergoing preoperative UDS assessment prior to POP surgery, re-ported that 20% of women had O-SUI and concluded that preoperative evaluation of POP is incomplete without UDS, but failed to show any outcomes benefit(171). In another retro-spective study of 392 women with a variety of LUTS undergoing preoperative UDS prior to POP surgery, the authors found that except for the demonstration of O-SUI, UDS rarely changed the surgical plan or counselling (3.5%). It was most useful for women with SUI that also had concomitant voiding symptoms and/or elevated PVR, where the decision to per-form or not perform an incontinence procedure or treatment of BOO was affected, although outcomes were not assessed(172). A prospective trial of women undergoing stage III and IV POP repair called into question the reliability of invasive UDS to diagnose O-SUI vs. physi-cal exam (PE). 60% of 105 consecutive women had O-SUI. Of these, in 48 (76.2%) O-SUI was identified by both tests, in seven (11.1%) women O-SUI was identified by UDS and not by PE and in eight (12.7%) women, O-SUI was identified only by PE. The sensitivity to de-tect O-SUI during PE and UDS was 88.9% and 87.3%, respectively. Twenty-nine percent of women with no SUI on PE had O-SUI. However there was no association with surgical outcomes(173). A retrospective study of 322 women undergoing POP repair showed that the negative predictive value of preoperative UDS for postoperative SUI in patients undergoing any POP repair was 97.9% [95% confidence interval (CI) 92.7–99.7%](174). This led the au-thors to conclude that their study supported using preoperative UDS as a screening tool to avoid unnecessary concomitant continence procedures.

A study on 164 women from a single center showed that occult urodynamic stress inconti-nence and previous history of SUI are significant predictors for de novo SUI following the single-incision mesh surgeries(175).

Regarding the predictive role of UDS to add a concomitant anti-incontinence procedure, a single-center retrospective study including 87 women with O-SUI showed that urodynamic parameters, obtained before POP repair surgery, were associated with O-SUI and could be useful in providing adequate counseling to facilitate decision making on whether to add a concomitant anti-incontinence procedure. However, another retrospective evaluation was undertaken of 155 patients with at least second-degree POP who underwent POP surgery after UDS assessment and found that clinically incontinent patients with MUCP ≤50 cmH2O will gain the greatest benefit from concomitant POP and SUI surgery(176). Finally van der Ploeg et al reported data from two RCTs comparing postoper-

ative SUI in vaginal POP repair with and without MUS(177). They evaluated those women without SUI not undergoing SUI surgery at the time of POP repair. Only 9% developed post-operative SUI, with only 3.5% undergoing surgery for de novo SUI. And furthermore, all women who underwent treatment for de novo SUI showed SUI during basic office evaluation.

1.6.3. Discussion

ICI2016 recognized some of the limitations of UDS in patients with POP with or without SUI prior to surgery. Absolute indications for UDS were not given but rather considerations for clinicians based on SUI in uncomplicated vs. complicated patients. Current evidence with respect to both UDS and surgical outcomes would suggest that clinicians should carefully discuss incontinence and potential incontinence after surgery and the relative risks and ben-efits of treating and not treating incontinence(178). In patients without SUI and no occult incontinence on physical exam, stress incontinence surgery is not indicated and therefore UDS will likely not be helpful. In patients with SUI, UDS evaluation may be helpful in guid-ance of invasive treatment and counselling when SUI is complicated or associated with voiding dysfunction.

Recent data adds to the uncertainty of surgical outcomes. Previous consultations had rec-ommended UDS for all patients with symptoms of SUI and POP. Based on the recent trials' conclusions, but also already before the publication of those trials, many patients under-went midurethral sling surgery after a diagnosis of SUI was established based on signs and symptoms. Systematically collected long-term follow up data is scarce, and difficult be-cause of patients lost to follow up, and the now available publications usually report single centre expert outcomes. Nevertheless, there has not been much epidemiological evidence that the management of patients with 'clinically uncomplicated SUI' without UDS is very risky. However, surgery is invasive, potentially morbid or irreversible, and therefore estab-lishing a confirmed diagnosis prior to that is in the patient's interests and needs careful counselling about the pros and cons of UDS and the surgery itself. It should also be borne in mind that the recruitment rate for the published trials evaluating the need of UDS, notably, in expert centres, has been fairly low. This seems to allow the interpretation that the inci-dence of patients with 'uncomplicated SUI' has been relatively low and that a large percent-age of patients with the complaint of UI, or with SUI symptoms plus other LUTS or compli-cating factors, deserves UDS.

1.6.4. Recommendations 2021:

- The committee recommends that clinicians may non-surgically manage a patient with uncomplicated SUI, or uncomplicated O-SUI on physical exam without a UDS diag-nosis. However, it recommends to discuss the role of invasive UDS in select pa-tients if considering invasive, potentially morbid or irreversible treatments after dis-cussing the likelihood of success and/or the possibility of side effects or failure of surgical management of stress urinary incontinence. Level of Evidence 2, Grade of Recommendation C
- The committee recommends that clinicians utilize UDS in a patient with complex SUI and POP with UDS in a manner similar to a patient without POP if the patient is considering surgery for the treatment of SUI. Level of evidence 3, Grade of Rec-ommendation C
- The committee recommends that clinicians may perform invasive UDS on patients without SUI and no O-SUI on physical exam if the patient would be interested in treating O-SUI and the results of UDS testing would help them make that deci-sion. Level of evidence 2, Grade of Recommendation C
- The committee recommends considering including the complete and systematically gathered results of UDS in the management plan for patients with POP and SUI when UDS is done. Level of Evidence 2, Grade of Recommendation B

2. URGENCY URINARY INCONTINENCE AND OVERACTIVE BLADDER SYNDROME

2.1. Frequent Voiding and Urgency; Overactive Bladder Syndrome

2.1.1. Recommendations 2016

Studies have not been able to show a strong association between OAB-S and DO. Various studies have directly or indirectly concluded that the individual prediction of the response to treatment for OAB-S, on the basis of the characterization or quantification of DO during UDS, is impossible. A single centre retrospective study with good power confirmed the lack of association between subjective symptom severity and bother and objective measure-ments reinforcing the need for objective assessment, especially in proof of principle stud-ies. However, it was also observed that UDS cystometric capacity, compliance, as well as onset of first contraction were associated with perceived severity of symptoms(179). An-other well powered multicentre study demonstrated that subjective symptom assessment for women with LUTS was not reliable to uncover the pathophysiology that caused the symp-toms(140).

The ICI2016 recommended (Grade B) that investigators and clinicians discuss with patients with DO that neither the quantity nor specific characteristics of DO predicts the response to any of the therapeutic approaches. Furthermore, the committee recommended that investi-gators and clinicians discuss with patients with OAB-S that when UDS is performed neither the quantity nor specific characteristics of DO predicts the response to any of the therapeu-tic approaches, but that the absence of DO is relevant for further management.

2.1.2. New evidence 2021

Since ICI2016, many studies have investigated the role of UDS in OAB-S and UUI, in an attempt to find UDS predictors of outcomes of treatment. Unfortunately, none have been successful. Thus, the principal role of UDS remains for the patient in whom the diagnosis is uncertain or an underlying secondary condition (e.g. voiding phase dysfunction, SUI) is suspected. In 2018 the International Consultation on Incontinence Research Society sought to determine if different patterns of DO are clinically relevant(180). Specifically, they re-viewed the literature on several defined patterns of DO: Phasic, Terminal, Sustained, Com-pound, and Post Micturition. They noted that some studies showed some correlation be-tween different patterns of DO and phenotypes of OAB-S. However, they concluded that there is not enough evidence in the literature that the different patterns of DO have clinical relevance and that more research studies are necessary. Two new studies added to the ex-isting body of literature have shown that urodynamic outcomes were not beneficial in pre-dicting response to OAB-S treatment: one for sacral neuromodulation(181) and one for mir-abegron(182).

2.1.3. Recommendations

The committee recommends that investigators and clinicians discuss with patients with DO that neither the quantity nor specific characteristics of DO predicts the response to any of the therapeutic approaches (Grade B).

Furthermore, the committee recommends that investigators and clinicians discuss with pa-tients with OAB-S that when UDS is performed neither the quantity nor specific characteris-tics of DO predicts the response to any of the therapeutic approaches, but that the absence of DO is relevant for further management (Grade B).

The committee also recommends that UDS be considered in the patient with OAB-S in whom voiding dysfunction in suspected (Grade B).

2.2. Urgency Urinary Incontinence

2.2.1. Recommendations 2016 (Grade B)

The committee recommended UDS in the following circumstances:

- Whenever there is doubt about the pathophysiology causing LUTS (including UI) whether the UI is uncomplicated or not.
- For patients that have had failed conservative and medical therapy.
- For women that have LUTS and/or UI and representative ineffective voiding (i.e. significant PVR) and or reduced flow rate.

2.2.2. New Evidence 2021

New evidence regarding UUI is concordant with new evidence on OAB-S, as many patients with OAB-S in studies also have UUI (see above). UDS parameters and DO characteristics do not reliably predict response to treatment in patients with UUI. The diagnosis of BOO or other voiding phase dysfunction remains an important indication for UDS in women with OAB-S and UUI. One new study showed a high incidence of voiding phase dysfunction in women with OAB-S, 87% of whom had MUI. In this group 19.7% of women had BOO and 3.3% had DU(183). Not surprisingly, the presence of DO and higher PVR were independent predictors of BOO, but the only independent predictor in the pressure-flow study was a smaller voided volume. One large, longitudinal prospective study of 687 women with OAB-S assessed the impact of UDS on treatment outcomes(184). It should be noted, however, that the intent of the study was to assess the diagnostic accuracy of bladder ultrasound in diag-nosing DO. Almost all women had UUI (61% had urgency predominant MUI, 33% had UUI). Women were eventually treated with either bladder relaxants alone, SUI surgery, DO surgery, or no treatment. Those who were treated concordant with UDS diagnosis (DO surgery – DO on UDS; SUI surgery – SUI on UDS; bladder relaxants – DO or normal UDS; no treatment – normal UDS) were more likely to report improvement in bladder symptoms (57%) then those whose treatment was not based on UDS findings (45%) on follow-up questionnaires (re-sponse rate 69%). The study was not an RCT, and by the authors' admission results are subject to unknown confounders, which may bias the results, including decisions to treat being based on information from sources other than UDS.

2.2.3. Recommendations (Grade B)

- The committee recommends UDS in women with UUI whenever there is doubt about the pathophysiology causing UI, for women who have failed empiric initial therapy, and for women in whom voiding phase dysfunction (BOO or DU) is suspected based on clinical history, elevated PVR, or reduced urinary flow rate.
- The committee recommends to include specific recommendations in the guidelines for management, based on proof of principle or specific evidence, of patients with OAB-S that have normal filling phase results on UDS, especially no DO.

V. PATIENT EVALUATION: MEN

1. URODYNAMIC TESTING OF MEN WITH SYMPTOMS AND SIGNS OF LOWER URINARY TRACT DYSFUNCTION

1.1. Conclusions and recommendations 2016

UDS for men with LUTS has demonstrated relevance for the diagnosis of bladder sensation, bladder compliance and detrusor relaxation. It has also demonstrated relevance in the quan-tification of BOO. UDS is in all guidelines referred to as the gold standard test to evaluate men with signs and symptoms of LUTD. Most elderly men who present with OAB-S have voiding symptoms also and a consistently reported large percentage have UDS evidence of BOO. BOO, DO, reduced cystometric capacity, PVR and/or DU can occur in any combina-tion per individual, independent of the symptoms presented, and can all be quantified on the basis of UDS. Specific evidence that UDS improves outcomes is limited, and pragmat-ic, symptom-based management is demonstrated to be very possible in many men. Never-theless, UDS is the basis for therapy when it is directly aimed at the pathophysiology that is responsible for the symptoms if the patient and/or the physician consider that relevant.

1.2. New evidence 2021

A pilot MRI study, observing the bladder during voiding in a cohort of healthy men and men with BPH and LUTS showed the greatest bladder wall displacement at the bladder dome in healthy men, compared to a decreased and asymmetric bladder wall motion pattern in BPH/LUTS men(185).

Ambulatory UDS might have a role in predicting sacral neuromodulation (SNM) in patients with bladder emptying problems. A single centre retrospective study, not using standardized criteria, found that in their hands, UDS overestimated the number of patients diagnosed with DU or acontractile bladder. Patients with reduced contractility on ambulatory UDS had a lower chance of SNM success. Hence, ambulatory UDS may be apliccable to select pa-tients with a truly acontractile bladder and predict SNM failure, especially when patients are unable to void as usual during UDS in clinic(186). In patients with OAB-S in whom SNM is considered, UDS parameters are not predictive of therapy outcome. Both cohorts however, contained only a very small subgroup of males and grade of outflow obstruction was not considered(181,186). Cystometric capacity and bladder compliance are improved with beta-3 agonists and vesicoureteral reflux grade was observed to decrease in patients with low-compliance bladder in a single centre retrospectively selected cohort of patients with neuro-genic LUTD on CIC(187).

A meta-analysis using nine Asian articles including a total of 932 patients with BOO with a median number of 92 patients per study (range 40-190) evaluated the finding of preoperative DO on outcomes following BOO surgery . The nine studies included conventional tran-surethral prostatectomy in four studies, photoselective vaporization of prostate in three studies, and other surgical modalities in two studies. In patients with DO, the pooled mean difference

in the IPSS was not significant for a better or poorer improvement. These results demonstrated that preoperative DO, as the single predictor, had no significant effect on subjective outcomes after treatment for obstruction in male patients The analysis has not evaluated or reported prostate size, grade of BOO and/or voiding contraction(188). For oth-er conservative management options, no new reports exist about whether or not UDS influ-ences the outcome of management.

1.3. Recommendations 2021 (grade C)

- The committee recommends invasive UDS for a male patient for whom objective elucidation of the pathophysiology of the LUTD is deemed relevant, especially when conservative options fail.
- In general, UDS is relevant when invasive management is considered, but it may al-so be relevant in symptomatic men of a relatively young age and/or relatively small prostates, relatively good flow rates and/or with relatively large PVR, when initial management fails.
- The committee recommends invasive UDS for patients that have experienced failure of surgery for LUTS and/or incontinence after treatment for obstruction.

2. LUTS AND OAB-S IN MALE PATIENTS

2.1. Conclusions and recommendations 2016

LUTS in men >50 years of age are highly prevalent and storage LUTS are frequently report-ed. In male patients, OAB-S-wet symptoms are associated with DO. UI in the elderly male may also be a sign of dysfunction in which DU, elevated PVR and/or BOO may exist. UDS is the gold standard to diagnose storage dysfunction (DO, reduced compliance) and/or bladder outflow dysfunction (bladder neck obstruction, DU and BOO) or combinations of these, in men with LUTS. Storage symptoms, with or without UUI, diminish gradually over time following TURP but this also has been demonstrated after vaporisation of the prostate. Patients with preoperative terminal DO might have less rapid improvement of OAB-S symp-toms after TURP. Nocturia is an important and highly prevalent cause of LUTS. Epidemio-logical studies have shown that non-urological causes for nocturia are prevalent and noctur-nal polyuria can be diagnosed with a 24 h frequency-volume chart in a significant number of patients. UDS in elderly men indicate however that DO and BOO with inefficient voiding do also play a role in a significant proportion of patients with nocturnal enuresis and/or UI. New onset, night-time UI, in an elderly male, warrants clinical assessment, including rectal exam and UDS-PFS. UDS studies have shown that use of a phosphodiesterase inhibitor does not objectively change LUT function in men, although it does often favorably affect symp-toms.

2.2. New evidence 2021

The committee has again specifically concentrated on LUTD within the scope of UI, to be within the scope of this consultation.

In an attempt to predict DO in male patients with LUTS, higher OAB-S symptom score (OAB-SSS) urgency UUI subscores, as well as greater intravesical prostatic protrusion, were found to be useful parameters(189). However in another study intravesical mid-lobe prostatic ob-struction was not a good predictor for OAB-S, but indicated a higher frequency of nocturia(190).

Several studies looked at the possible predictive role of bladder wall thickness (BWT) or detrusor wall thickness (DWT) in male patients with LUTS. A first study showed that BWT and Qmax can non-invasively predict the presence of DU in patients with LUTS and BPE, and presents the first available nomogram for the prediction of DU in patients with LUTS(191). In another study, BWT or DWT was associated with BOO in men aged 70 years or older, sug-gesting, according to the authors, that BWT or DWT thickness might serve as a non-invasive parameter in the management strategy decision for elderly men with LUTS(192). To evaluate the role of BWT as a predictor of DO in patients with LUTS/BPE without BOO, a study showed how BWT in male patients may be a consequence of DO other than BPO(193).

Subjectively successful treatment outcomes of intravesical onabotulinum toxin-A injection for OAB-S patients were associated with improvement in OAB-S symptoms but not with increased bladder capacity(194).

In patients with DO, adding trigone, and bladder neck/prostatic urethra as sites of onabotu-linum toxin-A injection produced 1-2 points larger reduction in OAB-SSS score and less residual urine volume with a 15 mL difference in cystometric capacity but a lower volume at urgent desire to void in comparison with detrusor only injections(195,196).

Males with DO in addition to DU had higher age and number of daily micturitions and were more likely to report urgency with or without urgency incontinence than males with DU with-out DO. They also had lower volumes for first desire to void, volume voided, and post void residual urine, lower abdominal pressure at Qmax and were less likely to report a history of retention or reduced bladder filling sensation than males with DU without DO(197).

To evaluate the impact of OAB-S on patients diagnosed with retrograde ejaculation, a clini-cal study revealed the coexistence of retrograde ejaculation with OAB-S upon performing UDS and showing that anticholinergic treatment is effective in selected patients(198).

2.3. Recommendations 2021

- The committee recommends considering UDS for the objective diagnosis of male LUT storage function, especially in elderly men with UI or in young men with LUTS and relatively small prostates not responding to management or medical treatment based on clinical examination. Recommendation grade C
- The committee recommends considering UDS for objective diagnosis of LUT func-tion in men with prostate enlargement to ensure specific management of the dys-function causing the LUTS. Recommendation grade C

3. URINARY INCONTINENCE AFTER TRANSURETHRAL RESECTION OF THE PROSTATE AND OPEN PROSTATECTOMY FOR BENIGN DISEASE

3.1. Conclusions and recommendations 2016

Many case series show that sphincter weakness is the most common aetiology of male UI after prostatectomy for benign disease (eg. TURP). However, case series and reviews show that other LUTD besides sphincter incompetence play an incident role in post radical prosta-tectomy incontinence (PRRP-I). Case cohorts

showed conflicting evidence whether DO be-fore prostatectomy is an important indicator for post-operative persistence of UI, or for the outcome of interventions to treat the UI.

3.2. New evidence 2021

The urodynamic alterations after sub-urethral sling surgery (SUSS) in patients with PRRP-I was evaluated during free uroflowmetry, and no parameters showed any statistically signifi-cant difference pre- and postoperatively. During cystometry, there were also no statistical differences and the same was observed at PFS; the exception was detrusor pressure at maximum flow rate (pdetQmax), that was lower post-operatively (p=0.028). In relation to the presence of urinary dysfunctions associated with post-prostatectomy incontinence (PPI), there was a significant reduction of DO (p=0.035) in relation to the pre-operative period. In conclusion, SUSS surgery significantly reduced DO and PdetQmax; however, there were no alterations of other evaluated UDS parameters(199).

The clinical and UDS parameters affecting the treatment outcomes of PRRP-I surgery were reviewed in patients with PPI who received an artificial urinary sphincter (AUS) or adjustable male sling (MS). Previous pelvic irradiation, prior PPI surgery, and volume of incontinence were inversely, significantly associated with the success of PPI surgery. In patients who received AUS, a history of neurological disease was inversely associated with treatment success. Also, in patients with an adjustable MS, previous pelvic irradiation, prior PPI sur-gery, and degree of incontinence were inversely associated with treatment success. From these results, adjustable MS should be avoided in patients with previous pelvic irradiation, prior PPI surgery, or severe symptoms. The treatment outcome of AUS might be compro-mised in patients with neurological disease. One centre confirms that these parameters are relevant(200), but isolated UDS parameters were on average not predictive of the outcome.

3.3. Recommendations 2021

The committee recommends UDS be considered in male patients have persistent LUTS and/or UI after surgical treatment for prostatic BOO if further surgical or invasive treatment is planned. Grade D recommendation.

4. RETROPUBIC RADICAL PROSTATECTOMY

4.1. Conclusions and recommendations 2016

The main cause of UI after retropubic radical prostatectomy (RRP) is sphincter weakness, but reduced compliance and DO with or without neo-bladder neck outflow obstruction con-tribute in an unknown proportion of these patients. UDS have demonstrated value to identify the aetiology of LUTD after surgical or radiotherapy treatment of prostatic carcinoma. Both urethral and detrusor function are prone to be affected after RRP. Decreased bladder com-pliance, lower detrusor pressure during voiding, higher Qmax, and reduced MUCP can be seen immediately after RRP. DU is commonly observed in patients with UI after RRP and may be a risk factor for the development of neo-bladder neck (stricture).

LPPs and urethral pressures, measured in their various ways, are consistently reported to be improved after anti-incontinence treatment using the various surgical techniques, and their improvement is associated with cure or reduction of UI volume and/or pad use. Clinical indi-cators for reduced chance of success of post RRP UI surgery are lesser amounts of urine loss, less pad use, and higher preoperative Valsalva LPP; however precise actionable val-ues for these are not precisely or universally defined. Anastomotic stricture (which may also prevent UI from being demonstrated during UDS), reduced compliance and DO as well as Valsalva voiding are UDS predictors of failure although with unknown specificity. Retro-grade LPP may be a good tool for the setting of male sling tension by adjusting the re-sistance during post-RRP UI surgery.

4.2. New evidence 2021

A prospective data collection study in 1814 patients identified the following factors as pre-dictive to develop post retropubic radical prostatectomy incontinence (PRRP-I): preopera-tive severity of LUTS, higher age, extent of nerve-sparing surgery and surgeon experience. The authors also provided an online prediction tool(201). In another study, the preoperative perfusion quality of the levator ani was studied by multiparametric MRI and found to be related to the postoperative continence status. This could according to the authors facilitate the preoperative patient consulting and decision making(202).

To examine chronological changes in urethral and bladder functions before, immediately after, and 1 year after robot-assisted radical prostatectomy (RARP), UDS were prospective-ly performed. Urethral sphincter and bladder storage function were observed to worsen im-mediately after RARP and to recover over time, when patients with and without incontinence were grouped together. However, the urethral sphincter function did not return to its pre-operative level and was considered the most prevalent factor for urinary incontinence after RARP(203).

Studies have been done to demonstrate the anatomical and functional changes in inconti-nent men after radical prostatectomy compared to continent men, as well as to evaluate the use of UDS in the work-up for PRRP-I prior to treatment. UDS have been used to have a better understanding of the anatomical and functional changes in incontinent men after RRP; however, the role of UDS to select a treatment recommendation is still to be determined(204).

SUI is a frequent adverse effect for men who have undergone prostate surgery. Artificial urinary sphincter (AUS) insertion or a synthetic sling for men which elevates the urethra are used for treatment after failure of conservative measures. The UK-NHS MASTER trial aimed to determine whether the male synthetic sling is non-inferior to implantation of the AUS for men who have SUI after prostate surgery (for cancer or benign disease), judged primarily on clinical effectiveness but also considering relative harms and cost-effectiveness, however, regrettably without considering UDS as a predictor of success or failure(205).

To examine which preoperative factors, including UDS, and operative procedures could predict continence status after RARP, a study was conducted. Univariate and multivariate logistic regression analyses of pre-operative factors predicting 24-hr pad test >2 g/day at 1 year after RARP were examined in 111 patients enrolled in this study. The number of pa-tients with incontinence at 1 year after RARP was 39 (35.1%). The only predictive factor for urinary continence was nerve sparing (NS) grade. To investigate the contribution of NS to urinary continence, 84 patients underwent UDS three times: before, immediately after, and 1 year after RARP. Chronological UDS revealed that recovery patterns of storage and voiding functions were the same among non-NS, unilateral-NS, and bilateral-NS groups, and that higher degrees of NS contributed to lesser decreases in MUCP and longer functional ure-thral length (FUL) after RARP. It was concluded that preoperative factors, including the re-sults of UDS, could not predict continence 1 year after RARP. The NS procedure contribut-ed to continence status. NS favourably

affected MUCP and FUL; however, it did not affect bladder function after RARP(145).

The storage symptoms following RARP, focused on de novo OAB-S and the factors related to de novo OAB-S occurrence. 245 patients without OAB-S who underwent RARP were pro-spectively examined. At 3 months after RARP, the patients were divided into two groups: patients with de novo OAB-S (de novo OAB-S group) and those without OAB-S (OAB-S free group). De novo OAB-S was observed in 37.8% (87/230) of patients. Post-operative conti-nence rate was significantly higher in the OAB-S free group (79.7%) than in the de novo OAB-S group (8.0%). There was a significant difference in preoperative IPSS-QoL score, continence rate, pre-and post-operative MUCP, and postoperative functional profile length (FPL) between both groups. Multivariable logistic regression analysis showed preoperative IPSS-QoL score and postoperative MUCP were significant predictive factors for de novo OAB-S. The incidence rate of de novo OAB-S after RARP was about 40% and seemed un-expectedly high. Decreased urethral function was significantly related to de novo OAB-S after surgery(206).

4.3. Recommendations 2021 (grade C)

- The committee recommends that invasive UDS for patients with RRP UI is not only done to evaluate SUI but that it is also done specifically to evaluate bladder storage function as well as voiding dysfunction.
- The committee recommends that UDS should be considered, in cases where it will help in diagnosing or counselling and follow-up.
- The committee suggests to perform UDS in patients with PRRP-I with an outlet closed by penile clamp or cuff if early fill volume leakage occurs, to better evaluate filling properties until capacity.

5. UDS FOR PATIENTS WITH POST (RADICAL) PROSTATECTOMY URINARY INCONTINENCE AND PERSISTENT SYMPTOMS OF LOWER URINARY TRACT DYSFUNCTION AND/OR FAILED SURGICAL MANAGEMENT

5.1. Conclusions and recommendations 2016

The committee has recommended UDS for patients with post RRP UI and failed surgical management when co-existing dysfunctions of the LUT cannot be excluded on the basis of clinical history, e.g. radiotherapy, signs and/or non-invasive UDS and symptoms.

5.2. New evidence 2021

A study investigated UDS findings in prostate cancer patients with self-reported persistent severe PPI as well as the outcome of incontinence surgery. The main aim was to evaluate the ability of preoperative LUT dysfunctions to predict the outcome of incontinence surgery. Of the 94 men with severe PPI more than 12 months after RRP, 76 patients (81% response rate) presented for clinical examination. Among them, 99% had intrinsic sphincter deficien-cy, and 67% had coexisting bladder storage dysfunction. The presence of preoperative bladder dysfunction was not predictive of the outcome of PPI surgery. Preoperative use of fewer pads (contrary to ICI 2016 conclusion), less severe PPI, and a longer interval between RP and PPI surgery were associated with the successful outcome of one or fewer pads/day. Longer duration from RP to PPI surgery was the only preoperative factor associ-ated with the successful outcome of satisfaction. Hence, presence of preoperative LUTD was not considered predictive of the outcome of PPI surgery in this study (146,207).

The concept of 'urethral atrophy', which is often cited as a cause of recurrent incontinence after initially successful implantation of an artificial urinary sphincter (AUS), and the specific cause of the malfunction of the AUS in severe PPI patients was investigated. UDS was used in this analysis and DO was reported to be relevant, however without further details about DO. The remaining results speculated that recurrent PPI, years after initially success-ful implantation of an AUS, is because of material failure, probably attributable to its age and consequent loss of its ability to generate pressure, and that urethral atrophy does not occur(208). The mid-term (mean 3 y) durability of the AdVance sling for PPI and impact of prior radiotherapy and storage dysfunction was assessed in a retrospective single center review of 80 men. Men with radiotherapy or DO were reported to have significantly poorer outcomes indicating a return to baseline degree of incontinence. Preoperative UDS (specifi-cally exclusion of DO), and prior radiotherapy were considered important when counselling men for AdVance sling. Compliance and maybe PdetQmax are predictors of outcome following artificial urinary sphincter (AUS) implantation for PPI. An internally validated nomogram has been developed that may be used to determine an individualized likelihood of AUS suc-cess. This nomogram may be used as a counselling tool to objectively set realistic expecta-tions of continence post-AUS implantation(149).

On the basis of a systematic literature review, it was confirmed that DO could be considered as another possible (or co-existing) underlying mechanism for PPI although sphincter in-competence and weakness are the most prevalent and/or important mechanisms(209). A single centre article argued that retrograde LPP could be used as an objective and potential-ly more reliable substitute to pad weight to objectify and stratify UI in PRRP-I patients(210), but also found that cystometric capacity and DO during cystometry up to normal capacity (done with an occluded urethra to prevent fluid loss when leakage at early volumes occured) were predictive of the outcome of AUS implantation.

A study evaluated the filling phase of men with PPI and used a penile cuff to prevent early leakage as a way of mimicking the situation after surgery for PPI-UI. DO was observed as well as reduced compliance, affecting outcomes (149).

LUTS are common following RP or curative radiotherapy in prostate cancer patients. One quarter of those treated with RP experience biochemical failure and are subsequently of-fered salvage radiotherapy (SRT) to the prostatic bed. Long-term LUTS after surgery and SRT are common and need further elucidation. In a study to evaluate long-term UDS charac-teristics in patients treated with SRT, several UDS parameters were affected. This indicates that SRT primarily affects bladder compliance, maximum cystometric capacity and BOO. LUTS were proven to be strongly related to UDS parameters(211).

Another study reported that UDS was performed before surgical treatment of PPI UI and that patients with DO were excluded. Regrettably no further details were given(212).

To compare the UDS in patients presenting with social continence (0-1 pads/day) after AMS800 or ZSI375 insertion, vesical pressure (pves), FUL, maximum urethral pressure (MUP), MUCP and Qmax were recorded with standard urodynamic equipment. 27 male patients with AMS800 and 28 with ZSI375 were recruited. Results of UDS were reported to be similar for both types of AUS(213).

To evaluate the effect of radiation on male SUI and to assess the relative value of preopera-tive UDS in radiated vs nonradiated men with SUI, a retrospective chart review was conduct-ed of all male patients with SUI who underwent UDS testing. The impact of UDS findings on treatment decision making was assessed. Radiation therapy appears to increase the likeli-hood of bladder dysfunction in male patients with SUI. The UDS findings did, however not alter the plan to treat SUI in any patients in this series, and consequently the role of UDS (and reported history of radiation) before SUI surgery in male patients was not examined in the reported practice(214).

5.3. Recommendations 2021 (grade C)

- The committee recommends that UDS should considered in cases where it will help in diagnosing or counselling and follow-up when RRP UI has not spontaneously im-proved, and conservative measures have failed.
- The committee suggests to perform UDS in patients with PRRP-I with an outlet closed by penile clamp or cuff if early fill volume leakage occurs, to better evaluate filling properties until capacity
- The committee recommends UDS for patients with post RRP UI when co-existing dysfunctions of the LUT (neo bladder neck BOO, valsalva voiding, significantly re-duced bladder compliance and/or DO) cannot be excluded on the basis of clinical history, e.g. radiotherapy, signs and/or non-invasive UDS and symptoms.

6. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

6.1. Conclusion and recommendations 2016

Case series indicate that it is possible to monitor patients with neurogenic lower urinary tract dysfunction (NLUTD), without (congenital) anatomic abnormalities of the LUT (especially adult age spinal cord injury (SCI)) with cystometry and ultrasound of the UUT. Uncontrolled cohort studies indicate that non-invasive tests are less sensitive to relevant abnormalities in comparison with UDS and investigators have concluded that UDS is necessary when LUTS arise in patients with neurological abnormalities. The optimal frequency and techniques of follow-up UDS in patients with NLUTD are still debated. Furthermore, there is no conclusive evidence on the predictive value of ice-water testing or ambulatory UDS towards better di-agnosis or the outcome of treatment.

Nocturia, nocturnal enuresis or LUTS may be the first, or an early, sign of Parkinsonism in elderly male patients, and may occur also in other neurological conditions (e.g. multiple sclerosis (MS),). UDS is of value to establish a diagnosis of the LUT dysfunction(s) re-sponsible for the symptoms. LUTD in male patients with Parkinsonism (or other neurological conditions) can be the result of DO, benign prostatic BOO, dyssynergic voiding, DU or elevated PVR or any combination thereof. DO and DU, with or without urethral sphincter (pseudo-) dyssynergia, are commonly found in male patients with Parkinson's disease.

6.2. Recommendations 2016

- This committee recommends that UDS evaluation should be considered at the time of first evaluation of patients with signs and symptoms or with suspicion of NLUTD and that VUDS is considered when anatomical abnormalities with the NLUTD are not unlikely.
- The committee recommends that the frequency of testing and the techniques ap-plied in the follow up of patients with NLUTD be critically analysed and optimised and continues to recommend that guideline recommendations on the basis of those analyses should be developed.
- The committee recommends that UDS in patients with NLUTD is done with special attention to the specific needs of the patients. It is highly preferable that all profes-sionals involved are specifically trained for that purpose.

6.3. New evidence 2021

NLUTD is very common in patients with multiple sclerosis, and it might jeopardize renal function and thereby increase mortality. Although there are well-known urodynamic risk fac-tors for UUT damage, no clinical predictive parameters are available.

High Expanded Disability Status Scale (EDSS) score is significantly associated with urody-namic risk factors for UUT damage and allows a risk-dependent stratification in daily neuro-logical clinical practice to identify MS patients requiring further neurourological assessment and treatment(215).

Neurogenic bladder dysfunction after SCI is generally irreversible. One proof of principle animal study and a phase 2 human study have suggested that initiation of SNM immediately following SCI can prevent neurogenic DO and preserve bladder capacity and compliance(216,217). A multicenter randomized clinical trial was designed to evaluate the effectiveness of early SNM after acute SCI, but currently no data have been reported(218). In a prospective cohort study in 54 patients with NLUTD due to acute spinal cord injury who underwent urodynamic investigation within the first 40 days after injury at a single university spinal cord injury centre, an acontractile detrusor was observed in only 20 of the 54 patients (37%) but unfavourable urodynamic parameters in 34 (63%). The authors found DO in 32 patients, detrusor sphincter dyssynergia in 25, maximum storage detrusor pressure greater than 40 cmH2O in 17, vesicoureteral reflux in 3 and low bladder compliance (less than 20 ml/cmH2O) in 1. More than one unfavourable urodynamic parameter per patient was possi-ble. In contrast to the common notion of an acontractile detrusor during acute spinal cord injury (spinal shock phase), almost two-thirds of the studied patients showed unfavourable urodynamic parameters and "active" detrusors within the first 40 days after spinal cord inju-ry. Considering that early treatment of NLUTD in patients with acute spinal cord injury might improve the long-term urological outcome, the authors recommended that urodynamic in-vestigation should be performed promptly to optimize patient tailored therapy (219).

Another study assessed which urodynamic parameters are associated with renal deteriora-tion over a median of 41 years follow-up after traumatic spinal cord injury. Renal deteriora-tion was diagnosed as split renal function ≤30% in one kidney or relative glomerular filtration rate ≤51% of that expected according to age and gender. Detrusor function, presence of detrusor sphincter dyssynergia, maximum detrusor pressure, post-void residual volume, and cystometric bladder capacity were obtained. In patients with DO, a DO/cystometry ratio was calculated using duration of detrusor contraction(s) during filling cystometry divided by total duration of

filling cystometry. A total of 73 patients were included in the study, and the me-dian follow-up time was 41 years after injury (range 24-56). Sixty-four patients (88%) used reflex triggering or bladder expression as bladder emptying method for the longest period after injury. During follow-up 60% changed to clean intermittent catheterization. The majority of the patients (68%) had neurogenic DO. In 35 patients, a DO/cystometry ratio could be calculated and a ratio > 0.33 was significantly associated with renal deterioration ($p < 0.02$). No significant association was found between maximum detrusor pressure or other urody-namic parameters and renal deterioration. The authors concluded that the duration of DO longer than one third of the duration of cystometry is associated with renal deterioration after spinal cord injury(220).

6.4. Recommendations 2021 (grade C)

- This committee recommends that UDS evaluation should be considered at the time of first evaluation of patients with signs and symptoms, or with suspicion of NLUTD and that VUDS is considered when anatomical abnormalities with the NLUTD are not unlikely.
- The committee recommends that in SCI patients, VUDS should be considered at the latest after 6 weeks after trauma.
- The committee recommends that the frequency of testing and the techniques ap-plied in the follow-up of patients with NLUTD be critically analysed and optimised and continues to recommend that guideline recommendations on the basis of those analyses should be developed.
- The committee recommends that UDS in patients with NLUTD is done with special attention to the specific needs of the patients. It is highly preferable that all profes-sionals involved are specifically trained for that purpose.

VI. PATIENT EVALUATION: CHILDREN

1. INTRODUCTION

1.1. Conclusions and Recommendations 2016

ICI2016 concluded that retrospective and prospective studies have shown that symptoms and signs (of UI) do not adequately represent LUTD and UDS diagnosis in children. This is observed in healthy children with LUT signs and symptoms, in children with myelomeningo-coele (MMC), anorectal malformation (ARM), spinal cord injury (SCI), spinal cord tethering, cerebral palsy/spasticity, sacro-coccygeal teratoma, and in children with urethral valves, vesico-ureteral reflux (VUR), bladder exstrophy, nocturnal enuresis (NE) and OAB-S.

Retrospective and prospective studies have shown that a UDS-diagnosis is relevant in chil-dren with the above-mentioned pathologies, but also that initial conservative management of (otherwise healthy) children with UI is possible without UDS-diagnosis. No good evidence existed in 2016 to support optimal selection of VUDS (versus standard UDS) in most situa-tions of children with UI, apart from MMC and VUR or to support individual decisions re-garding UDS or VUDS for follow-up in children.

The ICI2016 committee recommended that non-invasive UDS including voiding diary and flowmetry with PVR measurement, is utilized to evaluate the voiding function prior to any invasive procedures. Flowmetry plus EMG is recommended in the ICS- Children's Good Urodynamic Practice(221). Furthermore, ultrasonography of the urinary tract is considered a useful tool with acceptable reproducibility for initial assessment when evaluating LUTS in children. Ultrasound LUT-studies in children include not only PVR and bladder volume but also bladder wall thickness (BWT). Ultrasound has been used to evaluatie both morphology of the LUT, functional change of bladder wall, as well as pelvic floor muscle function.

The committee recommended to consider VUDS when relevant anatomical abnormalities are expected and recommended the need to improve pelvic patch surface-EMG technique, standards, and evaluation/reporting. The committee recommended that patients with NLUTD receive (V)UDS when it is considered possible to initiate treatment as a consequence of the diagnosis based on the (V)UDS and when first line management has failed. They also rec-ommended ambulatory UDS in patients with relevant neurological abnormalities.

The committee recommended the International Children Continence Society (2015) guideline on the use of UDS in children, summarized the available evidence and expert-based knowledge, and provided expert recommendations, and presented in 2016 a specific stand-ardized expert report for VUDS. A meticulous and complete history, physical examination including a clinical neurological one and assessment by voiding diaries, are essential.

1.2. New Evidence 2021

During invasive UDS, a pressure recording catheter needs to be inserted into the bladder either transurethrally or suprapubically (222). The indications for UDS evaluation in children include neurological, anatomical and/or functional abnormalities,with the types of studies to be performed being based on the presumed underlying patho(physio)logical conditions rather than on the presenting symptoms. Retrospective and prospective studies have shown that UDS has been popularly used in the evaluation of paediatric UI, not only in the diagno-sis, but also in the follow-up of the treatment response, in making treatment protocols, pre-dicting disease evolution, and assessing the effect of treatment. In addition, not only the literature on children with UI induced by NLUTD, MMC, ARM, SCI, spinal cord tethering, cer-ebral palsy / spasticity, sacro-coccygeal teratoma, urethral valves, VUR or bladder exstro-phy, but also that induced by OAB-S and NE increased.

Non-invasive UDS are more acceptable and applicable to children. It is able to identify clini-cal conditions that will benefit from further invasive UDS.It has been recommended to eval-uate all children with UI by UDS. These include voiding diary, flowmetry with PVR measure-ment and/or EMG, andupper tract ultrasound evaluation. Remote or Internet-based voiding diaries have been recommended to make it an easier and more precise recording of chil-dren's voiding pattern (223). A consensus has been reached that non-invasive UDS (uroflowmetry ± simultaneous EMG, assessment of PVR, renal/bladder ultrasound, and pel-vic ultrasound) when used appropriately can provide valuable information to facilitate deci-sion making during the evaluation of children with LUTD. The exact role and reproducibility of uroflowmetry is still under consideration, but flows plus PVR measurement and/or pelvic floor EMGis recommended (224). To exclude NLUTD in infants less than 6-months-old, sa-cral spinal ultrasound or anteroposterior lumbosacral X-ray or MRI are recommended to find (occult) spinal dysraphism or spinal bifida occult.

It has been recommended that ultrasonography is a useful tool with acceptable reproducibil-ity for initial and follow up assessment of LUTS in children before and after treatment. Ultra-sound LUT-stud-

ies in children not only include PVR and bladder volume but also bladder wall thickness(BWT) (225,226). They are not limited to a morphological analysis of the LUT, but also to dynamic analysis, with evaluation of the full and of the empty bladder (227), and evaluation of the pelvic floor muscles movements and muscular endurance(228).

However, more research in this area in children are scarce although recently similar studies in adults have been reported which suggested a significant relationship between the pre-treatment BWT and the success of urinary incontinence treatment. The mean BWT may be used as a benchmark in assessing the responsiveness to treatment of urinary incontinence types (229). For validating BWT ultrasound measurements, a study on cadaveric bladder wall caliper measurements has been performed and found that high-frequency ultrasound is more accurate for assessing BWT (230). Lack of standardization of BWT measurements remains a potential confounding factor. BWT measurements of the ventral and dorsal walls in children with spina bifida at pre-defined points during video-UDS showed a lack of corre-lation with pressures suggesting that such measurements might not be a suitable substitute (231).

The aim of invasive UDS in children is to provide objective knowledge about LUT function, to identify the underlying causes for voiding symptoms, and to quantify related pathophys-iological processes. It also provides understanding to the caregiver and to the patient (and her or his parents). It includes filling cystometry and pressure/flow study (PFS). It is indicat-ed when history and clinical examination raises a suspicion of either anatomical and/or NLUTD involving primarily the storage phase (filling cystometry) or the voiding phase (PFS), or when there is a question that cannot be answered by less invasive testing (222,232). VUDS give additional information on morphologic changes of LUT and whether DSD exist or not.

Invasive UDS is used to establish as clearly as possible a baseline, so that changes result-ing from treatment and/or growth can be assessed (indicating that the investigation may need to be repeated), and to provide some guidelines for the choice of treatment (although results of UDS may not necessarily be the deciding factor) (232). Paediatric UDS show many differences from those in adults. However, a validated guideline on the use of UDS in children is still lacking although educational modules and terminology of ICCS have been published (222,232–235). Furthermore, a specific standardized expert report for VUDS was presented in 2016 (236) as well as a review on urodynamic application on children with cere-bral palsy (237).

The reliability and variability of measurements in children can be influenced by developmen-tal effects as well as by the unfamiliar clinical environment. Alternatively, ambulatory UDS is less influenced by this because it is measured over a prolonged period and is conducted in a child-friendly environment. Recently, an analysis showed that more diverse voiding pat-terns were identified in ambulatory UDS compared with conventional in office UDS, with a lack of consistency in identified voiding patterns in both methods. Therefore, the urodynam-ic findings in children may have to be analysed in more detail, taking the variations into ac-count (238,239).

The parameters used in UDS in children are far from established. Children's growth and de-velopment make it difficult to have an identical standard procedure and interpretation of the UDS evaluation and results(240) compared to adults. More research is needed to establish the normal criteria for UDS in the different age groups. It's known that voiding symptoms and signs do not adequately represent LUT dysfunction in children especially in infants who are still in the developmental stage of voiding control (240). There are specific challenges in making a diagnosis of detrusor sphincter dyssynergia (DSD) due to the lack of reliability of patch EMG recording and difficulty in differentiating an involuntary phasic contraction from a volitional void (241).

UI in children is relatively more often seen (compared to adults) in combination with other LUT (or lower bowel or pelvic floor) dysfunctions. On the other hand, UI and the develop-ment of 'full-grown' LUT function are the result of a normal maturation process that can be delayed in some and may 'spontaneously cure' (or 'resolve') without requiring medical inter-vention. UDS is used to establish as clearly as possible the baseline situation where needed, so that changes resulting from treatment and/or growth can be assessed, and some guid-ance is obtained in the choice of treatment.

2. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

More than 85% of NLUTD in children is due to spinal dysraphism which is an incomplete fusion of the spine during embryologic development and encompasses a spectrum of con-genital anomalies that can affect the spinal cord, nerve roots, and vertebral column. These anomalies can be categorized into open and closed spinal dysraphism. Open spinal dysra-phism is also known as spina bifida aperta. The neural tissue in these lesions is exposed, Myelodysplasia is mainly seen in open spinal dysraphism (meningoceles and myelomenin-goceles. Closed spinal dysraphism is also referred to as occult spinal dysraphism (OSD)(242). Urological abnormalities, prenatally and congenitally induced by these condi-tions are variable with regard to anatomy and dysfunction and, often need evaluation with UDS before treatment and later during follow up.

2.1. Myelodysplasia

2.1.1. ICI2016 Conclusions and Recommendations

The bladder volume at which leaking occurs should be noted, as it may be important for a particular patient to organize their clean intermittent self-catheterization (CIC) regimen (243).

Retrospective and prospective studies have shown that the UDS diagnosis of (neurogenic) DO and/or reduced detrusor compliance in patients with myelodysplasia or (occult) spinal dysraphism is not predictable based on clinical signs or symptoms. Both initial and follow-up evaluation often reveals clinically relevant results with regard to management and surgical or medical treatment. Evidence for the optimal interval and frequency of (V)UDS follow-up in patients with children with NLUTD is lacking.

VUDS testing is preferable as compared to conventional UDS but the exact advantage of repeated VUDS in the follow-up of children with known (morphological or anatomical) ab-normalities is not substantiated. Various studies have shown that LUT function in children with myelodysplasia or (occult) spinal dysraphism may change over time (and with physical growth).

Comprehensive UDS is advised in all symptomatic patients with myelodysplasia or (occult) spinal dysraphism throughout the entire life on a regular basis from earliest childhood. UDS should also be considered when changes in signs and symptoms occur in the lower limbs, pelvis and/or urinary tract or when significant (surgical or medical) treatments have been instigated. The advantages and disadvantages of the addition of video (x-ray/fluoroscopy) to UDS

should be considered in children with myelodysplasia or (occult) spinal dysraphism on an individual basis. The timing and technique of UDS in patients with myelodysplasia or (occult) spinal dysraphism must be selected on an individual basis. To help identify children at risk for subsequent urinary tract deterioration or a changing neurological picture, initial UDS very early in the neonatal period (e.g. starting from 3 months age), should be consid-ered for children with myelodysplasia or (occult) spinal dysraphism. Anorectal function or dysfunction is recommended to be simultaneously evaluated with LUT function in children with myelodysplasia or (occult) spinal dysraphism (see also the chapter on faecal inconti-nence in the book). The committee recommended research to determine the optimal interval and frequency of follow-up UDS in children with NLUTD.

2.1.2. Discussion and New Evidence 2021

Many retrospective and prospective studies have recommended that UDS should be used to evaluate all cases with myelodysplasia, before and after treatment during follow up. What types of UDS (conventional UDS or VUDS) should be chosen depends on severity of cas-es and the underlying mechanism the clinician would like to evaluate. The parameters ob-tained from UDS are helpful in the decision of treatment protocol. It is recommended to follow classification based on UDS to make a treatment protocol in patients with UI(244). After initial invasive urodynamic evaluation, non-invasive UDS are recommended for the follow up in those cases with symptoms but no significant increase in PVR and normal UUT ultrasound findings. Otherwise, VUDS should be considered also in the follow up.

To identify the risk of subsequent UUT deterioration, initial UDS in the neonatal period had been recommended for children with myelodysplasia(245). This concept has been confirmed by ICCS recommendations and EAU guideline(244) for congenital neuropathic bladder(246).

The updated EAU/ESPU guideline advocates more proactive use of UDS to evaluate chil-dren with myelodysplasia. For those with intrauterine closure of the defect, UDS are recom-mended to be performed before the patient leaves the hospital; those with closure after birth UDS should be done within the next 3 months. Close follow-up including ultrasound, bladder diary, urinalysis, and UDS are necessary within the first 6 years and after that, time intervals can be prolonged, depending on the individual risk and clinical course. In all other children with the suspicion of NLUTD due to various conditions such as tethered cord, in-flammation, tumours, trauma, or other reasons as well as those with anorectal malformations, UDS and preferable VUDS, should be carried out as soon as there is a suspicion of NLUTD. Conservative treatment should be started soon after confirmation of the diagnosis of neu-rogenic bladder. If the UDS confirmed DO, oxybutynin (dosage 0.2-0.4 mg/kg weight per day) should be applied(244).

Based on expert opinion, VUDS testing is preferable above conventional UDS because the anatomy and morphology can be evaluated simultaneously. The significance of bladder morphological changes was studied in 81 children with myelomeningocele at video-UDS. The authors calculated the ratio of the maximum height of the bladder to the maximum width at maximum cystometric capacity. Children categorized as high risk (those with maximum detrusor pressure of ≥40cm H20) were noted to have a higher ratio (1.50 vs 1.37, p=0.004). A cut-off of 1.40 was associated with sensitivity of 87% and specificity of 57% for predict-ing high risk findings(247).

Various studies have shown that LUT function in children with myelodysplasia may change over time and with physical growth. No studies have been published that precisely deter-mine the optimal timing and frequency for follow up myelodysplasia. UDS and the presence of neurological impairment were considered to have had crucial roles in determining the optimal timing of surgery in patients with lipomeningocele, and in diagnosing the onset of tethered cord(248).

Because renal transplantation in patients with myelodysplasia and persistent LUT dysfunc-tion carries increased (post –renal) risks for the grafted kidney, the existence or creation (augmentation cystoplasty) of a UDS confirmed low pressure bladder with adequate cysto-metric capacity before transplantation is deemed necessary(249).

UUT deterioration (UUTD) is a life-threatening complication of NLUTD. Early identification of risk factors for UUTD and institution of remedial measures may probably prevent UUTD. A cross-sectional, observational study over 2 years including 30 children found that delayed presentation with palpable bladder lump, recurrent UTI, increased BWT, bilateral VUR, in-creased PVR, and DLPP > 40 cmH2O were identified as potential risk factors for UUTD. This study highlights the potential of BWT as a predictor of UTD in neurogenic bladder. A limita-tion of this study is the small number of patients and heterogeneous clinical diagnosis(250). Another study of 637 children with myelodysplasia found that lack of bladder sensations, long duration of symptoms, reduced maximum cystometric capacity, reduced compliance and elevated residuals were independent risk factors for UUTD(251).

Currently due to the good responses towards early combination of drugs and/or intermittent self-catheterization, bladder augmentation is performed less frequently. However, selected patients with spinal dysraphism and children with congenital malformations like bladder ex-strophy and resulting small bladder capacity might require bladder augmentation(252). UDS can play a key role in decision of bladder augmentation and later follow up the treatment results, but the exact UDS parameters as well as frequency and interval of the UDS remains undefined. Bladder augmentation is performed to relieve or prevent UUTD and/or VUR (usu-ally without necessity of simultaneous anti-reflux repair) when conservative treatment op-tions (CIC, anticholinergic drugs and botulinum injections) are not sufficient(253). However, the studies in the adult population are controversial. A recent retrospective study in 160 adult patients indicates that ureteral reimplantation concomitant with augmentation cysto-plasty may be beneficial in patients with low pressure or high-grade vesicoureteral reflux and/or severe upper urinary tract dilatation(254). In another study, 29 patients with a poorly compliant bladder associated with VUR had undergone bladder augmentation with no cor-rection of the existing reflux. VUDS showed a significant improvement of bladder capacity, diminution of intravesical pressure, and resolution of reflux after bladder augmentation in more than 90% of patients during 2 years follow up. Thus, in the latter study, ureteral reim-plantation was found not to be necessary when augmentation enterocystoplasty was rec-ommended for patients with high-pressure, low-compliant bladder and VUR(255). Therefore, whether simultaneous reimplantation in patients with augmentation is mandatory needs to be further investigated in the future. Expert reviews have recommended follow up of the pa-tients with UDS, but interval and frequency of follow up UDS after operation are not precise-ly established.

UDS have been used to follow children with NLUTD who underwent bladder outlet enhance-ment surgery (bladder neck myofascial sling or bladder neck reconstruction using the Young-Dees-Ledbetter technique) without augmentation cystoplasty. Two recent stud-

ies showed the limited value of this approach with substantial risk for needing follow up sal-vage therapy: 40% children needed augmentation cystoplasty in follow up with the devel-opment of hydronephrosis and reflux in one study(256) while 53% needed salvage botuli-num toxin injection or augmentation at a mean follow up of 5 years in the other(257).

The efficacy of intradetrusor injections of botulinum toxin has been confirmed in patients with myelomeningocele at recent few years. A systematic review on the efficacy of intra-detrusor injections of Botulinum Toxin A (BTX-A) in spina bifida patients with neurogenic DO refractory to antimuscarinics included 12 studies covering 293, all <18 years old. There were no randomized studies comparing BTX-A versus placebo and most studies had no control group. Most studies reported a clinical and urodynamic improvement with resolution of in-continence in 32-100% of patients, a decrease in maximum detrusor pressure from 32 to 54%, an increase of maximum cystometric capacity from 27 to 162%, and an improvement in bladder compliance of 28-176%. Two studies suggested lower efficacy in patients with low compliance bladder compared to those with isolated DO. Obviously, intra-detrusor in-jections of BTX-A could be effective in children with spina bifida but this assumption is not supported by high level of evidence studies(258).

A study in 19 children showed that repeated botulinum toxin injections are a safe treatment modality and can be offered as an effective alternative, instead of more invasive surgery, in children with neurogenic DO due to myelodysplasia. The detrusor compliance and the max-imum detrusor pressure significantly improved following injections(259). Another study in 31 children with myelodysplasia and all had VUR (22 unilateral), botox injection resulted in in-creased bladder capacity, enhanced continence, and prevented VUR. Although above re-sults are promising, a larger group of long-term prospective studies are warranted to inves-tigate this method of treatment(260).

The efficacy of mirabegron has (off label) been studied by UDS in 37 children (mean age 12.7y) with NLUTD (31 myelomeningocele). Patients were studied in two groups, one which was refractory to antimuscarinics alone (Group A) and another was refractory to abobotuli-num toxin A (Group B). Treatment with mirabegron 25mg resulted in significant improvement in maximum cystometric capacity (increase of 136ml and 133ml respectively, both $p<0.001$) and a fall in end fill pressure (reduction of 10 and 19 cm H20 respecitvely, both $p<0.001$) in both groups(261). (Long term) Results considering effects of this management on blood-pressure cardiac function or other side-effects are at present not available. Especially also in this group of patients renal function should closely be monitored (and included in the indication for this treatment).

A single centre study on 39 patients with myelodysplasia, classifying patients according to detrusor and sphincter behaviour, found that the early evaluation and treatment of patients is essential for decreasing renal impairment, reducing the need for surgery and improving the continence options(262).

Tarcan et al investigated more accurate cut-off levels for the detrusor leak point pressure (DLPP) in terms of UUT protection in a cohort of children with myelodysplasia. They found that more than half of the children with myelodysplasia had normal UUT function even with a DLPP of 40 cm H2 O and over. Therefore, DLPP, should not be the sole decision-making parameter to rely for more invasive therapies in children with myelodysplasia. On the other hand, a DLPP cut-off value of 20 cm H2 O showed a higher sensitivity to predict UUTD instead of 40 cmH2O in patients with myelodysplasia (263).

An expert review discussed 9 papers addressing routine spine ultrasounds for children with sacral dimples and showed that 3.4% of the 5166 patients had abnormal spine ultrasounds, compared with the 4.8% reported by another study for children without sacral dimples. The authors concluded that sacral dimples do not predict underlying spinal cord malformations, and spine ultrasounds should not be performed for neonates with simple sacral dimples(264). Whether BWT is useful in predict the UUTD is still controversial and far from established. In 2015, Kim et al(265) found that even if bladder wall thickness is measured at specifically defined bladder volumes, it cannot predict video-urodynamic findings other than bladder trabeculation in children with spina bifida. A total of 23 males and 30 females with spina bifida (median age 7.8 years) underwent measurement of bladder wall thickness at maximum cystometric capacity. In a later editorial comment, it was suggested that specific aspects of the study methodology and population might have contributed to a lack of cor-relation with high-risk urodynamic findings. The application of non-invasive modalities to LUT assessment of NLUTD remains a promising and relevant area of future research to pre-vent progression to end stage LUT changes for all individuals with spina bifida(266).

Approximately 90% of children born with MMC will have a preserved UUT at birth. Over time, in the absence of proactive urological care, DO, reduced bladder compliance, detrusor-sphincter dyssynergia and/or high LPP will result in UUT and/or LUT deterioration. The main identified UDS risk factors are: decreased bladder compliance of <9 mL/cmH2O, increased DLPP of >40 cmH2O and presence of an acontractile detrusor(267). Bladder wall thickness measurement was also found as a predictor of LUT impairment. When conservative treat-ment such as CIC, anticholinergic drugs and botox injections are not sufficient, bladder augmentation is performed to relieve or prevent UUTD and/or VUR, usually without necessi-ty of simultaneous anti-reflux repair. UDS follow-up should be used to evaluate the effect of this treatment.

Expert reviews have recommended periodic UDS when new onset VUR, hydronephrosis, or UI develops in children with myelodysplasia. However, the interval and frequency of follow up UDS are not precisely established. UDS and the presence of neurological impairment were considered to have had crucial roles in determining the optimal timing of surgery in patients with lipomeningocele. Also in diagnosing the onset of tethered cord, UDS were more relevant towards the outcome of neurosurgical interventions (untethering) than pelvic floor muscle needle EMG.

UDS have been relevant to evaluate the treatment efficacy of drugs in the long-term. Over a period of 15 years, intravesical oxybutynin treatment showed adequate suppression of de-trusor activity, increase in cystometric capacity, and mean end-filling pressure had returned to the safe zone(245).

Adam et al retrospectively reviewed patients born with myelodysplasiathat received follow up before 1 year old and treated with clean intermittent catheterization (CIC), anticholinergics, surgical interventions according to the results of ultrasound and VUDS. The study reported that the initial high incidence of hydronephrosis resolved in the first decade of life. The 8-11-year incidence of kidney disease and upper tract changes was low(268).

2.2. Occult spinal dysraphism

2.2.1. New evidence

Most common pathologies of occult spinal dysraphism (OSD) are isolated vertebral defects which arethe least severe forms. Others include neuroenteric cysts, split notochord syn-drome, split spinal cord malformation, sacral meningeal cysts, spinal lipomas, caudal re-gression syndrome, dorsal dermal sinus tracts and cysts, and tethered cord syndrome. It is recommended that all OSD with LUTS should be evaluated by conventional UDS. If UUT morphological changes are found by ultrasound, VUDS should be considered.

As awareness and frequency of tethered spinal cord (TSC) has increased with magnetic resonance imaging (MRI), variability exists in its evaluation and management. Tethered spi-nal cord syndrome (TSCS) is a clinical entity that presents with neurological, urological, and/or orthopaedic symptoms caused by primary or secondary tethering of the spinal cord, which may result in ischemic damage of the neural tissue and symptom development. There is relative agreement that patients with symptomaticTSC will require surgical intervention. However, it is still debatable as to how to approach asymptomatic patients with primary TSC. A study in 22 cases with TSC (8 of them were asymptomatic) showed that spinal cord un-tethering is beneficial in terms of clinical and UDS outcomes with statistically significant improvement in the median percentage of change of actual bladder capacity, median in-travesical pressure for patients with pre-operative pressure ≥40 cmH2O at total cystometric bladder capacity, and median bladder compliance at 75% bladder capacity (269).

The International Children's Continence Society (ICCS) published level I data and summa-rized the current recommendations for diagnosis and treatment of OSD. It is suggested that infants with classic cutaneous markers of OSD, with progressive neurologic, skeletal, and/or urologic findings, present no diagnostic or therapeutic dilemma: they routinely undergo MRI and spinal cord untethering (SCU). Conversely, in asymptomatic patients or those with fixed, minor abnormalities, the risk profile of these OSD cohorts should be carefully considered before SCU is performed. Irrespective of whether or not SCU is performed, patients at risk for progression should be followed carefully throughout childhood and adolescence by a multidisciplinary team (270).

Tarcan et al investigated the role of magnetic resonance imaging (MRI) in detecting OSD in children with LUTD and a normal neurological examination in a cohort of children over 5 years of age who did not respond to an initial treatment of 6 months (271). A spinal MRI was performed in 61 children with ongoing LUTS or UTI. Nineteen of 61 children (31%) had cuta-neous stigmas. MRI detected spinal abnormality in 2/42 children with a normal sacral exami-nation in comparison to 7/19 children with an abnormal sacral finding (Chi-squared test, $P < 0.005$). The sensitivity and specificity of an abnormal sacral finding in predicting MRI ab-normality were 0.76 and 0.77, respectively. Urodynamic parameters did not predict an ab-normal spinal MRI. The authors concluded that abnormal sacral findings, but not urodynamic studies, were strong predictors of OSD. A normal sacral examination did not rule out OSD(271).

It has been reported that UDS before neurosurgical intervention is able to identify LUTD in clinically silent cases and also to identify deterioration in these patients(272). However, an-other study showed that pre and post untethering UDS did not predict continence status(273), but UDS and prone MRI were considered to be the best tools for screening those patients at risk of symptomatic retethering(274). The utility of UDS in preoperative work-up, monitoring for retethering, and long-term urologic follow-up is confirmed but re-quires further examination.

Lipomyelomeningocele (LMM) may present with no obvious functional concerns. Indications for and timing of tethered cord release in LMM are therefore controversial. Yerkes, et al performed a retrospective study that identified 143 patients from the multidisciplinary clinic who underwent tethered cord release for LMM between 1995 and 2010. Fifty-six patients were studied. Median age at tethered cord release was 4.4 months (range 1.0-224.0) with a median follow-up of 10.7 years (range 1.3-19.1); In this series of primary tethered cord re-lease for LMM, 93% of patients were urologically asymptomatic before tethered cord re-lease, and prospects for continence were excellent. Families can anticipate 23% likelihood of CIC, which is considerably less than in meningomyelocele, but long-term urologic follow-up is still strongly recommended. Clear predictors for continence after tethered cord release will require additional long-term patient outcomes(275).

A total of 130 expectantly managed infants/young children with spinal dysraphism and initial DMSA and UDS before age 2 were reviewed. They found that VUR, bladder trabeculations, end-fill pressure (EFP) ≥ 40 cm H20, initial volume (IV) drained at UDS catheter placement ≥50% of EBC, and detrusor pressure at initial volume (DPIV) >10 cmH2O were associated with subsequent DMSA abnormalities managed expectantly. Many of these parameters were associated with febrile UTI and early CIC. The combination of trabeculations and/or VUR outperformed other UDS parameters in identifying those high and low-risk for adverse uro-logic outcomes. Routine DMSA scan may have limited utility in patients with a non-trabeculated bladder without VUR, as none developed an abnormal DMSA. Most (71%) abnormal DMSAs were in patients with trabeculations and/or VUR following a febrile UTI. Given these findings and that incidence of febrile UTI may be lower in those with trabecula-tions while on CIC, patients with trabeculations and/or VUR should be managed aggressive-ly to protect kidneys (276).

2.2.2. Conclusions (Level 2/3)

- Retrospective and prospective studies have confirmed that in patients with myelodyspla-sia or (occult) spinal dysraphism UDS play a unique role in detecting DO and/or reduced bladder compliance, which is not predictable on the basis of clinical signs or symptoms; also, UDS both initial as well as in the follow-up reveals clinically relevant results with regard to management and surgical or medical treatment.
- Repeated routine VUDS as opposed to non-video UDS in the follow-up of children with known (morphological or anatomical) abnormality is not substantiated. Exact timing of re-peat UDS (and in select cases VUDS when clinically indicated) in children with NLUTD are currently at the discretion of the clinician as no studies have been published that help to determine the optimum of timing and frequency of UDS follow-up. This should be guided by the necessary to know how UDS parameters that might affect decision on changing treatment.
- Based on expert opinion, regular non-invasive UDS is encouraged to be used at follow up whenever possible.
- Various studies have shown that LUT function in children with myelodysplasia or (occult) spinal dysraphism may change over time (and physical growth) (Level of Evidence: 3). Therefore, invasive UDS should be performed every year in symptomatic patients with MMC, non-invasive UDS in asymptomatic cases is recommended.

2.2.3. Recommendations in children with myelodysplasia or (occult) spinal dysraphism

- Comprehensive UDS is advised in all patients with myelodysplasia or symptomatic (oc-cult) spinal dysraphism throughout the entire life on a regular basis from earliest childhood. Once non-invasive UDS find unexplained abnormal UDS parameters, invasive UDS or VUDS is recommended. The committee recommends research the application of non-invasive UDS in these cases and to determine the optimum of interval and frequency of follow up UDS. (Grade B/C)
- UDS should also be considered when a change in signs and symptoms, or relevant lower body half and/or urinary tract clinical or neurologic signs or symptoms arise or when signifi-cant (surgical or medical) treatment changes have been instigated. (Grade B/C)
- VUDS is recommended when non-invasive UDS indicated bladder morphology changes and UUT dilatation and timing and technique of UDS must be selected on an individual ba-sis. (Grade C)
- UDS is a validated procedure to evaluate tethered cord release results. (Grade B/C)
- To help identify children at risk for subsequent UUT deterioration, initial UDS very early in the neonatal period should be considered. (Grade C)
- Anorectal function or dysfunction evaluation simultaneously is recommended. (Grade C)
- UDS guided CIC (safe bladder capacity determined by UDS) should be considered when this procedure is used. (Grade C)

2.3. Sacral Agenesis

2.3.1. ICI2016 Conclusions and Recommendations

- UDS of LUT function in children with (partial) sacral agenesis reveals a substantial inci-dence of clinically hidden dysfunction.
- Approximately one third of children with anorectal anomalies (ARM) have MMC and/or tethered spinal cord, associated with UDS demonstrable and clinically relevant LUTD.
- Clinicians should consider UDS in all children with sacral agenesis and also after (surgery for) sacrococcygeal teratoma. (see section f – Tumours)
- Clinicians must consider that in children with LUTD, otherwise clinically silent sacral agene-sis can exist.

2.3.2. Discussion and New Evidence 2021

Sacral agenesis (SA) or caudal regression syndrome, is a congenital malformation of the spine of varying degree of severity, refers to the absence of part or all of two or more lower sacral vertebral bodies. Urinary and/or faecal incontinence usually manifests at an older age when the child fails to toilet train on time. A careful physical examination noting flattened buttocks and a short gluteal crease is pathognomonic for the diagnosis. It can be associat-ed with neurogenic bladder dysfunction that does not necessarily correlate with the level of spinal or skeletal defect.

It is recommended that symptomatic patients with SA should undergo UDS to guide LUT management. Whether asymptomatic patients with SA should undergo UDS to find bladder dysfunction in time need more investigation to clarify in the future.

A retrospective study in 43 infants and children with SA evaluated by UDS including cysto-metrogram and electromyography, and showed that in 30% neurogenic DO, but none devel-oped end-stage renal disease or required spinal cord detethering(277). However, another study concluded that symptomatic neurogenic bladder due to SA may cause renal damage in a similar way as ARM. The UDS study that children with SA had poor compliance (6.7 ml/cmH2O, interquartile range [IQR] 4-13.6 ml/cmH2O), reduced age-adjusted bladder capaci-ty (59%, IQR 22-85%), elevated end-fill pressure (22 cmH2O, IQR 11-28 cmH2O), hydro-nephrosis (88%), and reduction in eGFR (29%), all comparable to ARM or cloacal malfor-mation without the SA (22 cases) indicated(278).

Sacral agenesis also shows variable association with ARM and/or spinal cord anomalies . These studies reveal that 30 to 40% of these patients have a lesion type with DO and an intact, but dyssynergic sphincter, 25 to 50% have areflexic detrusor and denervation in the sphincter, and 15-20% may have normal LUT function(282). MRI is recommended for the evaluation of all patients that have sacral agenesis (279), and the extension of the sacral defect can serve as a prognostic factor for retethering(283). When MRI shows sacral or spi-nal cord anomalies, UDS should be considered, preceded by neurological exam and con-sidering neurophysiological (evoked potentials) testing. The authors of this and subsequent studies recommend a non-invasive evaluation for all other children, and UDS when NLUTD is suspected(284).

2.3.3. Conclusions (Level 3)

- Case series have shown that UDS of LUT function in children with (partial) sacral agenesis reveals a substantial incidence of clinically hidden dysfunction.
- Approximately one third of children with anorectal anomalies (ARM) have MMC and/or tethered spinal cord, associated with UDS demonstrable and clinically relevant LUTD.

2.3.4. Recommendations (Grade C)

- UDS should be considered in all SA children with voiding symptoms and also after (sur-gery for) sacrococcygeal teratoma. (see section f – Tumours)

2.4. Spinal Cord Injury

2.4.1. ICI2016 Conclusions and Recommendations

- Retrospective studies have shown that UDS in all children with SCI is relevant.
- Retrospective studies have shown that UDS in children with SCI results in diagnoses and treatment similar to adults with SCI.
- The committee recommends that UDS in children with SCI is planned on an individual ba-sis, but should be considered at the latest after 6 weeks after injury.

2.4.2. Discussion and New Evidence 2021

Patients with SCI have a higher risk of developing UUTD. Reduced compliance and high DLPP were major risk factors for UUTD. It had been demonstrated that the mandatory role of UDS in the management of NLUTD, standardization and better implementation of as-sessments in daily practice may further improve outcomes of neuro-urological patients in-duced by SCI based on objective measurements(285). UDS of children with SCI results in diagnosis and treatment is similar to adults with SCI. It is important to measure detrusor compliance in order to determine the potential risk for VUR and hydroureteronephrosis(286).

All studies are single centre, retrospective and use historical controls for comparison. In the presence of elevated UDS filling and voiding pressures, a 30% incidence of UUT deteriora-tion can be

expected(287), while effective voiding with pressures below 40 cm-H2O in the absence of detrusor-sphincter dyssynergia ensures a stable UUT(288). UDS monitoring has been demonstrated to be relevant in the follow up and prevention of UUT deterioration(289). In another study on 17 children aged 6 months-18 years with cervical (4), thoracic (8) and lumbar (5) SCI, all but one showed DO on first evaluation, which was changed to acontrac-tile and/or compliant detrusor pattern by medical treatment; 7 had increased cystometric capacity and 8 decreased DLPP at follow-up; only 2/17 developed minor UUT impairment(290). As in adult patients autonomic dysreflexia can occur also in children and adolescents(291).

2.4.3. Conclusion (level 2/3)

- UDS is relevant to all children with SCI, which shown an important value in diagnoses and treatment strategy making SCI children similar to that of adults.

2.4.4. Recommendations (Grade C)

- The committee recommends that UDS in children with SCI is done with special attention to the specific needs of the patients (e.g. autonomic dysreflexia and positioning). It is highly preferable that all professionals involved are specifically trained for that purpose.

2.5. Cerebral Palsy

2.5.1. ICI2016 Conclusions and Recommendations

- Some studies have shown that clinically unexpected LUTD can occur in children with cere-bral palsy (CP), especially when voiding symptoms are present.
- Observation and non-invasive testing are helpful, but UDS should be considered when UTIs or UUT dilation occurs in children with cerebral palsy.
- Clinicians should evaluate voiding in children with cerebral palsy and should consider complete UDS when dysfunction is suspected.
- UDS is to be considered in all patients with spastic cerebral palsy. Undiagnosed and un-treated patient's bladder dysfunction remains pathological and potentially dangerous and may damage the UUT.

2.5.2. Discussion and New Evidence 2021

In a recent study on the urodynamic findings in children with CP, 24 boys and 10 girls (mean age 6.6 years) diagnosed with CP who were scheduled for a dorsal rhizotomy operation were evaluated(292). The most common complaints of the study group were urinary inconti-nence (58.8%), encopresis (32.4%) and constipation (17.6%), and 41.2% of the patients were on diapers. The most common urodynamic findings were low bladder compliance (85.3%), DO (67.6%), hyposensitive bladder (52.6%), and low bladder capacity (41.2%). No patient had UUTD.

A recent systematic review on 27 studies, describing prevalence of LUTS or UDS findings, found that 55% of the patients have at least one LUTS: storage symptoms are more com-mon, and patients with pelvic floor overactivity are more prone to progress to UUT dysfunc-tion in adult life(237).

Uroflowmetry and PVR are considered first line evaluation of LUT function in children with cerebral palsy(293) UDS can direct management. Negative prognostic factors are the spas-tic subtype with quadriplegic distribution, moderate to severe functional impairment and severe cognitive impairment(237). A careful study by uroflowmetry on 57 patients showed that the symptomatic children (52%) had lower Qmax (P .013) and abnormal flow rate curves (P .022) (294), indicating non-invasive testing as a good screening tool. The vast majority of the children with cerebral palsy tend to gain normal LUT function, but often at an age that is later than expected for from DO(295). Bladder (cystometric) capacity is decreased in most children with cerebral palsy, and PVR is present in an important proportion.

It has been suggested based on expert opinion that cystometry and sphincter EMG are to be considered, but only when frequent toileting or anticholinergic therapy fails to control incontinent episodes, the child develops UTI from ineffective voiding, or when ultrasonog-raphy reveals hydronephrosis. VUDS assessment can be considered in all patients with infantile cerebral palsy as at least half of the children with spastic cerebral palsy have clini-cally silent bladder dysfunction. 100% of children had clinical improvement postoperatively (selective dorsal rhizotomy), 71% who were incontinent preoperatively became continent and none had deterioration on UDS(296,297).There is a spectrum of clinical and UDS LUT (dys)function in children with cerebral palsy; e.g. 77% void spontaneously but have UI. Chil-dren with UI have a significantly lower age related cystometric capacity(290), and also lesser than expected for age voided volumes on uroflowmetry (plus PVR)(298).

2.5.3. Conclusion (Level 3)

- Some studies have shown that clinically unexpected LUTD can occur in children with cere-bral palsy, especially when voiding symptoms are present.
- Observation and non-invasive testing are helpful, but UDS should be considered when UTIs or UUT dilation occurs in children with cerebral palsy.

2.5.4. Recommendations (Grade C)

- Clinicians should evaluate voiding in children with cerebral palsy and should consider complete UDS when dysfunction is suspected.
- UDS is to be considered in all patients with spastic cerebral palsy. Undiagnosed and un-treated patient's bladder dysfunction remains pathological and potentially dangerous, and may damage the UUT.

2.6. Tumours

2.6.1. ICI2013 Conclusions and Recommendations

According to ICI2016, it was shown in single centre cohorts that UDS testing is relevant after resection of a sacrococcygeal teratoma. A study showed that all children with central nerv-ous system tumours can have LUTD regardless of the location of the tumour. LUTD exists after sacrococcygeal teratoma resection and recently again it was proposed, on the basis of a single centre cohort, that UDS is necessary for those children(299,300). A recent study showed that children with central nervous tumours can have UDS abnormalities, whether the tumour is in the spinal cord or not. A single centre and selected cohort study concluded that a child with a central nervous system tumour needed urological investigation including UDS regardless of tumour location(301). A controlled cohort study of 17 patients with sacrococ-cygeal teratoma and 85 healthy control patients shown that uncontrolled voiding, difficulty in bladder emptying, pyelonephritis, and constipation were more common in patients with sac-rococcygeal teratoma than in healthy children.

Dysfunctional outcome was more prevalent in children with large and immature teratomas(302).

2.6.2. Conclusion (Level 3)

- It was shown in single centre cohorts that UDS is relevant after resection of a sacrococ-cygeal teratoma.
- A study showed that all children with central nervous system tumours can have LUTD re-gardless of the location of the tumour.

Recommendations (Grade C)

- It is recommended that UDS should be considered before and after resection of sacro-coccygeal teratoma and central nervous system tumours.

3. ANORECTAL MALFORMATION AND PERSISTENT CLOACAL ANOMALIES

3.1. ICI 2016 Conclusions and Recommendations

Various studies have shown that a significant proportion of children with anorectal malfor-mations (ARMs) have primary or secondary LUTD, LUT innervation abnormalities or pelvic floor dysfunction. Clinicians should consider UDS in children with imperforate anus when clinical signs of LUTD exist. Clinicians should consider UDS in children where, based on an MRI, or based on clinical examination, relevant neurological abnormalities exist, before and/or after reconstructive surgery independent of (the existence of) LUTS.

3.2. Discussion and New Evidence 2021

UI and LUTD may result from iatrogenic injury or from a pre-existing congenital neurological lesion in children with ARM. With the advent of the posterior sagittal anoplasty, this compli-cation has been eliminated as a cause for subsequent UI, although bladder neck incompe-tence may be a consequence of extensive mobilization of the sigmoid colon to transfer the rectum to its final location(303). UI after definitive repair is reported as to be the result of ineffective emptying causing ‘overflow urinary incontinence’ and DU or acontractile detrusor, rather than urinary sphincter injury. Similarly, it has been reported, on the reconstruction of cloacal anomalies, that the main clinical characteristic of bladder dysfunction was a failure to empty(304,305), presumably due to iatrogenic injury from extensive dissection, which can lead to peripheral nerve damage.

In a prospective study on children with ARM, prior to, and following definitive procedure, only 9 of the 19 patients had normal UDS pre-operatively, and LUT function worsened post-operatively(306). UDS is required to evaluate LUTD in patients following repair of ARM (and cloacal anomalies). The reliability and reproducibility of findings among the various studies analysed confers an important role for VUDS as an integral part of the evaluation and man-agement of these children. Even asymptomatic children with high ARM often have an unsafe intravesical (detrusor) pressure suggesting the need for an aggressive evaluation approach for these children(307).

A retrospective cohort study showed again that children with ARMs have a high proportion of bladder dysfunction and/or genitourinary anomalies. In patients who had been treated for a recto-bladder neck fistula, the most urodynamic findings included the presence of DO in 30 (75%) patients, median leak point pressure of 56.0 cmH2O (range, 14-140), median func-tional cystometric capacity at 40 cmH2O of 125.5% age-expected capacity (range, 36-473%), and median maximum cystometric capacity of 131.0% age-expected capacity (range, 44-473%). A mildly decreased GFR or worse developed in 13 (24%) patients. Of the 52 (78%) patients who were followed by paediatric urology with a median follow-up of 30.9 months (range, 0.0-86.8), 35 (67%) were at least 4 years of age and could be assessed for continence. Continence was achieved in five (14%) patients voiding spontaneously and 15 (43%) performing CIC. Recurrent urinary tract infections (UTI) were an independent predictor of incontinence, while urethral anomalies were an independent predictor of chronic kidney disease (CKD) on multiple logistic regression analysis(308).

Spinal cord tethering screening in all patients with ARM is recommended although the preva-lence of tethered cord in these children is still unknown. A survey was performed in a large cohort of European paediatric centres, supporting tethered cord screening in all patients with ARM and conservative management of the tethered cord. However, the definition of tethered cord, screening tools, and complementary tests are controversial(309).

It has been reported that spinal MRI’s reveal a 35% incidence of distal spinal cord abnormal-ities in children with an imperforate anus(310) NLUTD occurs in 50%(279), and 40-60% of those patients who have tethered cord needed untethering(283). Evaluation of all patients with ARM using MRI is recommended and when MRI shows sacral or spinal cord anomalies, non-invasive should be done, and UDS when NLUTD is suspected(280). To detect spinal cord abnormalities in neonates, spinal ultrasound has been largely used as a screening test up in children to 5 months of age; a study on 244 ARMs showed a 100% specificity but a very low sensitivity (15%), thus stating that ultrasound is not suitable as a screening test for MMC in ARM, with MRI being necessary when symptoms occur(311). By combining the inci-dences in 3 studies it was found that the presence of an abnormal sacrum increases the likelihood of LUTD to as high as 76% (38 of 50 children)(279,312,313). When the rectum ends above the levator ani muscle there is a much greater chance of LUTD than when it ends below the pelvic floor(280) and the older the child is at the time of UDS the more likely he/she is to have abnormal LUT function(314).

Patients with cloacal anomalies have a high incidence of associated urinary tract and spinal anomalies. Although the majority of cloaca patients can achieve faecal and urinary conti-nence with the surgical reconstructive procedures performed today, many require addition-al/multiple urological procedures to achieve continence, treat bladder dysfunction and to protect renal function. One half of patients will develop renal failure, so regular and lifelong monitoring bladder function is mandatory(315–317).

A study on 466 persistent cloaca (PC) and 229 cloacal exstrophy (CE) cases found that 45.6% of CE patients have myelomeningocele. Varies of urological procedure has used to treat the LUTD in the neonatal and infantile periods, the respective rates of bladder dysfunc-tion, clean intermittent catheterization, and permanent enterostomy were 32.6, 22.5, and 7.3% in PC patients and 60.7, 28.4, and 73.8% in CE patients. The clinical outcomes of PC and CE remain unsatisfactory and the treatment guidelines is still lacking(318). Obviously, UDS should be considered to follow up LUT function before and after above procedures.

3.3. Conclusions (Level 3)

A significant proportion of children with ARM has primary or secondary LUTD or pelvic floor dysfunction. The incidence of congenital urachal, bladder, and cloacal anomalies is low, but has a high

incidence of associated anomalies most commonly in urinary tract and spinal.

3.4. Recommendations (Grade C)
- Clinicians should consider UDS in children with ARM (cloacal anomalies) when clinical signs of LUTD exist.
- Clinicians should consider UDS in children where, on the basis of an MRI, or on the basis of
- clinical examination, relevant neurological abnormalities exist, before and/or after recon-structive surgery independent of (the existence of) LUTS.
- Spinal cord tethering screening in all patients with ARM is recommended

4. ANATOMIC ABNORMALITIES OF THE URINARY TRACT

4.1. ICI2016 Conclusions and Recommendations
In children with posterior urethral valves (PUV), urethral stricture, ectopic ureterocele, VUR or with bladder exstrophy, the frequent UDS abnormalities are predominantly DO and reduced bladder compliance or large cystometric capacity with impaired filling sensation. Invasive UDS has been shown to be of help to determine when further medical or surgical manage-ment is indicated in children with these abnormalities.

The use of UDS has aided in an objective measurement of treatment success or failure for these abnormalities. Therefore, clinicians should consider complete UDS of the filling and voiding function, at least once, in children with above anatomical abnormality. UDS in chil-dren should be done with special attention to their specific needs, and with careful attention to minimize mental trauma and to ensure reproducing symptoms as much as possible. Clini-cians should consider regular uroflowmetry and PVR assessment in the follow-up and fur-ther management of children with PUV, urethral stricture ectopic ureterocoele, VUR or with bladder exstrophy, and the necessity of follow-up UDS should be decided on an individual basis and as less frequent as possible.

4.2. Discussion and New Evidence 2020
Literature available has recommended to use non-invasive tools as much as possible in conditions which are not treated with surgical correction (i.e VUR and/or valve patients); while major abnormalities (i.e. exstrophies or ARM or cloacal anomalies) need UDS evalua-tion prior to decide complex corrections. The evidence still consists of uncontrolled case series and expert opinions although many clinicians now feel its usefulness is beyond ques-tion.

4.3. Posterior Urethral Valves
UDS are not only a basic tool to understand voiding function, persistence of UI and UUT (and renal) impairment evolution, but also help in judge the results of treatment procedures in boys with PUV. In a series of UDS after valve ablation, the type of bladder function ob-served, correlates with the time elapsed from surgery; DO was the predominant pattern ini-tially(319) but changes are noted in both DO and compliance over time(320–322). Despite early valve ablation, a large proportion of boys treated for PUV have gradual detrusor ‘de-compensation’, persisting DO and/or secondary bladder neck outflow obstruction leading to obstructive voiding and finally DU or acontractility.

A retrospective study on 28 consecutive patients treated for PUV who underwent foetal intervention or postnatal surgery. Pre- and postnatal treatment modality included foetal vesico-amniotic shunt, endoscopic valve ablation, and vesicostomy. UDS showed that the mean maximum detrusor pressure was significantly lower in patients with a foetal shunt than in others (37.7 vs 73.0 cmH2O, P = .019). Bladder capacity was greater and residual urine volume was lower in the postnatal vesicostomy group than in the primary valve ablation group, but without statistical significance. Vesicostomy is more beneficial in the recovery of renal function and is not inferior in terms of bladder function, even in patients with severe PUV disorder. It is a reliable surgical option that can spare renal function and guarantee adequate bladder function in the long term(323).

The importance of bladder neck secondary obstruction which may require further interven-tion on the basis of the UDS observation that DO and high maximum voiding detrusor pres-sures decreased consistently after bladder neck incision(324). Singh et al. summarized 81 children with PUVs including 40 cases underwent bladder neck incision (BNI) in addition to valve fulguration (Group I), and the remaining 41 patients underwent conventional tran-surethral valve fulguration (Group II). UDS follow up showed no statistically significant dif-ference regarding DO, compliance, end-filling pressure, and max Pdet at Qmax in the both groups. However, improvement of peak flow and postvoid residue (PVR) in Group I in com-parison to Group II was significant(325).

In addition, VUDS is useful for many aspects of valve bladder, and is increasingly used in cases with vesicoureteral reflux, changing or inconsistent urodynamic studies, and bladder neck obstruction. VUDS has also been used in pre-operative evaluation of patients with end-stage renal disease receiving a kidney transplant. However, additional research is re-quired to better define the proper circumstances for its use(326). The role of VUDS in diag-nosis of the condition that late-presented PUVs is still unclear although cystoscopic exami-nation is still the preferred for those cases to diagnose this condition(327).

The persistence of UUT changes is related to the bladder’s unresponsiveness to medical therapy for the DO and/or for DU (usually CIC). However, it is possible that this condition is secondary to insufficiently frequent voiding in the face of increased urine production. BOO from a secondary hypertrophied bladder neck can also occur, requiring further intervention(328). Several studies have shown the predictability of the development of renal failure based on specific detrusor patterns seen on UDS: persistent poor compliance, high detrusor pressures, BOO and/or chronic failure of the detrusor to adequately contract during voiding with increased PVR(329,330). In a study on 54 cases, it was found that the non-symptomatic PUV patients had lager filling volume (135 ± 46% of EBC) than the sympto-matic PUV patients. PUV patients with LUTs had a higher rate (19/28, 67.9%) of impaired bladder compliance than non-symptomatic PUV patients (11/26, 42.3%, p = 0.0489). The PUV patients with LUTs had a trend of worse kidney functions in lower GFR, higher serum creatinine and lower estimated GFR(331).

Whether pressure pop-offs, such as high-grade vesicoureteral reflux with renal dysplasia, is beneficial for renal and bladder outcomes in boys with PUV, or beneficial for renal function is still controversial. A retrospective study of 48 cases with PUV show that patients with pop-offs required more extensive interventions to achieve continence and achieved conti-nence and toilet-training less frequently than patients without pop-offs. Their study conclud-ed that pop-offs do not appear to impart significant benefit to bladder outcomes and may indicate more severe bladder dysfunction(332).

A respective study on the correlation of bladder contractility index (BCI) with development of chronic kidney disease stage IIIB or more in 270 boys with PUV who underwent valve fulguration between 2000 and 2010 was followed up by recording BCI, end filling pressure (EFP), compliance (ΔC), bladder outflow obstruction index, and bladder volume efficiency, and the authors concluded that BCI may be a useful tool for early detection of boys with PUV who are likely to progress to chronic kidney disease stage IIIB or more(333). It is im-portant to note that the BCI was not validated for use in children or women.

It is well known today that the LUT conditions are at risk for UUT deterioration, therefore it is reasonable to follow the patients who underwent neonatal valve ablation and aggressive and early bladder training, by non-invasive UDS exams. In a multivariate analysis study, detrusor thickness greater than 1.3 mm was considered the only independent risk factor for later impaired bladder function(334). Non-invasive UDS seems to be as safe and effective as invasive UDS in the long-term management of boys with PUV, and invasive UDS may be reserved for cases of progressive deterioration of LUTD or renal function.

4.4. Bladder Exstrophy

Once the bladder exstrophy (BE) is closed it may be difficult to manage persistent UI, UUT dilation or VUR. In addition, as more children undergo complete primary repair of the BE in the neonatal period, the most accurate assessment of bladder function is by UDS; compli-ance reduces in up to 50% after surgery(335,336). Studies have correlated UI with age relat-ed cystometric capacity, compliance, DO and/or LPP(337). UDS remain helpful to evaluate LUT before (and after) further surgical procedures and for research matters. To check poten-tial injury to pelvic neuro-urological anatomy after complete primary repair of bladder ex-strophy, needle EMG was done in 13 children to evaluate the external urethral sphincter re-sponse to sacral reflex stimulation and during voiding, finding normal individual motor unit action(338).

The role of UDS on prediction of certain risks in BE has been reported. A retrospective mul-ti-institutional review of bladder perforation in seven male and two female patients with clas-sic bladder exstrophy-epispadias (E-E) showed that UDS may identify those at risk. CIC with or without augmentation should not be delayed once poor bladder emptying and/or high pressure are identified(339).

UDS has also been used to evaluate the long-term efficacy of Young-Dees bladder neck reconstruction (YDBNR) alone versus YDBNR plus bladder neck injection in patients with BE(340). A multi-institutional cohort assessed the probability of bladder augmenta-tion/diversion and CIC in 216 patients with classic bladder exstrophy. On long-term follow-up probability of bladder augmentation/diversion increased with age, with 1 in 2 patients by age 10 years and the majority in adulthood. Almost a third of patients, including adults, with a closed native bladder performed clean intermittent catheterization. Considering all adults only 14% did not perform clean intermittent catheterization(341). Obviously, BE needs life-long care and UDS assessment.

4.5. Ectopic Ureterocele

The literature on UDS application in ectopic ureterocele is still limited. UDS in babies with an ectopic ureterocele had shown that several cases had a larger than normal cystometric ca-pacity and DU(342), but in a multicentre analysis of 616 children it was found that LUTD is present only in ectopic ureterocele(343). Recently, there is an increasing agreement in favour of conservative management of paediatric duplex system ureteroceles, by mean of simple endoscopic puncture followed by close surveillance: VUR can resolve spontaneously in a significant number of patients, and bladder function should be conserved(344), and even if secondary bladder surgery is needed, significant bladder dysfunction is rare(345,346).

4.6. Vesicoureteral Reflux

VUR may be a secondary phenomenon resulting from LUT dysfunction(347). There is evi-dence that DO may lead to VUR in a marginally competent ureterovesical junction mecha-nism(348). This DO may be a natural phenomenon in the infant bladder(349) and/or a learned dysfunction in older children. Among UDS parameters, high bladder pressure at the onset of VUR was found a positive prognostic factor for spontaneous resolution of VUR, inde-pendently of VUR grade(350). The highest degree of VUR was found associated with high-est detrusor pressure in the group with 'urgency syndrome'(351), and no differences in reso-lution rates observed from grades I to V VUR in children with LUT conditions, patients with dysfunctional voiding having the most improvement and greatest(70%) resolution of VUR(352). A study on 153 children with vesicoureteral reflux and accompanying non-neurogenic LUTD were retrospectively evaluated. It was found that the absence of signifi-cant post-void residual urine volume, and a low Dysfunctional Voiding and Incontinence Symptom Score increase the likelihood of spontaneous resolution rates of vesicoureteral reflux in children with non-neurogenic LUTD(353).

Another prognostic finding regarding the spontaneous resolution of VUR is intravesical vol-ume at the onset of VUR: large cystometric capacity correlated with VUR during filling, while VUR at voiding correlated with low cystometric capacity, with the first pattern showing a lower resolution rate within the third year of life, in a longitudinal study by videocystometry(354). There is ample evidence to show that treating the DO and/or voiding dysfunction leads to a faster rate of resolution of VUR (63-92% within 1 year) than treating only with antibiotics(25-54%)(355). We now understand that sterile VUR is benign and most reflux spontaneously resolves over time, the initial approach in majority of children is non-surgical with continuous antibiotic prophylaxis (CAP) and correction of bladder and bowel dysfunction(356).

UUT damage is more likely to occur in children with abnormal LUT function(357). In this set-ting, history taking about voiding habits and accurate non-invasive UDS evaluation become paramount. A study on 50 children has shown the usefulness of the non-invasive test and the classification of urinary dysfunction in children aged over 3 years prior to the first endo-scopic treatment of VUR(358). A prospective study with simultaneous performance of filling cystometry and cystosonography in 43 children showed that cystosonography can replace conventional cystourethrography as an imaging test associated with UDS. It has been able to indicate the treatment to our patients, subjecting them to a single catheterization and without exposing them to ionizing radiation(359).

Question remains if cystometry with PFS in older children are advised. In a study on 40 pa-tients, VUDS showed LUTD in 76% of the children(360), and in a recent prospective study of 147 children with high grade VUR, normal patterns were found in only 23% of them(361). In patients who had post-treatment UDS, biofeedback, pelvic floor muscle training and treatment with antimuscarinics effectively decreased detrusor pressure, increased cystomet-ric capacity and maximum flow rate, and reduced the grade of VUR(362). It is nowadays reasonable to diagnose LUTD by non-invasive tests and to consider VUDS in therapy re-sistant patients, paying attention to bladder neck dysfunction, which was shown to be rele-vant

in a randomized trial(363). Many clinicians advocate UDS especially for those patients that still have UI, renal damage, or who are about to undergo surgical correction(364,365), even if precise UDS (pressure-flow) criteria for outlet conditions in children are still unde-fined.

4.7. Urethral Stricture

Congenital urethral stricture disease in boys is rare(366). Paediatric urethral stricture is aris-ing from a previously unsuspected straddle injury or the late result of hypospadias repair, even the modified procedures have been used nowadays(367). Some meatal stenosis is due to circumcision(368), bladder outflow obstruction comprising PUV, urethral atresia, and urethras with variable degrees of stenosis.

Uroflowmetry can accurately predict the presence of a urethral stricture in 88% of affected males(369). A urethral (meatus or stricture) outflow obstruction after hypospadias repair may develop as symptomatic and uroflowmetry can be helpful(370), demonstrated by signifi-cantly different pre- and post-meatotomy findings of Qmax (P .001) and voiding times (P.03)(371). Follow-up uroflowmetry, analysing and comparing the maximum flow rate, void-ing times and curve pattern may alert the clinician to early signs of (re-) stricture formation but the precise interval, frequency (and efficacy) of periodic uroflowmetry testing in these patients has not been corroborated(372). A prospective study following 25 symptomatic toilet-trained boys before and after meatotomy showed that symptom evaluation and physi-cal examination should be the hallmark assessing children with meatal stenosis. Uroflowme-try provides objective assessment as well as surgical success(373).

4.8. Conclusions (Level 3)

- Frequent UDS abnormalities, predominantly DO and reduced bladder compliance or large cystometric capacity with impaired filling sensation, in children with PUV, urethral stricture, ectopic ureterocele, VUR or with bladder exstrophy.
- Proper UDS has been shown to be of help to determine when further medical or surgical management is indicated and evaluating the treatment results during follow up in children with these abnormalities.
- The use of UDS has aided in an objective measurement of success or failure of treatments for these abnormalities.

4.9. Recommendations (Grade C)

- VUDS at least once, in symptomatic children with PUV, urethral stricture, ectopic ureterocele, VUR should be considered before invasive treatment is adapted
- UDS in children should be done with special attention to their specific needs, and with careful attention to minimize mental trauma and to ensure to reproduce symp-toms as much as possible
- Clinicians should consider regular uroflowmetry and PVR assessment in the follow-up and further management of children with PUV, urethral stricture ectopic uretero-cele, VUR or with bladder exstrophy.
- Clinicians should consider the necessity of follow-up UDS on an individual basis and as less frequent as possible.

5. FUNCTIONAL DISORDERS OF THE LOWER URINARY TRACT

5.1. ICI2016 Conclusions and Recommendations

Various studies show that treatment for children with functional UI can be initiated based on history, clinical exam, bladder diaries, bladder ultrasound and uroflowmetry with PVR as-sessment. It has been suggested that UDS should be considered in children with UI and nocturnal enuresis resistant to initial (conservative) treatment. Epidemiological studies have shown that several neurological/cognitive/behavioural disorders (i.e. genetical diseases, autism, ADHD) have an association with LUTS and UI. Social and/or behavioural conditions (i.e. obesity, bullying) have a significant incidence of high LUTS-score and/or UI. The neuro-logical diseases and social conditions with potential LUTS and UI should be evaluated at least by bladder diaries and questionnaires, possibly by non-invasive UDS. The potential risk factor for adult women to have UI if they suffered from LUTS as girls may require long-term accurate follow-up.

Uroflowmetry with pelvic floor EMG and PVR assessment as ‘non-invasive urodynamic’ screening and evaluation in all children with LUTS, UI and/or with nocturnal enuresis resistant to first line therapy. Urological signs and symptoms should be assessed in children with chronic constipation and/or faecal incontinence. Complete UDS in children with UI and/or with nocturnal enuresis resistant to conservative treatment should be performed if invasive or clinical (dry-bed training) treatments are contemplated. In addition, the committee gave some suggestions for research. The further integrated approaches to the diagnosis (and management) of children with bowel dysfunction, in combination with LUTD should be un-dertaken. Longitudinal studies on persistence of LUTS/UI in adults are suggested, to be integrated with retrospective studies in adults suffering of UI, in order to evaluate if having LUTS in children is a risk factor for UI in adulthood.

5.2. Discussion and New Evidence 2021

Many infants experience chronic incontinence into childhood. UDS, especially flowmetry and PVR measurement has been used frequently in evaluation of voiding function of chil-dren(374). When assessing LUTD in children, one must consider the dynamics of the matur-ing nervous system, learned habits of elimination for bladder and bowel function and social influences.

5.3. Diurnal Incontinence

LUTD is a broad term describing the full spectrum of disorders in any of the stages of bladder function-storage or voiding including OAB-s, voiding postponement, stress inconti-nence, giggle incontinence, and dysfunctional voiding and they are common in childhood(375).

In all children with non-neurogenic LUTS, non-invasive UDS is warranted to determine the presence of different forms of disorder, and to assess bowel dysfunction as well. Uroflow-metry with a PVR measurement and/or simultaneous EMG recording are first choice to eval-uate the voiding dysfunction in children. Voiding diary might be considered in cases to know the patient’s voiding “Frequency/ Volume”. Both small bladder volume and overfilling the bladder might decrease the Qmax. The residual urine in normal infants and children, with an average time delay due to catheterization of 4–5 min, is less than 10 ml, unrelated to age, sex or bladder capacity(222,376,377). The uroflow is considered normal if the bladder emp-ties at least once during two uroflow measurements(232). A retrospective survey of 153 children who were diagnosed with vesicoureteral reflux and accompanying non-neurogenic LUTD showed

that the absence of significant post-void residual urine volume together with a low "Dysfunctional Voiding and Incontinence Symptom Score" increased the likelihood of spontaneous resolution rates of vesicoureteral reflux in children with non-neurogenic LUTD(353).

Pressure / flow study has a limited place in diurnal (day and night) UI. History and clinical investigation are very important in evaluation of UI. Therefore, it is imperative to formulate a 'urodynamic question(s)' following a comprehensive history, careful physical examination, and standard urological investigations, possibly with the aid of validated questionnaires (378–380).

UI resistant to conventional therapy may require (V)UDS. UDS is helpful for us to under-stand the aetiology of diurnal UI and improved making strategy of treatment. Pre-treatment UDS is recommended in any case with UI before invasive treatments. Approximately 6% of 7-year-old children and 1% older adolescents affected by daytime urinary incontinence (DUI) which contains a wide variety of subtypes. Effective treatment requires precise identification of the subtype (381,382).

Different UDS findings have been reported, with DO (in 57%), dysfunctional voiding (in 22%) and also normal findings in 14%(383,384). Dysfunctional voiding was also reported associated with DO in up to 76%. If a low PVR is demonstrated during free flow uroflowme-try then any raised PVR during the urodynamic assessment can be considered as an artifact due to the artificial circumstances of the test and the presence of an in-situ urethral catheter(232).

Several recent studies, well designed by validated questionnaires, including a case-controlled one on autism spectrum disorders(385) and another in children with attention def-icit-hyperactivity disorder (ADHD) have shown a significant incidence of LUTS(386). Other social and behavioural conditions were investigated in children referred with signs and symptoms of LUTD, such as obesity or underweight(387); 415 bullying (a quarter of Ameri-can school children are regularly bullied)(388); and sexual abuse and found these to have a higher LUTS score and/or a higher incidence of UI (389,390).

Greater attention has been recently paid to check the prevalence of LUTS and UI in a series of genetic disorders with cognitive/behavioural or potential neurological problems, such as children with Down's syndrome, to reassure the families and to screen the cases which may require treatment. It was found that there is a marked delay in toilet training (average 5.5 years), and UI was reported in 46% of (versus 24% in controls) previously toilet trained children(391).

OAB-S, defined by urinary urgency, usually accompanied by increased urination frequency and nocturia, with or without urinary incontinence. The prevalence of paediatric OAB-S in 5–13-year-olds is as high as 16.6%, but the pathophysiology and epidemiology have not been sufficiently elucidated. A retrospective study on 126 children with OAB-S evaluated by bladder pressure and urethral pressure recording simultaneously (synchro-cysto-urethrometry) found that urethral instability plays an essential role in the pathogenesis and progression of OAB-S in children. The authors concluded that synchro-cystourethrometry is a useful urodynamic technology to precisely diagnose OAB-S, and transcutaneous electrical pudendal nerve stimulation may be an effective treatment for OAB-S children induced by urethral instability(392).

Fuyama et al. observed 117 children with OAB-S including neurogenic LUTD (spina bifida) aged between 5 and 15 years by abdominal ultrasound and uroflowmetry. The recovery pe-riod (=time to cure =incontinence reported <1/month, achieved by 67% of the children.) was significantly shorter in the group with bladder wall thickness ≥5 mm than with bladder wall thickness <5 mm. Children with a tower-shaped curve on uroflowmetry had a significantly shorter recovery period than those with a bell-shaped curve. The authors concluded that bladder wall thickness and uroflow curve shape are related to the recovery period of paedi-atric OAB-S(393).

UI are commonly associated with gastrointestinal co-morbidities, such as constipation or faecal incontinence in children. Bowel dysfunction, in the absence of any anatomical or neu-rological deficit, often affects LUT function. Constipation had been shown in the past to be associated with DO and a reduced functional bladder capacity(394). Understanding and eliminating this possible aetiology can normalise LUT function, as stated by the report from the Standardisation Committee of the International Children's Continence Society(395). In a recent prospective study from urological and gastroenterological clinics in one centre, 68% of subjects referred with UI, and/or constipation and/or faecal incontinence and included, had at least a 50% reduction in number of daytime UI episodes and 27% became complete-ly urine -continent by successful relief of bowel (constipation and/or faecal incontinence) dysfunction(396).

Whether minimal invasive UDS should be used evaluating the voiding function before treat-ing these Bladder / Bowel Dysfunction(BBD) with non-invasive procedures such as behav-ioural modification, biofeedback training, drug therapy is still controversy(397,398).

5.4. Nocturnal Enuresis

Nocturnal enuresis (NE) is a common complaint in children, with a prevalence of around 15% at age 6 years(399). It has been categorized as monosymptomatic nocturnal enuresis (MNE) and non-monosymptomatic one (NMNE). Multiple risk factors have been reported related to NE, including genetic factors, maturational delays, sleep disturbances, social causes, psy-chiatric conditions(386), LUTD and/or abnormal vasopressin secretion(233,400). Recently, the delay of elimination communication has been found to be one of risk factors to contrib-ute to the increase of EN prevalence in China(401).

Minimal invasive UDS (flowmetry + ultrasound PVR) is recommended for evaluation of void-ing function before medical treatment(402). The role of uroflowmetry in evaluation of NE might be limited. A retrospective study on 93 children who underwent uroflowmetry three times on the same day showed that uroflowmetry did not reflect the urinary symptoms of children with NE. The abnormal uroflowmetry curve patterns did not differ significantly be-tween NE children with and without DI. However, the DVSS questionnaire scores differed significantly(403).

A study on 100 children with NE found that elevated PVR was a significant predictor for lower chance of complete response to treatment whether they had high "Dysfunctional Void-ing Symptom Score" (DVSS) or not(404). Pressure/flow study or VUDS were indicated for refractory cases. An abnormal micturition history, or dysfunctional voiding symptoms like squatting and/or abnormal voiding charts, predicted abnormal UDS results correctly, with a sensitivity of 81% and specificity of 86%(405). A bladder volume and bladder wall thickness index less than 70 was a predictor for the presence of DO at cystometry in one cohort(406). In a double-blind, placebo-controlled study, 24 children with severe OAB-S and DUI (mean

age 8.5 ± 1.2 years) underwent 48h natural fill UDS. No immediate objective effect of transcutaneous electrical nerve stimulation (TENS) on bladder activity was found. There was no significant difference in the proportion of different bladder contraction types between the two groups. TENS did not significantly influence the number of bladder contractions not leading to a void(407).

A study on total of 184 NE and 180 control patients showed that spina bifida occulta (SBO) is more common in NE patients than in non-NE patients. Response to NE treatment is lower in SBO patients with severe LUTS; for this population, advanced treatment options may be considered earlier(408). Whether the NE patients with SBO needs UDS is still unknown.

Both maximal VV and nocturnal urine volume were lower (P < 0.001) in patients with NMNE compared to MNE. Out of 500 patients who were initially referred as desmopressin resistant, 33% of these became dry on desmopressin monotherapy, demonstrating how relevant the UDS diagnosis of enuresis is in subtyping them for treatment selection(402). On this regard, it was shown that treating the non-monosymptomatic child using antimuscarinic agents can be very effective (as high as 77% cure) when based on the findings of UDS(409,410). An emerging issue which requires further research, is the progression of enuretic children into adulthood. Enuretic children were found more likely to have nocturia and urinary urgency if they had nocturnal enuresis when> 12 years of age(411) A retrospective, descriptive cohort study, concerning 907 patients aged 11 years and older, suffering from enuresis of at least one wet night per fortnight showed that both small maximum voided volume (MVV) and nocturnal polyuria (NP) were found frequently in adolescent and adult enuresis patients, which is in line with the current thoughts on causal factors(412).

A retrospective cross-sectional chart study comprising 52 Ataxia telangiectasia patients showed that secondary enuresis affecting 15% of the cases heralding loss of ambulatory capacity, tough its pathophysiological mechanism is largely not understood(413).

Recently, laser acupuncture, a non-invasive, painless tool, with no side effects and lower recurrence rate, has been reported more effective than desmopressin acetate in treatment of NE becoming potential therapy for patients with NE(414). However, the effect of laser acu-puncture on the bladder function might need evaluating by UDS in the future.

5.5. Conclusions (Level 2/3)

- Treatment for children with functional UI can be initiated on the basis of history, clinical exam, bladder diaries, bladder ultrasound and uroflowmetry with PVR assessment.
- UDS or VUDS is relevant in children with refractory UI and NE resistant to conservative treatment.
- Synchro-cystourethrometry is a useful urodynamic technology to precisely diagnose OAB-S related to DO or urethral instability.
- There is evidence from epidemiological studies, carried out by validated questionnaires, that several neurological/cognitive/behavioural disorders (i.e. genetical diseases, autism, ADHD) have an association with LUTS and UI.
- There is evidence that also social and/or behavioural conditions (i.e. obesity, bullying) have a significant incidence of high LUTS-score and/or UI.
- The potential risk factor for adult women to have UI if they suffered from LUTS as girls may require long-term accurate follow-up.
- The delay of elimination communication and occult spina bifida might be a risk factor for children suffering from primary nocturnal enuresis.

5.6. Recommendations (Grade B/C)

- Uroflowmetry with PVR assessment by ultrasound as ‘non-invasive urodynamic screening and evaluation should be considered in all children with LUTS, UI and/or with NE.
- Pressure /flow study and/or synchro-cystourethrometry should be considered in children with UI and/or with NE resistant to conservative treatment, if invasive procedures are con-templated.
- The committee suggests urological signs and symptoms assessment in children with chronic constipation and/or faecal incontinence.

5.7. Suggestion for Research

- Longitudinal studies on persistence of LUTS/UI in adults are suggested, to be integrated with retrospective studies in adults suffering of UI, in order to evaluate if having LUTS in children is a risk factor for UI in adulthood.
- The potential risk factors such as delay of elimination communication or prolong usage of disposal diaper of UI and/or NE should be investigated in the future.
- The committee suggests that further integrated approaches to the diagnosis (and manage-ment) of children with bowel dysfunction, in combination with LUTD are undertaken.

6. TECHNICAL CONCERNS: RELIABILITY AND REPRODUCIBILITY OF TESTS

6.1. ICI2016 Conclusions and Recommendations

The ICI2016 concludes that UDS in children is reliable and reproducible; the limitation is same as that of adult. Non-invasive tests are gradually achieving more evidence level, by constructing normative values and more standardized performing of the tests. Although, it is plausible and considered useful to reduce filling speed and catheter size in relation to pa-tient size, the exact values cannot be given and the influence of the transurethral catheter size on voiding is unknown in children. The committee concludes that standards for Pres-sure/flow study (PFS), and information on non-invasive PFS in children are lacking.

The ICI2016 recommended (Grade C) that the specific demands of children, physically as well as psychologically are considered, before UDS is carried out as well as during the test-ing. The specialized workers, units and equipment needed to ensure this. Non-invasive diag-nostic tests should be preferred, and invasive ones should be done only if indicated by the results of non-invasive procedures, in neurogenic LUTD to discover risk conditions, and when the outcome will or can alter management. The variability and test-retest differences of UDS in children and the effect of the (apparent psychologically stressing) laboratory-situation on the child’s behaviour, and the implications for the results of the tests should be take into account.

In addition, the ICI2016 suggests elaborating on standardization of UDS evaluations and on criteria to judge how the ‘laboratory’

circumstances have influenced the child's (LUT) behav-iour, with the aim to better include how well UDS have represented the actual LUTD, in the evaluation of the test, to verify if, how and when non-invasive tests can substitute UDS in the accuracy of diagnosis of functional LUTD in children.

6.2. Discussion and New Evidence 2021

With the popularization and clinical application of guidelines and standard terminology, dif-ferences in UDS parameters existing from one study to another are decreasing. However, the standard criteria of UDS parameters in children are far from established. The reliability of UDS could be influenced by development effects and measurement variability, as well as by the unfamiliar clinical environment in children.

A recent study, comparing (conventional) UDS with ambulatory UDS: found that even if flow rates were similar between methods, more diverse voiding patterns were identified in ambu-latory UDS, suggesting that UDS may not be sensitive enough to the variability of LUT pathophysiology in children(239). 'Functional' bladder capacity (as derived from the voiding diary, without the first void in the morning) is presented as a relevant parameter for the clini-cian in the ICCS definitions(415,416).

Bladder diary, uroflowmetry with or without EMG, pelvic floor muscle activity (PFMA) has been recommended as first line procedure to evaluate voiding dysfunction in children. They have been used to evaluate the efficacy of biofeedback-assisted pelvic floor muscle thera-py (PFMT) on symptoms, bladder capacity, uroflowmetry before and after treatment in 24 children with refractory OAB-s(417). Bladder diary has been used in a prospective, random-ized study in 64 children to evaluate the efficacy of biofeedback and para-sacral electric nerve stimulation (TENS) for the treatment of children with LUTD(418). Uroflowmetry plus EMG for evaluating the voiding pattern of children with VUR is also reported to guid under-stand the abnormality and making treatment protocol(419).

A prospective treatment study (Level I: Randomized controlled trials with adequate statistical power to detect differences (narrow confidence intervals) and follow up >80%) comprised of 46 anatomically and neurologically normal children with non-neuropathic urinary inconti-nence. By using uroflowmetry with electromyography (EMG), a complete voiding diary and a dysfunctional voiding scoring questionnaire at the baseline, the combination of biofeedback therapy and transcutaneous interferential electrical stimulation had been demonstrated a potential effective modality in treating non-neuropathic urinary incontinence in children(420).

Daily pads use and episodes of urinary incontinence (UI) were recorded in a 3- day voiding diary had been used to evaluate the prevalence and types of bladder and bowel disfunction (BBD) in young and adult patients affected by autism spectrum disorder (ASD). It has been found that young and adult patients with ASD present with a high prevalence of BBD and concomitant antipsychotic medications could to play a contribution in induction and/or maintaining of BBD(421).

An observational study comparing data values, reliability, consistency and compliance col-lected by electronic and paper diaries of differing durations from patients with OAB-S, showed that 7-day or continuous electronic diaries improved the accuracy and reliability of micturition and incontinence frequency data compared with shorter collection periods and paper diaries(422).

Available evidence has demonstrated that children with suspected LUTD should be evaluat-ed properly by detailed history taking, validated questionnaire on voiding and defecation, voiding and bowel diary, urinalysis, screening ultrasound, uroflowmetry and post-void resid-ual measurement. Invasive urodynamic study such as VUDS should be reserved for children in whom standard treatment fails(398). Uroflowmetry is an indispensable first-line test for children with suspected LUT dysfunction, must be accompanied by ultrasound PVR meas-urement. More accurate nomograms were recently stated for uroflowmetry analysing, 721 records(423), and for PVR, analysing (single and dual) PVR in healthy school children(424). Unfortunately, there is still a tremendous amount of intra- and interobserver variation in de-fining the shape of curves, but studies are showing how uroflowmetry-analysis can be more reproducible using standardized evaluation and using a 'flow index'(425). Uroflowmetry may be also more reliable if performed with simultaneous EMG(426,427).

Ultrasound bladder wall thickness measurement has been reported a good sensitivity (based on anterior wall thickness: 67% and based on posterior wall thickness 83%) for symptoms of dysfunctional voiding in a study of 324 children, both healthy and dysfunc-tional voiders(227). Another study in children with BOO (PUV), found detrusor thickness greater than 1.3 mm as the only independent risk factor for later impaired bladder function in a multivariate analysis(334). Dynamic pelvic floor ultrasound is under evaluation for norma-tive values of endurance and direction of pelvic floor movements(228). A cut-off diagnosis for specific non-neurogenic dysfunction for any of the non-invasive tools would be desira-ble.

Filling cystometry is indicated when history and clinical examination raises a suspicion of either anatomic and/or NLUTD involving primarily the storage phase, or when there is a question that cannot be answered by less invasive testing. Additionally, filling cystometry is relevant when BOO (PFS) (eg, valve bladder syndrome, detrusor-sphincter dyssynergia as-sociated with N-LUTD), or congenital anomalies of the bladder (exstrophy, ureteroceles, multiple bladder diverticula) may be causing symptoms and signs of dysfunction that may need further delineation(222,416). The indications for PFS are similar to that for cystometry. PFS should be considered as one procedure, along with a "free" voiding uroflowmetry and filling cystometry, but not the only one, to clarify the diagnosis and to make therapeutic decisions as well as to follow up treatment responses to the voiding dysfunction, when less invasive studies are inconclusive. To understand the characteristics in PFS, normal voiding parameters as well as following Good Urodynamic Practice (GUP) recommendations from the ICS and ICCS are the basis of successful testing(232).

To assess the voiding phase, PFS studies are performed immediately after filling cystome-try. In children, the transition from filling to voiding is not as easily managed as in adults. To avoid missing this important transition, cystometry and pressure-flow/EMG measurements should preferably be performed as one continuous study(392). Available literature has shown that average detrusor pressure at voiding a wide range, to be 127cmH2O in boys and 72 cmH2O in girls on standard fill cystometry(428), similar to what found in a natural fill cys-tometry(429). It was supposed to be physiological dyscoordination, probably due to imma-ture detrusor-sphincter function, also to the different anatomy of the urethra(428,429). Later, it was demonstrated that high voiding pressure is related to DSD(430). The maximum detru-sor pressure (mean±SD) during voiding was 66.1 (13.1) and 56.6 (14.7) cmH2O and the max-imum voiding pressure was 73.9 (16.6) and 62.7 (16.2) cmH2O in symptom free boys and girls without DSD(376,431). A high voiding

detrusor pressure (usually >74 cmH2O in boys, 63 cmH2O in girls7) with a low urine flow indicates BOO; low pressure with a low flow indi-cates DU. A PFS-plot is useful to evaluate the pressure and flow relationship in this regard, although clinical calibration is not yet available for children(232,377).

When filling by catheter, slow fill cystometry (5–10 percent of estimate bladder capacity per minute, or <10 ml/min) is recommended, as compliance (predominantly) and DO (possibly) may be significantly altered by faster rates of filling(432). Room temperature normal saline is still the most common used in UDS. Most children readily tolerate a 6, 7 and 8 Fr. double or triple lumen transurethral catheter to fill the bladder and record pressure (bladder and/or urethral). In selected cases, a suprapubic catheter may be inserted under general anaesthe-sia the previous day or several hours earlier on the same day, but risks need to be juxta-posed against benefits of this approach(221). Use of 5F air-charged catheters has been shown to be safe and easy in children but comparative data with traditional water-filled cath-eters is not available(433). Avoiding general anaesthesia is important as this affects the natural state and eliminates the chance for voiding(221). Most children can undergo UDS without pre-medication; only the most agitated may require some degree of sedation(434). Cooperation is important for successful UDS. To reduce anxiety, the study may also be performed with the child seated, watching a video or DVD and accompanied by one or both parents. A study examining anxiety in children undergoing UDS showed that maximum anxi-ety was induced by EMG needle electrode insertion and insertion of the urethral catheters. Not knowing what to expect was also associated with enhanced distress(435). Difficulty with catheter placement and pre-test anxiety was noted to predict pain as measured by a VAS scale in children above 3 years of age. However, perception of pain was not influenced by the age of the child or the duration of the test(436).

In children with neurogenic LUTD, repeat cycles of testing can give variable results. The ICCS recommends two cycles of testing to ensure an accurate assessment. A recent study examined 3 cycles of testing in 80 children myelodysplasia and found that while maximum cystometric capacity and DO remained unchanged, detrusor pressure during storage was significantly lower in the second and third cycle of testing as compared with the first and DLPP was also noted to be lower in the third cycle. At the least, these findings suggest the importance of repeat cycles in children with impaired compliance(437).

Following previous consultation recommendation(362,438,439), the ICCS standardization on UDS studies of the LUT in children confirmed that UDS in children are best performed under the auspices of a knowledgeable urologist or trained aerodynamicists; so that children should receive comprehensive UDS in a laboratory that is specialized in paediatric UDS with appropriately trained personnel(221,440). However, it is sobering that substantial variation in performance, interpretation and terminology was noted even across experienced centres during the UMPIRE Study for children with myelomeningocele across the USA(441).

Uncorrected bowel dysfunction can influence urodynamic findings through pelvic organ cross-talk. In a series of children with spina bifida, aggressive bowel management resulted in substantial improvements in cystometric bladder capacity (237ml vs 183ml), age-adjusted bladder capacity (0.75 vs 0.54), reduced maximum detrusor pressure (64.3 vs 46.4 cm H20) and a reduction in detrusor leak point pressure from 62cm H20 to 39cm H20 all of which were statistically significant(442).

6.3. Conclusions (Level 3)

- The committee concludes that UDS in children is reliable and reproducible, within the limits also provided for adults
- Non-invasive tests are gradually achieving more evidence level, by constructing normative values and more standardized performing of the tests
- PFS should be considered when history and clinical examination raises a suspicion of either anatomic and/or neurologic LUTD involving primarily the storage phase, or there is a question that cannot be answered by less invasive testing.
- Synchro-cystourethrometry might be considered to evaluate DSD and urethral instability.
- The standards for pressure flow analysis in children have been partially established by ICCS and ICS, but information on non-invasive PFS in children are lacking.

6.4. Recommendations (Grade C)

- The non-invasive diagnostic tests should be preferred, and invasive ones should be done only when indicated by the results of non-invasive procedures, or in neurogenic le-sions to discover risk conditions, or when the outcome will or can alter management.
- The specific demands of children, physically as well as psychologically are taken into account, before UDS is carried out as well as during the testing. The committee advises specialised workers, units and equipment to ensure this.
- Clinicians should take into account the variability and test-retest differences of UDS in children and also take into account the effect of the (apparent psychologically stressing) laboratory-situation on the child's behaviour, and the implications for the results of the tests.

6.5. Suggestion for research

- The committee suggest to verify if, how and when non-invasive tests can substitute min-imal invasive UDS in the accuracy of diagnosis of functional LUTD in children
- The standards for uroflow and PFS analysis in children should be investigated, with the aim to better include how well UDS have represented the actual LUTD, in the evaluation of the test.

VII. URODYNAMICS IN FRAIL ELDERLY PATIENTS WITH URINARY INCONTINENCE

1. INTRODUCTION

UI is common in the elderly with significant implications for physical and mental health in the individual and challenges for the health care system. The prevalence and severity of UI in-creases with age and it is most often mixed UI in type(443–445). While newly occuring UI is common, about one-third of both men and women may experience spontaneous remissions when observed for at least five years(446,447). Unfortunately, under-reporting of UI remains common(448). UI has a negative impact on HRQoL and is associated with depression, so-cial isolation(449–451) and diminished sexual activity(452). UI continues to be regarded as an inevitable consequence of ageing both among patients as well as health care workers(453). The resultant delay in diagnosis leads to use of coping

strategies in the elder-ly(454,455), although individual or group pelvic floor muscle training (PFMT) can improve the complaints(456).

DO and UI are associated with frailty(457,458) and show correlation with its severity(459). Lack of physical activity(460) as well as changes in body morphology and composi-tion(460–462) are associated with a diagnosis of UI in the elderly. Specifically, there is a decline in balance while standing(463–465). Hence, UI is an independent risk factor for falls(466). Nocturia and sleep disturbance are common and may contribute to this risk(467–469).

PFMT is effective in the elderly(470) and combining behavioural strategies with physical activity is more effective(471). Group therapy with a team approach or home-based training might be more effective(456,472,473). Antimuscarinic therapy for the older individual is modestly effective but cognitive dysfunction is a concern(474) and caution is recommended in the frail and elderly. Combination of antimuscarinics with mirabegron is effective and safe in the older individual(475). Patients with refractory OAB-S syndrome may benefit from in-travesical injection of Onabotulinum toxin-A (100U) but older age might be a risk factor for retention(476). Sacral neuromodulation can also be considered. In elderly women with stress UI, minimally invasive mid-urethral slings are effective(477). Concerns regarding use of syn-thetics need to be balanced against the minimally invasive nature of these procedures and lack of long-term outcomes. Use of bulking agents may be a viable alternative in the elderly(478) who often prefer less invasive treatments(479).

Delivery of health care to the elderly patient remains a challenge(480). Integrated health care programs and better training of health care staff might be critical to improving the delivery of care(481,482). The economics of health care has an important impact(483).

2. SUMMARY OF EARLIER CONCLUSIONS AND RECOMMENDATIONS

ICI 2016 concluded that UI is common in the frail elderly and is associated with impaired mental health and HRQoL. Despite this, the rates for seeking treatment remain low. OAB-S is common in the elderly and has a diverse etiology. Patients are also more likely to have associated voiding dysfunction that may worsen with treatment. Evaluation by a skilled cli-nician is vital and consideration must be given to general health, mobility, cognitive func-tion, neurological disease, associated urological disease and concomitant medication. Signs and symptoms are not entirely reliable for predicting LUT dysfunction. Hence, UDS is recommended prior to invasive therapies and is more likely to show DO and/or DU in the elderly. Asymptomatic bacteriuria is common but there is no evidence that elderly patients are more prone to harm from UDS.

The 2016 committee concluded that PVR measurement by a non-invasive method is recom-mended before institution of pharmacological or surgical treatment and uroflowmetry is recommended before any invasive treatment. When required, a comprehensive standard UDS is recommended.

3. URGENCY URINARY INCONTINENCE IN FRAIL ELDERLY PATIENTS

3.1. New Evidence 2021

Elevated PVR is not uncommon in women with overactive bladder syndrome (OAB-S) (484). In fact, PVR has been shown to increase with age in women presenting for a urogynaecolo-gy consultation(485). Older men may harbour large PVR of up to 400ml for years without apparent harm(486). However, voiding efficiency (487) may be more relevant than isolated PVR. Therapy with antimuscarinics has been noted to be associated with impairment of voiding in the elderly with an increased risk of urinary retention as compared with placebo (RR3.60; CI 1.67–7.76)(488). In contrast, mirabegron has been shown to be safe even in elderly OAB-S patients with DU. In a study of 25 elderly patients (mean age 79.3years) with UDS-confirmed DO associated with DU, treatment with mirabegron was associated with improvements in symptom scores, voiding efficiency (40% versus 63% at 3mo) and PVR (153ml versus 86ml at 6 mo) (489). In another study of 60 elderly women with OAB-S, treat-ment with mirabegron resulted in improvement in OAB-S symptoms with objective improve-ments in cystometric capacity. DO disappeared in 40% without impact on any urodynamic voiding parameters(490). The effect of transcutaneous posterior tibial nerve stimulation in the treatment of urgency and mixed urinary incontinence in elderly individuals in residential and nursing homes was examined across 37 centers in the UK. This large sham-controlled randomized trial of 408 men and women failed to find any benefit in the overall study popu-lation as well as various sub-analyses(491).

Elderly women with OAB-S often demonstrate an interrupted voiding pattern. Although ab-normal voiding patterns were noted more often in women with OAB-S having an elevated PVR (77.4%), 47.4% of women with low PVR also showed an abnormal voiding pattern suggesting that PVR measurement may fail to identify some at-risk patients(484).

Among the elderly population (≥65 years) DO has been shown to be associated with frailty independent of age. The adjusted odds ratio for DO was noted to be 2.1 (95% CI 1.3-3.4) and 2.1 (95% CI 1.1-4.0) for pre-frail and frail elderly individuals, respectively(492). DO was noted to be associated with impaired contractility in 18.8% and 5.5% of community-dwelling elderly men and women, respectively. Storage and voiding parameters tended to be worse in these individuals(493).

At the central level, functional brain MRI suggests that UUI might be heterogeneous and differences in the brain response between controls, treatment-responders and non-responders might indicate differences in etiopathology(494). Successful treatment of UUI is associated with a decrease in ventral attentional network activity(495).

3.2. Conclusions

- The committee concludes that PVR elevation is not uncommon in the elderly (LE 3).
- The committee also concludes that lack of voiding symptoms is not a reliable predictor of a low PVR in the elderly (LE 3).
- The committee concludes that uroflow identifies patients with abnormal voiding who might not have an elevated PVR (LE 3).
- The committee concludes that antimuscarinics are associated with increased residuals in the elderly (LE 1).

- The committee concludes that invasive UDS identifies lower urinary tract abnormalities in the elderly that can impact treatment decisions (LE 3).

3.3. Discussion

Voiding dysfunction in the elderly can confound diagnosis and impact treatment. Patients with chronic retention may have symptoms indistinguishable from OAB-S. Additionally, prostatic bladder outflow obstruction (BOO) is common in elderly men and prolapse may be relevant in elderly women. Use of medication (for other diseases) is prevalent and phar-macogenic LUT (voiding) dysfunction is very common. Symptoms are not entirely reliable in identifying patients with voiding dysfunction. Pharmacotherapy with antimuscarinics has the potential for aggravating voiding dysfunction. Beta-3 agonists, such as mirabegron, have not been shown to have such a propensity. PVR and uroflow measurements may help iden-tify patients at-risk and may also enable a more informed decision regarding choice of drug therapy. However, non-invasive tests are not entirely reliable at excluding alternate diagno-ses. Invasive therapy with intravesical Onabotulinum toxin-A injection or sacral neuromodula-tion carries significant implications. In this context, invasive UDS provides accurate charac-terization of LUT function in the frail elderly.

Invasive UDS can result in a clinical urinary tract infection. While some guidelines have rec-ommended routine prophylaxis for elderly patients(496,497), this has been questioned(498,499). Most of the available evidence is based on identification of bacteriuria after invasive UDS rather than symptomatic infection. A careful assessment of the risks and benefit of using antimicrobial prophylaxis is warranted for each individual.

3.4. Recommendations (Grade B-C)

- PVR measurement is recommended in the evaluation of UUI in frail elderly patients with symptomatic voiding difficulty or a history of urinary retention. Assessment of prostate size and assessment of prolapse as well as of current use of all medication (see chapter Clinical Diagnosis) should be taken into account while considering PVR.
- PVR measurement is recommended before initiation of antimuscarinics in the frail elderly patient with UUI
- Uroflow and PVR measurement is recommended in the frail elderly patient with urgency UI prior to invasive therapy.
- Invasive UDS is recommended in the frail elderly patient with urgency UI prior to invasive therapy
- The decision for antimicrobial prophylaxis in the elderly should be based on a considera-tion of the risks and benefits in each individual patient.

4. STRESS URINARY INCONTINENCE IN FRAIL ELDERLY FEMALES

4.1. New Evidence 2021

Detrusor contractility declines with age(500,501). Accordingly, invasive UDS in elderly wom-en with SUI is more likely to show associated voiding abnormalities. In a study of 625 wom-en with stress incontinence, a reduction in maximum flow rate and detrusor contractility and an increase in PVR was noted with advancing age(502).

Invasive UDS often shows unfavourable storage and voiding characteristics in the elderly. In a large retrospective study of SUI outcomes (Age groups ≤50y, 296; 51-69y, 680; ≥70y, 488), elderly women were noted to be more likely to have a low abdominal leak point pres-sure (93, 82 and 70cmH20 respectively, p<0.001), intrinsic sphincter deficiency (64%, 71% and 76% respectively, p=0.002) and DO (12%, 13% and 28% respectively p<0.001). Howev-er, this did not translate into a lower treatment success rate in the elderly(503).

Contrarily, in a study of 688 women (Age groups ≤64y 554; 65-74y 98; ≥75y 36) evaluated at one year following mid-urethral sling, older women showed lower objective (91%, 81% and 67% respectively; p<0.001) and subjective (89%, 78% and 58% respectively; p<0.001) cure rates compared with a younger cohort; these women were more likely to have intrinsic sphincter deficiency (4%, 14% and 28%, respectively; p<0.001).Older women with ISD were also more likely to fail surgery (OR 2.60; 95% CI 1.10-6.18)(504).

4.2. Conclusions

The committee concludes that elderly women with SUI are more likely to have unfavourable findings on invasive UDS (LE 2). The committee concludes that standard recommendations for non-invasive testing before surgery for uncomplicated stress UI are not applicable to the frail elderly woman (LE 4).

4.3. Discussion

UI associated with chronic retention can confound the diagnosis of stress UI and may result in a positive stress test in women. Asymptomatic elevation of PVR is common in the elderly (vide supra). While this does not always appear to carry health implications, measurement becomes clinically important in patients presenting with UI. Guidelines often regard the el-derly woman as a non-index patient for stress incontinence surgery and the usual recom-mendations for surgery without invasive UDS may not be appropriate.

4.4. Recommendations (Grade B-C)

- PVR measurement is recommended in the diagnostic evaluation of SUI in the frail elderly women.
- Invasive UDS is recommended prior to surgery for SUI in frail elderly women.
- The decision for antimicrobial prophylaxis in the elderly should be based on a considera-tion of the risks and benefits in each individual patient.

5. STRESS URINARY INCONTINENCE IN FRAIL ELDERLY MALES

5.1. New Evidence 2021

Elderly men seldom present with stress urinary incontinence unless they have undergone prostate surgery although men with overflow incontinence associated with chronic retention might mimic stress UI. Urinary incontinence is common after radical prostatectomy and de-spite spontaneous improvement, 4-31% of men need pad protection at one year (505). Stress UI is the commonest finding but presence of other forms of LUT dysfunction may dictate a different clinical pathway for management. In a study of 860 men following robotic-assisted RP (RARP), 64 (7.4%, median age 66 years, median 19 months after surgery) pre-sented with post-prostatectomy incontinence (PPI). UDS showed USI alone in 64%, DO alone in

3% and mixed USI with DO in 17%. Poor compliance was noted in 5%. PFS showed weak detrusor contractility in 46% (BCI<100). Five men had associated anastomotic strictures. Among those avoiding further intervention were the 16% of patients with normal UDS findings (506).

A study examining long-term effects in patients receiving salvage radiation therapy after surgery (n=16; median interval from radiation to UDS 7.7y; median age at UDS 73y) found reduction in compliance and capacity with strong correlation of LUT symptoms to the UDS findings (507).

Peri-catheter leak during UDS can mask storage pressure abnormalities and must be recog-nized. Use of penile compression is effective and enables adequate bladder filling without apparent compromise to pressure recording (508). Presence of a passable anastomotic stricture can lead to a spurious negative stress test with the urethral catheter in situ but this might not impact results of surgery(509).

UDS has also been used for assessing the severity of PPI. Low retrograde leak point pres-sure (RLPP) correlated well with higher pad leakage (Spearman's correlation coefficient r.0.56, P<0.01) in a study of 61 patients. RLPP avoids the effect of fluid intake and activity that can confound the pad test(510).

Results of invasive UDS have been shown to predict the outcome of surgery for PPI. Of 99 patients who underwent artificial urinary sphincter implantation, 68 men (mean 68y) who had a successful outcome had higher compliance (112 versus 34ml/cmH20; p<0.01) and were less likely to show DO (18% versus 55%; p<0.01) compared with 31 men (mean 70y) who had failure. When noted, peak DO pressure was lower in the success group (15 versus 36 cmH20; p<0.01)(511). Presence of preoperative DO was also associated with a lower suc-cess rate after sling surgery. In a multivariate analysis of 80 men (mean 68y) preoperative DO and prior radiation therapy were associated with higher pad use at 36 months(512).

Invasive UDS with standard evaluation (history, examination and cystoscopy) was noted to be cost-effective as compared with standard evaluation alone in elderly men with PPI(513). Crucially, this benefit was contingent upon the assumption that invasive UDS was perfectly accurate for making a diagnosis.

5.2. Conclusions

- The committee concludes that stress urinary incontinence is the commonest cause for PPI (LE 2).
- The committee concludes that other important LUT abnormalities may be seen in isola-tion or association (LE 3).
- The committee concludes that presence of other urodynamic abnormalities can impact treatment decisions and outcome (LE 4). Radiotherapy may be a marker for LUT abnor-malities (LE 3).
- The committee concludes that special manoeuvres during invasive UDS can help im-prove the utility of the test (LE 4).

5.3. Discussion

Elevated PVR may suggest associated voiding dysfunction or anatomical obstruction in patients with PPI and trigger further testing. However, a low PVR does not exclude voiding dysfunction. Invasive UDS testing allows for a precise diagnosis of LUT function. Inconti-nence by the side of the urethral catheter or vesicoureteral reflux may mask poor compli-ance. Also, chronic under-filling due to continuous catheter drainage may result in a spuri-ously low compliance. PFS may show BOO due to the vesicourethral anastomosis. Such obstructions might not always be clinically relevant if the catheter-free uroflow is normal. A uroflow should always be available prior to surgery. While it is logical that DO and DU would be more common in the older patient with PPI, no studies have been undertaken to directly study this issue.

There are very few published studies on the impact of radiation on UDS findings in frail elderly men. While an earlier study failed to show adverse impact on compliance, UDS eval-uation in that study was performed at 3 months, possibly too early to detect changes in compliance(514).

5.4. Recommendations (Grade B-C)

- PVR measurement is recommended in the evaluation of frail elderly men presenting with post radical retropubic prostatectomy UI especially when invasive management is con-sidered.
- Uroflow and PVR measurement is recommended prior to invasive treatment for post-prostatectomy (stress) UI in frail elderly men.
- In frail elderly men with suspected voiding or associated storage dysfunction or those with a history of radiation therapy, invasive UDS is recommended prior to surgery for post prostatectomy stress UI.
- In frail elderly men with post retropubic radical prostatectomy urinary incontinence, inva-sive UDS should be considered prior to surgery for post prostatectomy stress UI, pref-erably with a (e.g. penile cuff-) closed outlet when early fill leakage is noticed.
- The decision for antimicrobial prophylaxis for UDS in the elderly should be based on a consideration of the risks and benefits in each individual patient.

6. NEUROLOGICAL CONDITIONS ASSOCIATED WITH URINARY INCONTINENCE IN THE FRAIL ELDERLY

6.1. New Evidence 2021

OAB-S and urgency UI are common in patients with Parkinson's disease. A study of 42 pa-tients (29 men, 13 women; 74.5y old) with OAB-S symptoms showed DO in all patients (ter-minal 45%). PFS abnormalities were common: DU in 47% and BOO in 37%. 17% had in-creased PVR. These findings suggest that DO might not be exclusively responsible for the OAB-S symptoms(515). Mirabegron was noted to be effective in patients with OAB-S symp-toms although there was a small increase in postvoid residual urine(493). In patients with refractory storage symptoms, intra-detrusor botulinum toxin injection resulted in improved cystometric capacity. 40% patients failed to respond and 28% needed intermittent catheteri-zation(516). Degeneration of the dopaminergic neurons as measured by 123I-Ioflupane SPECT imaging shows an inverse relationship with urodynamic bladder capacity(517). Pa-tients with nocturia may benefit from sustained release melatonin administration at night with a reduction in nocturnal urine volume and bother(518). A recent study suggested that sphinc-ter bradykinesia, the delayed relaxation of striated urethral sphincter seen in patients with Parkinsonism, might not be bothersome and may not progress(519).

UI is also common in multisystem atrophy, a differential diagnosis for Parkinson's disease. UI is typically earlier in onset in multisystem atrophy and voiding abnormalities are more common. Unlike Parkinson's disease, results of surgery for the prostate are uniform-

ly poor(520). PVR may be more reliable than sphincter EMG for differentiating Parkinson's disease from multisystem atrophy. In a study of 241 patients, PVR was noted to be higher both on free flow evaluation (113ml versus 40ml, p<0.01) as well as during PFS (230ml ver-sus 72ml, p<0.01) in patients with multisystem atrophy. In contrast, there was considerable overlap in the EMG picture limiting its diagnostic ability(521). While delayed relaxation of the striated sphincter may be noted in Parkinson's disease, genuine detrusor sphincter dyssyn-ergia is rare(520).

UI is a defining symptom for another geriatric condition, normal pressure hydrocephalus(522,523). Urgency UI and nocturia are the most bothersome symptoms and DO is common(524). Shunting of cerebro-spinal fluid (CSF) can improve LUTS and lead to improvements in UDS findings(525). In a study of 48 patients (33 men, mean age 79 years) who underwent a shunt surgery, compliance and capacity improved significantly with resolu-tion of DO in 7 of 37 patients in whom it was noted. However, there was no change in void-ing function(523).

LUTS are common after stroke with half the patients complaining of bothersome urgency UI(526). DO incontinence is the commonest urodynamic finding(527). However, other forms of LUTD such as chronic retention, impaired awareness or severe global functional disability may also manifest with UI(528). LUTS show a correlation with cognitive and functional status and improve progressively in the initial few months following an acute stroke(526,529).

UI is common in patients with Alzheimer's disease. In an insurance database study of 933 patients compared with an age-matched cohort, patients were more likely to have UI (hazard ratio 1.54; 95% CI 1.13-2.09). Annual incidence of UI was noted to be 6.2%(530). The com-monest form of UI is urgency UI with DO noted in 58% in a study of 144 patients (58 wom-en)(531). A positive correlation has been noted between urgency UI and clinical dementia rating scores(532,533).

6.2. Conclusions

- The committee concludes that functional abnormalities of the lower urinary tract are common in geriatric neurological conditions (LE 3).
- The committee concludes that findings of invasive UDS may impact decisions and out-come of invasive treatments (LE 4).
- The committee concludes that cognitive and functional status may be important deter-minants of treatment choice (LE 4).
- The committee concludes that elevated PVR is common in the elderly and impacts ther-apeutic decisions (LE 3).

6.3. Discussion

Several neurological conditions are common in the elderly. Alzheimer's disease, stroke, Parkinson's disease and allied disorders, and normal pressure hydrocephalus are all asso-ciated with a higher risk of UI and show an increased prevalence with age. Evaluation and management are complicated by associated LUT pathology both functional and structural, co-morbid conditions, polypharmacy, impaired cognition, psychological disorders, physical disability, and the available social support structure. Patients may be more prone to the adverse effects of medication and invasive therapies, and it is important to consider the harms associated with treatment.

In view of multiple LUT abnormalities in men with Parkinson's disease, UDS is preferable prior to invasive surgery for the bladder outlet. When available, video-UDS is the preferred modality of UDS testing in this setting. In men with suspected voiding dysfunction, UDS may be preferable prior to intravesical injection of Onabotulinum toxin-A for OAB-S.

While a recent guidelines document recommended antimicrobial prophylaxis for patients with neurogenic bladder, the recommendation was based on literature pertaining to spinal cord injury(496). The applicability of this recommendation in geriatric neurological conditions is uncertain.

6.4. Recommendations (Grade B-C)

- PVR measurement is recommended before initiation or escalation of drug therapy for UI in geriatric neurological conditions
- Uroflow is recommended prior to any invasive therapies for UI in geriatric neurologi-cal conditions.
- Invasive UDS is recommended in UI in geriatric neurological conditions prior to in-vasive therapies or surgery for the prostate.
- The decision for antimicrobial prophylaxis in the elderly should be based on a con-sideration of the risks and benefits in each individual patient.

6.5. Subjects for Future Research

- Evidence with regard to the utility of UDS in elderly individuals with UI is lacking. This would require high quality studies designed specifically for the elderly.
- Defining changes in the normal lower urinary tract with aging.
- Functional studies of the neuronal tracts and their impact on lower urinary tract.
- Functional MRI of the brain to better define the symptom of urgency and the ex-plore different subtypes of patients with UI.
- Impact of urodynamic findings on the results of PPI surgery.
- The role of invasive testing in frail elderly neurological conditions.

I. INTRODUCTION

The Committee was given the task of updating the evidence on imaging, neurophysiological testing and other tests in the field of urinary and anal incontinence. The Medline, Embase and Cochrane databases were searched for the relevant subjects from February 2016 to January 2021. All references obtained from the database search were screened for relevance, full text papers were obtained and reference list were used as additional source of evidence where appropriate.

The chapter covers different issues including: imaging, neurophysiological testing, and other investigations (laboratory tests, tissue analysis and pad test) in the paediatric and adult population, male and female subjects, neurogenic and non-neurogenic patients.

The following keywords were used for the difference subjects:
- Imaging: the Medline database was searched using the following keywords: imaging, urinary incontinence, continence, anal incontinence and faecal incontinence; the search has been limited to period from 2016 to 2021.
- Neurophysiology: clinical neurophysiology, conventional urodynamics, neurourology, urinary dysfunction.
- Other investigations: keywords including urinary incontinence, continence, pad test, urinalysis, urine culture, cystoscopy and tissue analysis were used.

Members of the committee were allocated the different topics of the chapter based on their specific expertise in the field. The first draft of the chapter was reviewed by all committee members, the final draft was then edited first by the Committee Chair and then by the book Editors.

Diagnostic techniques were evaulated with reference to the technique and its standardisation, intraobserver and interobserver variability, diagnostic accuracy, cost/benefit ratio and clinical benefit. The level of evidence was graded taking into consideration that imaging, neurophysiological testing and the other tests pertain to the area of “diagnosis” and the quality of the published papers was graded according to the criteria specific for this area. Areas of future research were identified.

Notwithstanding the large body of evidence, research on imaging in anal and urinary incontinence, its clinical benefit remains questionable. Test-retest, intraobserver and interobserver accuracy are often provided for diagnostic tests although diagnostic accuracy is difficult to evaluate due to a lack of a gold standard. When ultrasound is used to measure bladder volume, catheterisation can be used as a reference standard and accuracy can be easily calculated but when sphincter volume is calculated with ultrasonography, there is no solid reference standard except another imaging technique (e.g.: MRI) or the validity of an imaging measurement is tested against another weak test such as Valsalva Leak Point pressure or the maximum urethral closure pressure. Imaging can either be performed to better understand the pathophysiology of incontinence and pelvic organ prolapse and it may be of importance, although no immediate clinical benefit is evident (e.g.: calculation of sphincter volume with ultrasound). It can be performed as a diagnostic test in patients undergoing surgery so that quantification of the clinical benefit requires complex clinical trials (e.g.: MRI of pelvic organ prolapse in patient undergoing prolapse repair) in which different reference standards can be used (e.g.: physical examination or anatomic finding during surgery). Although imaging can sometimes offer a better understanding of the anatomy underlying the condition (e.g.: presence of an enterocele) the clinical benefit of this additional information may not be observed in all patients.

Although imaging is clearly a difficult area for research, the consensus regarding introduction of a diagnostic test into our daily practise must rely on the evidence of clinical benefit in terms of safety, outcome or cost-benefit ratio.

Imaging studies belong to the area of diagnostic studies, they should follow the suggestions of the STARD initiative and they differ substantially from other types of clinical trials (1). The aim of clinical studies of diagnostic tests should be to provide information regarding the diagnostic accuracy of the proposed test although, this is not always possible.

A few considerations regarding the levels of evidence in imaging studies may be instrumental in reading this chapter and are summarised herewith.

Imaging of parameters with known prognostic value (e.g. PVR)
- The first issue is to prove that imaging studies image what they are supposed to image. Although the issue may be trivial in case of PVR imaging or anal sphincter imaging, the issue is relevant in other areas (eg: enterocele imaging) and should be approached by using imaging in cadavers or other approaches such as intraoperative confirmation of the observed condition as a gold standard.
- When the imaging is quantitative, accuracy versus a quantitative gold standard technique should be provided. When the imaging is qualitative (e.g. presence or absence of vaginal vault prolapse) the diagnostic value should be provided (sensitivity, specificity, positive and negative predictive value, accuracy, interrater and intrarater variablity).
- Once validity has been proven, one can assume that the predictive value of the imaging study is equal to that observed for the parameter measured with the gold standard. The same applies to its value for patient management.

Imaging of parameters with unknown prognostic value (e.g. MRI of the pelvic floor)
- When the imaging is qualitative (eg: intact versus damaged levator ani), once validity is proven, the diagnostic value should be investigated providing sensitivity, specificity, positive and negative predictive value, accuracy, interrater and intrarater variability in cadavers or patients undergoing surgery.
- Once validity is proved, the prognostic value for patient management should be investigated.
- Confirmation of the proposed imaging study by independent groups is required ideally for both validity and prognostic value

or at least for the latter parameter (we can assume that confirmation of the prognostic value is obtained, validity of the imaging technique can be inferred).

II. IMAGING IN URINARY INCONTINENCE AND PELVIC FLOOR DYSFUNCTION

This is a broad area that often requires a multiprofessional and muldisciplinary approach. The patient population is heterogenous including children, female and male subjects suffering congenital malformation of the genital and urinary tract, neurogenic disorders, iatrogenic conditions and traumatic lesions. Clinical guidelines always refer to the so called “standard patient” but the majority of subjects referred to secondary and tertiary referral centres cannot be defined as such and their management sometimes requires deviation from guideline recommendations. The large variability and the uniqueness of the observed cases may justify the adoption of a knowledge-based management in the absence of proven clinical benefit. Research on imaging of urinary incontinence (UI) and genital prolapse remains very active. Although all guidelines recommend not to use imaging in the evaluation of the standard patient, many clinicians believe this is an ideal adjunct to physical examination in evaluating the anatomical condition of the individual subject.

1. IMAGING OF THE UPPER URINARY TRACT

Urinary incontinence is defined as the complaint of any involuntary leakage of urine, it can be urethral or extraurethral (1). This latter condition either results from congenital anomalies such as ectopic ureters (inserting in the female distal urethra or vagina), iatrogenic or traumatic conditions such as fistula. In some patients, lower urinary tract dysfunction (LUTD) causing UI, might compromise the transport of urine from the kidneys to the bladder resulting in hydronephrosis and renal failure. The relationship between high bladder storage pressure and renal deterioration was first identified in myelodysplatic children and then considered to apply in all neurogenic patients (2) and automatically transferred to male and female patients with or without neurogenic problems; the value of 40 cmH2O of bladder pressure as threshold value at which the upper urinary tract (UUT) is at risk should therefore be used with caution. In male patients, chronic retention of urine can be associated with UI and lead to chronic renal failure. Lewis et al. reported that renal function at baseline and at the time of catheterisation were significantly worse in patients with chronic retention than with acute retention (3). Therefore, UUT imaging is needed in patients with urinary retention, especially with chronic retention. In women, severe urogenital prolapse may cause angulation of the pelvic ureter by the uterine arteries leading to hydronephrosis (4)

1.1. Indications

Generally speaking, there is no need for UUT imaging in patients with UI unless any of the previously described conditions is suspected or diagnosed. In children with extraurethral incontinence imaging of the UUT helps to identify the underlying cause.

The objectives of UUT in the incontinent patient are as follows:

- Evaluation of the UUT when the presence of an ectopic ureter or ureterovaginal fistula are suspected.
- Evaluation of the kidneys whenever UI is related to bladder dysfunction with high storage pressures (e.g. in neurogenic voiding dysfunction, chronic retention with overflow or low compliance bladders)
- Exclusion of hydronephrosis in cases of UI associated with severe uterine prolapse.

1.2. Techniques

UUT imaging modalities include intravenous urography (IVU), ultrasound sonography (USS), computerized tomography (CT scan), magnetic resonance imaging (MRI), and isotope scanning. No data regarding reproducibility, specificity, sensitivity, positive and negative predictive value in relation with the diagnosis and management of UI are available. The choice of the imaging modality also depends on availability, expertise, and local management policies. Generally speaking, low cost and low risk techniques such as USS are preferred. Unless otherwise described, the following considerations regarding the different imaging modalities are based on expert opinion.

1.2.1. Ultrasonography

USS is the gold standard technique for primary imaging of the UUT because of the relatively low cost of the equipment and the examination, its wide availability, the lack of any exposure to ionizing radiation. Renal USS is independent on kidney function and provides a good evaluation of kidney morphology. Concomitant renal disorders such as urinary lithiasis and neoplasms can also be diagnosed. In patients with LUTD, the detection of hydronephrosis is of importance and it can be related to either vesico-ureteral reflux or obstruction. USS is used for the first line evaluation of the UUT conditions in neuropathic patients. Sixteen percent of chronic spinal cord injured patients with hyperreflexic bladder had UUT deterioration revealed by USS, while 17.5% of patients with areflexic bladder also had it (5). UUT deterioration more frequently occurred in hyperreflexic bladder with higher reflex detrusor contraction pressure (115 vs. 72 cm H2O) mostly accompanied by type 3 detrusor external sphincter dyssynergia, and in areflexic bladder with higher storage detrusor pressure (58 vs. 24 cm H2O). In patients adequately managed with clean intermittent catheterization annual USS monitoring without routine urodynamic testing was suggested to be an effective surveillance strategy (6). UUT deterioration was demonstrated in 70 of 193 myelodysplastic patients who underwent USS, voiding cystourethrography, DMSA scan, and urodynamics at three years old (7). The sensitivity and specificity for UUT damage were 91.4%and 22.3% in DLPP >20 cm H2O, 77.1% and 32.0% in DLPP>30 cm H2O, and 52.9% and 51.8% in DLPP >40 cm H2O, respectively. Therefore, a DLPP cut-off value of 20 cm H2O showed a higher sensitivity to predict UUT damage instead of 40 cm H2O. In the cross-sectional survey of Dutch urologists 91.5% of them performed USS at least once every 1-5 years during the follow-up of adult myelodysplastic patients (8).

USS is also used to detect hydronephrosis in prolapse patients. Hydronephrosis was revealed by USS in 5%-50% of patients with pelvic organ prolapse (POP) that reconstructive surgeries were indicated for (9). The proposed mechanisms for hydronephrosis are 1) ureteric compression between the uterine body and the urogenital hiatus, and 2) ureteral kinking caused by the cardinal ligament (9). It was reported that hydronephrosis occurred in 12.6%-22.4% of patients with severe ureterovaginal prolapse as well as 3.9%-7.1% of patients with severe vault prolapse, indicating that hydronephrosis developed after hysterectomy (10, 11). It was supposed that the ureters may be pulled down and kinked by the downward traction of prolapse upon the bladder (9). Dancz et al. reported that 30.6% of their POP patients had hydronephrosis,

and that Ba-point (OR 1.68, 95% CI, 1.22-2.12), not C-point, and maximum cystometric capacity (OR 1.50, 95% CI, 1.08-2.07) were associated with hydronephrosis on a multivariate analysis (9). On the other hand, Beverly (11) and Gemer (12) reported that 7.7% and 17.4% of patients, respectively, had hydronephrosis, and that uterine prolapse was associated with hydronephrosis on multivariate analysis (OR 3.8, 95% CI, 1.4-10.5 and OR 1.9, 95% CI, 1.1-3.2, respectively). The presence of hydronephrosis do not affect the surgical procedures for POP repair and hydronephrosis improves in 70-100% of patients after surgery (10, 13). Therefore, USS should be performed in women with advanced POP, especially when surgical intervention is not indicated or delayed (9). Although, no strict correlation exists between the degree of dilatation and the severity of obstruction, the grade of hydronephrosis is correlated with the extent of cortical damage (14). In children, kidneys with a pelvic diameter >20 mm are considered to be at risk for deterioration and require intervention (15). Measurement of the resistive index in the interlobar and arciform arteries of the kidney has been proposed for the diagnosis of urinary obstruction but this is rarely used in the evaluation of the incontinent patient (16). Whenever hydronephrosis is diagnosed on USS, other imaging modalities are often used to evaluate renal function, the degree of obstruction or vesico-ureteral re ux. USS is an ideal technique to follow the degree of hydronephrosis over time or the response to treatment.

1.2.2. Intravenous Urography

IVU is the original radiographic examination of the UUT which allows evaluation of UUT anatomy and function. Recent Canadian guidelines recommended that a serum creatinine level (SCr) should be obtained, and an estimated glomerular filtration rate (eGFR) should be calculated within 6 months as an outpatient who is stable or within 1 week for inpatients and patients who are not stable (17). Patients with an eGFR of ≥60 mL/min have an extremely low risk of contrast-induced nephropathy (CIN) (17). Fluid volume loading remains the single most important measure, and hydration regimens that use sodium bicarbonate or normal saline solution should be considered when GFR < 45 mL/min in patients who receive intravenous contrast (17). Patients are most at risk for CIN when eGFR< 30 mL/min (17). Additional preventative measures include the following: avoid dehydration, avoid contrast medium (CM) when appropriate, minimise CM volume and frequency, avoid high osmolar CM, and discontinue nephrotoxic medications 48 hours before administration of CM (17). Also, Japanese guidelines showed that chronic kidney disease (CKD, eGFR< 60 mL/min/1.73 m2) is the most important risk factor to predict the risk of CIN in patients receiving iodinated contrast media (18). In addition, aging and diabetes associated with CKD are risk factors for the development of CIN (18). Recent systematic review recognised pre-existing CKD, diabetes, age, and cardiovascular comorbidity as risk factors (19). The existing guidance documents agreed in recommending pre-hydration as the main preventive measure, but there was difference in recommended total volumes, composition, rate and duration of the infused solutions (19). There was no consensus on the use of sodium bicarbonate and none recommended N-acetylcysteine as solitary preventive measure (19). Recent guidance documents recommend avoiding hypertonic contrast media, but did not recommend preference of iso-osmolar over low-osmolar contrast media (19). During IVU successful examination is dependent upon adequate renal capacity to concentrate urine, the poor concentration capacity of an impaired kidney limits the possibility to delineate the collecting system. A number of different conditions such as renal dysfunction, obstruction, congenital anomalies, fistula, stones and tumors may be detected. IVU is the appropriate first study in cases of extraurethral incontinence. When ectopic ureter is suspected (although this condition can also be responsible for urethral incontinence), delayed films and tomography are important because the renal unit or moiety associated with an ectopic ureter is often poorly functioning. In fact, IVU is sometimes unable to detect a small, malfunctioning moiety associated with a duplication and ectopic ureter or a poorly functioning or abnormally located kidney with a single ectopic system (20-22). In such cases where the diagnosis of ectopia is still suspected after IVU, another imaging modality such as CT, MRI or isotope scanning should be considered (23- 25). IVU is the appropriate first imaging study when uretero-vaginal fistula is suspected, usually after pelvic surgery. Typically, one sees ureteropyelocaliectasis proximal to the level of the fistula. This finding has been reported in 84-92% of cases (26, 27). Sometimes extravasation can be seen. Confirmation of the presence of the fistula, its size and exact location is often obtained with retrograde ureteropyelography.

1.2.3. Computerised Tomography (CT scan)

High quality information of the UUT anatomy can be obtained using multidetector helical CT scans and 3D reconstruction software. Differently from IVU which only acquires images in the anteroposterior or oblique CT acquires images in the axial plane. Pictures can then be reconstructed in 2D along any plane or in 3D when- ever required. CT scan can be used irrespective of renal function when no iodinated contrast medium is used. Whenever hydronephrosis is present, urine can be used to delineate the collecting system reducing the need for contrast agents. In general, intravenous contrast medium is required to highlight specific anatomic characteristics. CT scan is often used after the first line evaluation with USS and it has replaced IVU almost entirely. Several authors have reported the use of CT scan to detect ectopic ureter, in cases where the diagnosis is suspected, despite a normal IVU and ultrasound (28). In these cases the small size and poor function of the ectopic moiety make diagnosis difficult by IVU.

1.2.4. Magnetic Resonance Imaging (MRI)

MRI shares some of the advantages of CT over IVU in the evaluation of the UUT. Furthermore acquisition can be performed along any plane and pictures can then be presented in a 2D or 3D fashion. The paramagnetic contrast medium is free of allergic reaction risk although its use in the UUT remains dependent upon renal function and concerns about its nephrotoxicity have been recently raised (29). Low risk gadolinium contrast agents should be the choice, and dosage should be kept to a minimum, as higher doses have been linked to the development of nephrogenic systemic fibrosis (NSF)(30). While a pre-existing pro inflammatory state in the renal impaired is a high risk factor, liver insufficiency in itself is not a contraindication; however, patients may also have coexisting renal insufficiency and thus carry a risk of NSF (30). The development of the uro-MRI technique has gained an increasing role for the technology in the evaluation of hydronephrosis and urinary tract anomalies as an alternative to IVU. The use of MRI in the diagnosis of ectopic ureter has recently been described (31-35).

1.2.5. Isotopes

Isotopes are used primarily to examine morphological and functional characteristics of the upper urinary tract. Isotope scanning can be used to identify the location of a small kidney which is otherwise difficult to image with radiological techniques. Renography is used to examine the differential function of the two kidneys, to identify disorders of urine transit and to quantify obstruction of the upper urinary tract. There are many physiological factors and technical pitfalls that can influence the outcome including the choice of radio-nucleotide, timing of diuretic injection, state of hydration and diuresis, fullness or back pressure from the bladder, variable renal function and compliance of the collecting system (36, 37). Diuresis renography with bladder drainage is recommended when obstructi-

ve uropathy is suspected (38). Renal scintigraphy may be useful in the evaluation of ectopic ureters associated with hypoplastic kidneys (39). Detection rates of dysplastic kidney in single system ectopic ureter were 95.5% on DMSA, 95.5% on CT scan, 50% on USS, and 50% on MRI (40). DMSA would be a preferred option in this setting, because of its high detection rate and not requiring contrast medium.

1.2.6. Conclusions

Imaging of the UUT is rarely required in UI unless the condition originates from a malformation, a traumatic or an iatrogenic problem of the UUT. More rarely a condition of the lower urinary tract may endanger renal function, the preservation of which is required to guarantee a normal life expectancy in patients with UI.

1.2.7. Consensus Statement

- Imaging of the UUT is NOT indicated in the evaluation of non-neurogenic stress, urgency or mixed UI. (**Level of Evidence 3, Grade of Recommendation C**)
- Imaging of the UUT is indicated in cases of:
  - neurogenic UI with high risk of renal damage (due to high storage and/or voidingdetrusor pressure, e.g. myelodysplasia, spinal cord injury) (**Level of Evidence 3, Grade of Recommendation C**)
  - chronic retention with UI (**Level of Evidence 3, Grade of Recommendation C**)
  - severe uterine prolapse, vault prolapse, or anterior vaginal wall prolapse, especially when surgical intervention is not indicated or delayed (**Level of Evidence 3, Grade of Recommendation C**)
  - suspicion of extra-urethral UI by upper tract anomaly (**Level of Evidence 3, Grade of Recommendation C**)
- The choice of the imaging techniques and their sequence depend on the clinical question and their availability. The least invasive techniques should be preferred and should precede the more invasive, also taking into consideration cost effectiveness. (**Level of Evidence 3, Grade of Recommendation C**)

1.2.8. Suggested Research Areas

Prevalence of upper tract deterioration in various UI populations

- Natural history of upper tract changes
- Relation between upper tract dilation imaging, renal damage and bladder function

2. IMAGING OF THE LOWER URINARY TRACT

The use of imaging of the LUT in patients with UI dates back 40 years more than that e.g. Jeffcoate 1950's, particularly in female patients. The techniques have changed, over the decades from static to dynamic imaging, from qualitative to quantitative information. Although some of the techniques are now more than 50 years old their clinical value remains at best, unclear.

2.1. X-Ray Imaging

Voiding cystourethrogram (VCUG) was the mainstay of x-ray imaging of the LUT but it has been replaced almost entirely by USS because of its ease of use, low cost and availability. While CT has not gained acceptance because of the exposure of ionising radiation, MRI took the lead as the most promising imaging modality because it offered a comprehensive view of the pelvis and enabled visualisation of the position of visceral organs in relation to bony reference points. 3D/ 4D USS offers volume acquisition with limitations in the depth of ultrasound wave penetration and the volume that can be imaged. Progressive technical developments in imaging technology and techniques have made this research area particularly interesting.

In males the purpose of voiding cystourethrography has been mainly to locate infravesical obstruction separating the bladder neck from benign prostatic obstruction although it may play a role in the management of post-prostatectomy incontinence (1). In children the diagnosis and classification of reflux and diagnosis of posterior urethral valves have been the primary goals (2). The severity of the vesicoureteric reflux on one side determines the development of contralateral reflux and indicates a poorer resolution rate for reflux (3).

Female urethral diverticula can be diagnosed with positive-pressure urethrography which is more sensitive than voiding cystourethrography (4-6). MRI is the gold standard for the diagnosis of diverticula and planning surgical repair (7, 8). Pelvic floor ultrasound has also been shown to demonstrate urethral diverticula as clearly as MRI (9). Ultrasound is known to be operator dependent. High frequency (5-9MHZz) transvaginal probe with 3D function can offer good visualisation of urethral diverticula.

The rationale for imaging studies of the lower urinary tract in this field derives from the hypothesis that stress UI is caused by urethral hypermobility. This was the theoretical basis of the classification of UI published by Green in 1968 and then modified by Blaivas and Olsson in 1998 (10, 11). Investigation into cohorts of continent and incontinent patients failed to provide evidence to support the hypothesis and imaging techniques aiming at measuring bladder neck displacement during straining have been abandoned. The same applies to outcome research in urinary incontinence where surgery that limits bladder neck displacement does not necessarily lead to cure of the condition. A renewed interest derived from the availability of USS which took imaging out of the radiology suites and moved it into the urological and gynaecological outpatient clinics opening new opportunities for clinical research in this field. The possibility of imaging what was usually perceived during physical examination such as bladder neck mobility or POP increased the usefulness of USS. Research in the field of MRI first assessed the possibility of fast dynamic acquisition to image the displacement of visceral organs during effort to better quantify POP and then the morphological imaging of the pelvic organs muscular support to investigate the physiopathology of genital prolapse.

2.1.1. Female Cystourethrography

X-ray imaging of the urinary bladder and urethra has been used to assess the female urinary tract in women suffering UI to evaluate urethral/bladder neck hypermobility and to assess associated conditions such as urethral obstruction, vesico-urethral reflux, diverticula, fistulae, stones and tumours. In males, the purpose of voiding cystourethrography has been mainly to locate infravesical obstruction (1, 12).

The diagnosis and classification of reflux and diagnosis of posterior urethral valves in children have been the primary goals (2). In a study comparing cystourethrography with direct radionuclide voiding cystography and voiding urosonography with contrast medium were compared. Voiding sonography and direct radionuclide voiding cystography were shown to be the most sensitive (13).

2.1.1.1. Background

History and methodology of cystourethrography in females had been reviewed by Olesen (6). The technique is now over 80 years old. Voiding cystourethrography with lateral projection was first done by Mikulicz-Radecki in 1931 (14). The use of a metallic bead chain to identify the urethra was introduced by Stevens and Smith in 1937, and in 1956 Ardran, Simmons and Stewart reported on a cinematographic technique with contrast media also in the vagina and rectum (15, 16). In an attempt to combine qualitative and quantitative information regarding the function of the lower urinary tract, the combined used of fluoroscopy and pressure-flow recordings was proposed during the nineteen sixties and seventies (17-21).

2.1.1.2. Methodology (projection, positioning and exposures)

Bladder neck displacement is best viewed and quantified in true lateral projection although image quality is sometimes poor because of the increased body mass and the overlap of bony structures with the bladder neck area. Consequently, oblique projections are sometimes used notwithstanding the lack of quantitative information. Achieving a quasi-physiological voiding in a radiology suite is difficult because of the inevitable impact of the environment. The use of a sitting position is recommended for micturition studies as voiding while standing or lying will increase the embarrassment and therefore many impair the quality of the examination (14). Especially in patients with large body mass index, imaging of female urethra in a true lateral projection is difficult, it necessitates high radiation doses as the central x-ray beam must penetrate the trocanteric regions and further because the urethrovesical junction is sometimes overshadowed by the lateral parts of the bladder. A significant improvement in this area has been brought about by digital imaging which allows the subtraction of the bony structures. The position and mobility of the urethrovesical junction as well as urine leakage are supposed to be influenced by the filling volume as has been demonstrated on ultrasonography and leak point pressure measurements (22, 23). However, in VCUG the bladder is filled to capacity. Addition of a urethral bead chain or catheter and vaginal contrast to improve the visualisation of the urethra, bladder neck and trigone has been abandoned. Contrast in the rectum is not necessary for urinary incontinence purposes. Exposures at rest should be supplemented with provocative manoeuvres to test bladder neck mobility by contracting and relaxing the pelvic floor (e.g. coughing, straining, and squeezing). Whenever possible, pictures while the patient is voiding should be obtained. It is important to consider that coughing and straining result in a different effect on the pelvic floor. Straining might be associated with relaxation or contraction of the pelvic floor, and the imaging can change accordingly.

During coughing there is a reflex contraction of the pelvic floor, but coughs are of a short duration and difficult to capture on spot films. Bladder suspension defects were diagnosed at rest in 49% of 420 examinations, while coughing and micturition disclosed a further number of 20% and 4% respectively (14). Squeezing can demonstrate pelvic floor awareness and contraction (24).

2.1.1.3. Combined imaging and urodynamics

Videourodynamics has been regarded by some as the “gold standard” in the evaluation of LUTD (24). Reproducibility of the combined examination has not been assessed and further the radiation dose has to be considered (16, 21, 25-27). One study has attempted to compare videourodynamics with saline cystometry (24). Independent observers carried out the two procedures with 75 women having the saline cystometry first and a further 75 women had videourodynamics first. The degree of bladder descent noted on screening was greater than on clinical examination. Nineteen women had trabeculation and a further 11 women had bladder or urethral diverticula, urethral stenosis and vesicoureteric reflux (1, 12, 15). Only seven of the eleven women could have been predicted by a selective imaging policy based on history alone which would image 43% of the 150 women. This suggests that a selective policy of screening will unnecessarily expose patients to radiation while not using the optimal technique for investigation for all patients who need the test. Nevertheless simultaneous videomonitoring along with tracings of pressure and urine flow rate are important to ensure that the exposures are made at appropriate moments so that the radiographs can be representative of the various functional states (14, 19, 28, 29).

Patients with Parkinson’s disease and multiple system atrophy are best evaluated by videourodynamics with sphincter motor unit potential analyses to identify the characteristic features of these conditions including: external sphincter denervation, neurogenic sphincter motor unit potentials, open bladder neck at rest and detrusor-external sphincter dyssinergia (30). Neurogenic patients show severe bladder trabeculation with diverticula and pseudodiverticula, pelviureteric reflux, widening bladder neck and proximal urethra, and narrowing at the level of the membranous urethra can suggest, the presence of neurogenic dysfunction of the lower urinary tract (occult spinal dysraphism, non-neurogenic neurogenic bladder (Hinman syndrome)) even in the absence of neurogenic symptoms and signs (31-33). Urodynamic parameters in children do not discriminate between those with or without vesicoureteral reflux thus videourodynamics has been considered essential. Additionally children with non-neurogenic voiding dysfunction are found to have a number of abnormalities with videourodynamics (34, 35). Indications for videourodynamics include previous continence and vaginal surgery, neurological disorders and suspicion of urethral diverticula.

2.1.1.4. Normal and defective bladder support

The whole issue about the clinical value of VCUG is about the pathophysiology of defective bladder support in the pathophysiology of SUI in female patients and the relation between the surgical correction of such a defect and cure. The concept of urethral hypermobility was central to the classification of SUI and the concept that impaired transmission of abdominal pressure to female urethra could be responsible for the observed leakage. Little remains regarding the concept of urethral hypermobility in a modern view of female SUI and this contributed to the decreasing use of VCUG in the evaluation of a standard female patient.

The normal resting bladder has a smooth surface although bladder trabeculation is often seen in elderly women and not necessarily related to any pathological condition. The internal urethral orifice is located just above a horizontal line through the lowermost part of the symphysis in a coronal projection. The urethra is straight and runs anteriorly and caudally toward the external meatus.

On coughing and straining, relaxation of the pelvic floor results in downward movement of the bladder neck, which can be associated with a backward movement of the bladder neck resulting in a change in urethral axis. Squeezing (and sometimes also straining) results in contraction of the pelvic floor muscle with a cranial movement of the bladder neck. During voiding the bladder base is usually lowered about 1 cm, the angle between the urethra and the trigone is straightened, making a funnelled appearance of the proximal urethra and the bladder base, the bladder contour is rounded and a fine sawtooth irregularity of the mucosa becomes visible above the trigone. Angles and distances between the urethra, bladder base and symphysis pubis have been assessed radiologically. The following parameters have been assessed for reliability:

1. The posterior urethrovesical angle (PUV) is defined by lines along the posterior urethra and the trigone (36). Cut off values were usually 115° or more (37, 38);
2. The urethral inclination is between the proximal urethral axis and the vertical plane, which is a plane outside the patient and, therefore, the angle also varies with pelvic inclination. In Green type I and type II descent the angle is less or more than 45° respectively (38);
3. The urethropelvic (UP) angle is measured during voiding as the anterior angle between a line through the middle of the internal urethral orifice and the urethral knee and a line through the posterior surface of the symphysis through the lowermost part of the obturator foramen closest to the film. In normal subjects the mean UP is about 95° and the cut off point for bladder descent are values below 70° (14);
4. Symphysis orifice (SO) distance is measured at rest as the distance on a horizontal line from the symphysis to the internal urethral orifice. Normal values are 31 ± 6 mm (mean ± SD) and values less than 20 mm are the cut off points for descent (14);
5. The urethral axis at rest (UAR) and during straining (UAS)

Funnelling of the proximal urethra and flatness of the bladder base (both anterior and posterior to the internal urethral orifice) and the most dependent portion of the bladder base (the urethrovesical junction or a point posterior to that) are important qualitative parameters estimated on straining films (37).

Anterior bladder suspension defects or bladder base insufficiency (BBI) is defined as SO < 20 mm with a normally positioned vagina at rest, during coughing or micturition and/or funnelling of the bladder base at rest or with coughing. BBI can be graded 1-3, which corresponds to Green's type I descent (14, 39). The supportive defect is supposed to be in the fascial and ligamentous system and their abnormal detachments (eg., paravaginal defects).

Posterior bladder suspension defects are defined as a posterior-inferior bladder displacement and a UP of less than 70° (14). It corresponds to Green's type II (40). Sometimes only the trigone and posterior part of the bladder is involved. The supportive defect is supposed to be in the muscular pelvic floor, that is, the pubo-vesical part of the pubococcygeus muscle or in paravaginal detachment.

Interestingly, when UAR and UAS were examined in a group of 76 continent women and correlated with age, a perfect linear regression was noted between UAR and age (R^2= 0.28). Patients with stress urinary incontinence were found to have an average UAR value of 25° with a mean UAS of 43° leading to a threshold value of hypermobility of about 20°. When standing cystourethrograms were repeated 3 to 6 months after surgery for SUI, UAR and UAS values were found to be close to normal suggesting a relation between the correction of the defective bladder support and cure (40). A more structured definition of cystocele (ranked by height in centimetres) was also obtained, adding to the emerging data that the reliability of the pelvic organ prolapse quantification (POP-Q) system increases when measurements are performed in a more upright position (40).

2.1.1.5. Reproducibility

The observer variation has been evaluated in four university uro-gynecological units (Table 1) (24, 37, 41, 42). The inter-observer agreement was 43-79% and the intra-observer agreement was 53-99%. These figures are in the same range as has been found for other diagnostic tests (43).

2.1.1.6. Accuracy for the diagnosis of SUI and post-operative results

Evaluation of accuracy is the mainstay in the evaluation of a diagnostic technique. The sensitivity and specificity of a diagnostic technique depend on intrinsic factors such as reproducibility (as measured by intraobserver and interobserver variation) and extrinsic factors such as the characteristic of the patient cohort used to assess accuracy.

The accuracy of the previously mentioned radiological criteria have been measured by comparing imaging data with the 'so called' index-test which in this case was a clinical diagnosis of urodynamic stress incontinence and expressed as specificity and sensitivity or as predictive values. Unfortunately, the diagnosis of SUI is controversial and might be based on subjective criteria, urodynamic tests, or measurement of leakage. Even radiological criteria have been included in the diagnosis.

Reproducibility (e.g. test-re-test agreement) has not been measured, but intra- and inter-observer variation has been calculated and adjusted for expected chance agreement (kappa coefficient). The predictive values and the kappa coefficient are supposed to depend on the prevalence, and therefore, comparison between different materials are difficult (43).

No consensus has been reached in the peer-review literature as to the lack of discriminant value of VCUG between SUI and continence, the majority of published papers are consistently negative although new promising data have been published (38, 40, 44-46).

The specificity of 5 radiological parameters on static bead chain VCUG was 44-76% and the sensitivity 53-100% (46, 47). Neither was the degree of SUI correlated with the type or degree of suspension defects (24, 41, 48). The positive and negative predictive values for a bladder suspension defect were 0.70 (95% C.I.: 0.62-0.78) and 0.52 (95% C.I. 0.41-0.63) respectively on voiding colpo-cystourethrography (39, 49). In a later publication on 159 women, positive and negative predictive values of 0.56 and 0.74 were obtained (46). Evaluation of the urethral angle at rest and during stress in controls and in patients with SUI and various grades of anterior vaginal prolapse show a significant relationship between UAR and aging (from 2.4° ± 14.9° in the third decade to 29° ± 9.2° in the 9th decade; r^2= 0.28). In patients with SUI, UAR and UAS decreased from 25.7° ± 13.6 ° and 42.6° ± 15.9° to 16.6° ± 14.7° and 23.8° ± 17.5°, respectively; the observed changes were found to be statistically significant. A similarly significant difference was found in patients with moderate to grade 3 cystocele and urethral hypermobility (at least 5 cm descent of the bladder base below the inferior ramus of the pubic symphysis on the lateral view of a standing VCUG): UAR and UAS decreased from 48.1° ± 16.5 ° and 64.4° ± 16.8° to 22.3° ± 26.9° and 29.8° ± 22.8°, respectively.

Comparison of a randomly selected control cohort (aged-matched) with patients suffering SUI showed a significant difference of UAR and UAS at diagnosis while similar values were found after surgery. This was similar to patients with grade 3 cystocele in whom both UAR and UAS were significantly different from controls at baseline while showed similar values in the postoperative follow-up.

Measurement of the cystocele height obtained as the distance between the inferior border of the pubic symphysis and the inferior edge of the cystocele in controls and patients with mild and severe cystocele showed a significant difference between the two cohorts (16.63 ± 10.9 versus 27.4 ± 12.3 mm versus 73.4 ± 15.6 mm, respectively). Following formal cystocele repair, a significant change

Table 1: Inter- and intra-observer variation (agreement) on cystourethrography in females with urinary incontinence

Type of examination, patients and observers	Inter-observer variation	Intra-observer variation
Bead-chain [1] stress & urgency incontinence n°92 3 observers on 5 landmarks	45.8-80.7 %	
VCCU [2] stress incontinence n° 52 1 observer on type of descent	79% 95% c.l. 65-89	
VCCU [3] stress incontinence n° 29 2 observers on type of descent	70% 95% c.l. 75-89	53% 95% c.l. 27-78
VCCU [4] n° 93 stress & urgency incontinence 6 observers on type of descent	43-60% kappa 20-39%	72-99% kappa 57-98%
VCUG [5] Stress incontinence n° 11 2 observers on urethral angle shift from rest to straining	r = 0.83 (p=0.001) for UAR r = 0.82 (p=0.002) for UAS	

[1] static bead-chain cystourethrography with straining (37). The 5 landmarks were the posterior urethrovesical angle, urethral inclination, funnelling of the proximal urethra, flatness of the bladder base and most dependent position of the bladder base;
[2] voiding colpo-cystourethrography (VCCU) at rest and with coughing, straining, micturition and squeezing; one observer against original diagnosis (that is, normal appearance or anterior, posterior or combined suspension defects) made by a few senior radiologists (23);
[3] voiding colpo-cystourethrography at rest and with coughing, straining, squeezing and micturition. Possible diagnoses were: normal appearance or anterior, posterior or combined descent respectively (42).
[4] voiding colpo-cystourethrography at rest, coughing, with holding and voiding. Possible diagnoses were: normal appearance and anterior or posterior descent respectively (41);
[5] standing voiding cystourethrography, urethral angle was measured at rest (UAR) and during straining (UAS) (40).

of cystocele height values was found in patient with mild and severe cystocele (from 27.4 ± 12.3 mm to 13.9 ± 18.0 mm and from 73.4 ± 15.6 mm to 25.4 ± 24.6 mm, respectively (p<0.001).

These are the first data supporting the use of standing VCUG as an outcome measured, previous peer-review papers suggested the inability of its technique to distinguish postoperative failures from success (14, 24, 43, 45, 47, 50-53).

2.1.1.7. Comparison of cystourethrography and ultrasonography

The development of USS techniques for the evaluation of the lower urinary tract raised the question of the relationship between X-ray and USS imaging. Static bead chain cystourethrography has been compared with transrectal and perineal USS and voiding colpo-cystourethrography has been compared with perineal USS (47, 48, 54, 55). The findings correlated well regarding bladder neck position and mobility, PUV, urethral inclination, SO distance and rotation angle.

Specificity, sensitivity and interobserver agreement were also comparable for the two methods. All the authors seem to prefer the sonographic modality because imaging can be performed at the same time as the physical examination. This has also been the case in men with neuromuscular dysfunction (12). Simple and extensive funnelling is more easily imaged in upright patients during cystourethrography than in the supine position frequently used for ultrasound studies (31).

2.1.1.8. Comparison of cystourethrography and MRI

The introduction of MRI in the assessment of the LUT required adequate comparison of this technique with standard X-ray imaging. The comparison of cystourethrography and colpocystourethrography with dynamic MRI showed comparable data on bladder neck position and cystocele extension (56, 57). Although there is an obvious concern about the fact that dynamic MRI imaging is usually performed with the patient lying in a dorsal lithotomy position, comparison of standing and lying colpocystourethrography did not show any significant difference (57).

2.1.1.9. Conclusions

VCUG does not have a major role in the evaluation of the standard female patient with UI confirmatory results on the clinical utility of measuring urethral angle and cystocele height in patients with UI and POP who are scheduled for surgery still missing. Defective bladder support can be diagnosed on VCUG with a reliability comparable with other diagnostic tests.

Dependent on local facilities the method might be considered if the choice of a surgical procedure is based on type and degree of supporting tissue deficiencies and possibly if new procedures are evaluated for the ability to restore this deficiency.

2.1.1.10. Consensus statement

Cystourethrography is NOT indicated in primary uncomplicated stress, urgency or mixed female urinary incontinence (***Level of Evidence 3, Grade of Recommendation C***).

Cystourethrography may be a reasonable option in the preoperative evaluation of complicated or recurrent female urinary incontinence (***Level of Evidence 3, Grade of Recommendation C***).

2.1.1.11. Suggested Research Areas

Variation of VCUG parameters in patients with USI +/- ISD and prognostic value for surgical repair.

VCUG parameters in re-do surgery for USI compared with controls

2.2. Ultrasonography

The pelvic floor structures that can be visualused include the urethral sphincter, anal sphincter and perineal body. Ultrasonography has been used in the evaluation of urinary incontinence as early as 1980 (58). Over the past three decades the quality of the ultrasound image and its processing has improved beyond what could have been imagined during the 70's. Various new developments, such as the use of contrast medium, colour Doppler, 360° degree transducers and 3D and 4D imaging have been introduced and have led to the more widespread use of ultrasonography in the evaluation of the lower urinary tract and pelvic floor disorders.

There is a good correlation between ultrasound and x-ray evaluation of urinary incontinence (59-68). In particular, the position of the bladder neck at rest and during Valsalva manoeuvre has frequently been compared (67, 69), and all authors agree on a good correlation. Some authors even found better accuracy for ultrasound (62), especially in obese women (59). Ultrasonography is cheaper than X-ray imaging, it is often preferred by physicians because the imaging studies can be performed in their own office as part of the physical examination. Ultrasound requires the probe to be in direct contact with the patient at all times for the images to be acquired including during dynamic manoeuvres. Overall, ultrasound is highly acceptable to patients, because it does not involve radiation, particularly when compared to comparable imaging modalities for the posterior compartment.

2.2.1. Types of Ultrasonography

Different imaging approaches have been used for pelvic floor ultrasound, such as transabdominal, transvaginal, transrectal, transperineal and transurethral. Synonyms for the transperineal approach are perineal, introital, labial or translabial access, all use a similar method and there does not appear to be a substantive difference between these terms, a common agreed term needs to be decided upon. See Figure 1 for an example of an image from a 2D mid-sagittal trasnperineal scan in a healthy asymptomatic nulliparous woman.

Abdominal ultrasonography is not helpful in pelvic floo imaging because of the acoustic shadow caused by the pubic bones particularly in the obese patient (58). All approaches in ultrasound have a problem of distorting the tissue being imaged due to compression. With vaginal ultrasonography this risk is highest (70). Perineal ultrasonography allows the visualisation of all three compartments in one image. A study comparing endovaginal, transperineal with fluoroscopic and MRI proctograms, showed that endovaginal ultrasound is the most likely to underdiagnose prolapse, as it may act as a pessary, followed by transperineal ultrasound (71). Fluoroscopic proctography done sitting on a commode was the most physiological and was the most likely to demonstrate the pathology present.

Three-dimensional ultrasonographic systems has increased accuracy in measuring volumes of irregular structures as well as reconstructed images from novel directions and allowing pelvic floor imaging. Three-dimensional ultrasonography was first described for the female urethra in 1999 (72); the three-dimensional image can either be evaluated as a separate entity on the screen, or in combination with each of the two-dimensional planes from which it is derived (**Figure 1**). These three two dimensional planes are orthogonal to each other: the sagittal, coronal and axial planes. Three-dimensional images are built up as a rendered image of a self defined region of interest, major advantages over 2D imaging include the possibility of reviewing the acquired images from any investigator and the ability to analyse the acquired volume through any plane (similar to CT scans or MRI) (**Figure 2**). The disadvantage is that it is time consuming and requires specialist software analysis that is not practical in clinical practice.

The levator ani muscle can be visualised in 3D and 4D ultrasound (73).

The pelvic floor includes the vaginal walls, bladder, urethra, anal canal, perineal body, rectum and puboviscerales muscle (also known as levator ani muscles). The pelvic floor can be visualised with ultrasound and other imaging techniques (non-ultrasound) including X- ray cystourethrograms (74-76), magnetic resonance imaging (56, 77) and defaecation proctography (78). Computer tomography (CT) is not the modality of choice to visualise the pelvic floor. Pelvic

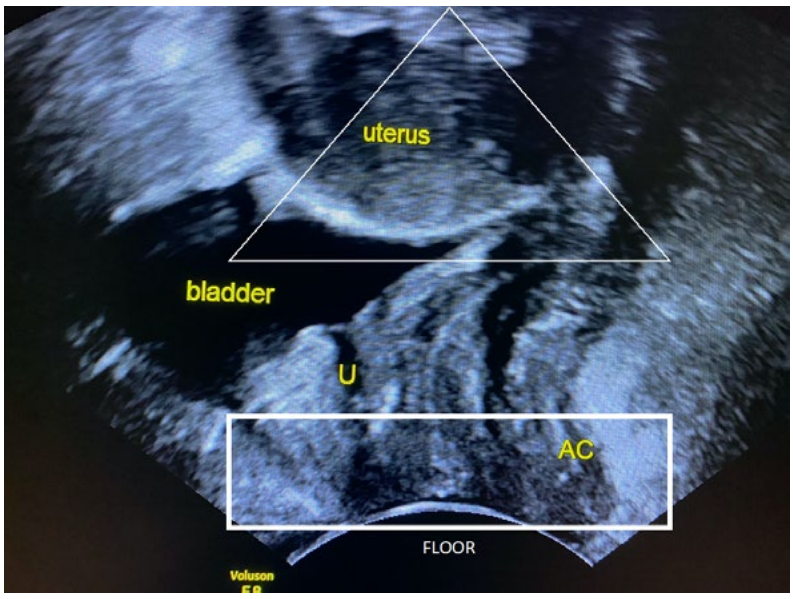

Figure 1. Transperineal ultrasound panoramic view with 2D midsagittal ultrasound. U - urethra. AC -anal sphincter complex.

Figure 2b Perineal midsagittal two-dimensional view. Normal anatomy of the levator ani muscle.

floor imaging, including ultrasound, seeks to diagnose and assess conditions including urethral diverticulum, fistula, surgical and mesh complications. Pelvic floor ultrasound includes transperineal, endovaginal and endoanal techniques (79). A wide variety of techniques have been described for the measurement of different structures on the pelvic floor since the 1980s. Consequently, a wide variety of probes and ultrasound machines have been used. The frequency of the scanning probe can affect the image quality and measurements acquired (80). The detail in the method of measurement and route of scanning (transabdominal, transvaginal or transperineal) can change the data acquired (81). These observations highlight the importance of these considerations when reviewing the literature.

Some techniques require offline analysis with specialist software on a computer away from the scanner. Offline analysis requiring techniques lend themselves mainly for research as this is cumbersome and time-consuming, therefore suitable for use in out-patient clinics. Techniques that can provide bedside data have greater

potential to be applied in clinical practice widely for the benefit of patient care. In clinical practice, the pelvic floor is assessed by the POP-Q score, which has been shown to correlate well with pelvic floor ultrasound assessment (82-84).

Pelvic floor imaging is challenging because of the dynamic pelvic floor organ movement. The dynamic nature of the pelvic floor during Valsalva manoeuvre and pelvic floor contraction, change the measurements acquired during scanning. Maximal Valsalva manoeuvre can produce increasing values on each attempt. An MRI study of repeated maximal Valsalva manoeuvres showed that 95% of women pushed the prolapse further on the second and third attempts (85) with the difference of first and third attempt being more than 2cm (85). Prolapse grade severity appearance has been shown to change on a supine versus a sitting position on MRI (86). The levator hiatus on 3D ultrasound is worse on standing (87). The positional differences are more marked for the posterior compartment (88).

2.2.2. Standardisation

No consensus has been reached as to the standardisation of image orientation. Some prefer orientation with cranial structures below (**Figure 3a**) (72) whereas others prefer presentation of the cranial parts above (**Figure 3b**) (89, 90). All authors agree that the symphysis pubis, and its inferior border in particular, is a well recognisable and fixed reference point. This point can be used in the evaluation of the various aspects of relevant structures at rest and during dynamic imaging. In general, ultrasonographic studies are performed in the supine position, with the knees flexed and comfortably apart (**Figure 4**). Small differences between the supine and standing position of the patient have been documented, although these differences disappeared during a Valsalva manoeuvre (91). Only a few studies have been performed in the standing position (92). There is no clear consensus on the amount of bladder filling, some authors prefer significant bladder filling, others prefer a nearly empty bladder because an empty bladder seems to descend more on Valsalva manoeuvre compared with a full bladder (93). Attempts to standardise Valsalva manoeuvre, ideally with intra-abdominal pressure measurements, has not been widely accepted (94). In one study a peak flow meter has been used where women were asked to “huff” maximally and to reach the same force during a number of “huffs” (92). It has been shown that the mobility of the bladder neck differs between coughing and Valsalva manoeuvre (95). Co-activation of the pelvic floor muscles during Valsalva manoeuvre has been documented and is one of the reasons for the lack of standardisation (95, 96).

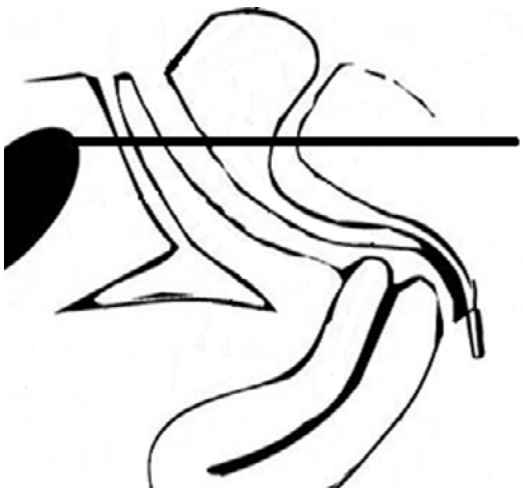

Figure 3a: Perineal midsagittal two-dimensional ultrasound view on three compartments and horizontal reference line according to Dietz.

A= horizontal reference line.
B= central line of the symphysis as reference line for bladder neck descent.

2.2.3. The Urethra and Bladder Neck

When collagen fibres and muscle fibres are located parallel to the ultrasound beam, the structure becomes hypoechoic. These same structures will become hyperechoic, however, when the fibres are located perpendicular to the beam. Ultrasonography may result in variable images of the urethra, since the echogeneity of the structures depends on the position of the transducer in relation to the urethra. This may produce confusing images, especially in the dynamic process of pelvic floor contraction and Valsalva manoeuvre. In the midsagittal plane on perineal ultrasonography, and with normal anatomical position of the urethra at rest, the internal sphincter and inner urothelial layer of the urethra will appear hypoechoic (Figure 1), thus making these structures indistinguishable on ultrasonography. In the midsagittal plane and with normal anatomical position of the urethra at rest, the striated external sphincter or rhabdosphincter will appear hyperechoic, and can hardly be distinguished from the surrounding structures. It will, however, be easily visible as a hyperechoic circular structure in the axial plane as seen on three-dimensional ultrasonography (97, 98). The rhabdosphincter has been found to be thinner dorsally (72), and both ventrally and dorsally (98) by various authors and more difficult to distinguish from the internal sphincter ventrally and dorsally compared with laterally (99). These differences may be due to the approach used to image the structures as well as types of probes applied but this has not been addressed in any study to date.

With the use of ultrasonography, thickness and length of the urethral sphincter muscle can be measured and urethral volume calculated (90, 99, 100).

Intra-urethral ultrasonography has been used for this purpose although complete imaging of the lateral parts of the sphincter are difficult due to the higher frequencies emitted by these probes (101),

Figure 4 Perineal ultrasound examination in the supine position.

others have used two- or three-dimensional ultrasonography of the urethra (72, 97, 98, 102).

Comparison of transvaginal and transrectal approach showed a lower degree of urethral compression with the latter approach (100, 103). Ultrasound measurement of the female urethra has been found to be reproducible (72, 97, 103). Sphincter volume may differ significantly when 2D or 3D imaging is used (97). Urethral volumes, measured by 3D ultrasonography, were positively correlated with the actual volumes in cadavers (99). A significant and positive correlation between rhabdosphincter volumes and symptoms and signs of urinary incontinence has been reported (104); correlation with the urethral pressure profile (UPP) measures has also been found (101, 102) but these data could not be reproduced (105). Ultrasonography imaging during micturition has been explored with the aid of a remote control systems (106). The use of intra-urethral ultrasonography with rotating probes (360°) has been proposed by various authors although no advantages over perineal US could be identified and incomplete imaging appears to be a problem due to the high ultrasound frequency emitted (104, 106-110).

The advantage of preoperative and intraoperative three-dimensional ultrasound scanning in women with urethral diverticula has been outlined by Yang et al (111, 112).

2.2.4. Bladder Neck

The bladder neck and proximal urethra are easily visible on all types of ultrasonography without the need for catheterisation (Figure 1). The terms urethral descent and bladder neck descent are interchangeable. Measurements are usually taken at rest, during straining (Valsalva manoeuvre), and sometimes during a cough and squeeze. The position and movements are measured in relation to the lower margin of the symphysis pubis. The difference between rest and strain is referred to as the bladder neck descent (the distance between the bladder neck and a horizontal line through the lower end of the symphysis pubis) (**Figure 5**). On Valsalva manoeuvre the bladder neck rotates in a posterior and inferior direction away from the symphysis pubis. The axis of the urethra in relation to a vertical or horizontal line can be measured in degrees and provide the degrees of urethral rotation or bladder neck mobility. Other parameters are the posterior urethrovesical angle and the anterior urethrovesical angle.

The first 2D technique for the assessment of urethral descent was described by Schaer in 1995. The Pubis was used as the reference line for assessing the descent of the bladder neck (proximal urethra)(61). Schaer measured the retro-vesical angle in the context of assessing for urethral funnelling seen in stress urinary incontinence (61). The Schaer method should be performed with a bladder volume of 300ml supine, standing, coughing, with pelvic floor contractions and the Valsalva manoeuvre (61). Later, the technique was developed to assess urethral movement in two planes (113, 114). Transperineal ultrasound has been shown to correlate well with lateral chain ultrasonography (60). The disadvantage of this technique is that it generates negative vectors when the bladder neck descends below the Pubis. This was followed by a 2D technique based n the Pythagorean theorem: $V= \sqrt{[(Vx-Rx)2 + (Ry-Vy)2]}$ (113, 114). Detailed analysis of urethral descent at 6 points along the urthral length in 3D/4D ultrasound based on the Pythogorean theorem formula, showed that the distal urethra is the most stable part of the urethral anatomy (115). Using this as a given, the bladder neck descent can be assessed during dynamic 2D scanning, where the bladder neck descent can be assessed relative to the position of the urethra at rest, by using the properties of parallel lines (116).

Urethral descent validated the use of ultrasonography in the assessment of the position and mobility of the bladder neck and proximal urethra. Good results for this validity testing have been reported (61, 94, 116-118). See Table 2.

Bladder neck descent is associated with stress incontinence (42, 44, 119, 120). Clinical techniques for the assessment of bladder neck descent include the Q-tip test (121, 122). Assessment of bladder neck descent is of relevance in clinical practice because patients with greater bladder neck mobility are more likely to benefit from stress incontinence surgery (121).

Multiparous women demonstrate a greater bladder neck mobility compared with nulliparous women (123-125). Bladder neck hypermobility is considered to be related to stress urinary incontinence (90, 105, 126). Ultrasonographic findings are correlated with urodynamic parameters (68, 127-134). Specificity and sensitivity of ultrasonography for the diagnosis of stress incontinence were 83% and 68% in one study (128) and 92% and 96% in another study (135). Other studies have demonstrated that ultrasonographic findings of bladder neck descent and rotation of the retro-vesical angle increase the odds for SUI by 2.5, however they concluded that ultrasonography's low diagnostic value does not allow it to replace urodynamics (136).

Table 2. Bladder neck descent in asymptomatic women. (from VA thesis) (submitted to Imperial college for VA thesis)

Technique	N	Cohort characteristics	Mean (mm)	Reference:
$V= \sqrt{[(V_x-R_x)^2 + (R_y-V_y)^2]}$	25	Antenatal (AN) third trimester vs post-natal (PN)	Bladder neck descent on Valsalva **Primips**: AN 15.6 +/- 6.9 vs PN 22.2 +/- 8.7 (p<0.001) **Muptips**: AN 11.4 +/- 5.5 vs PN 19.9 +/- 7.8 (p<0.001) **Elective Caesareans**: AN 9.5 +/- 2.5 vs PN 10.4 +/- 3.1 (p=0.3)	Peschers et al (114)

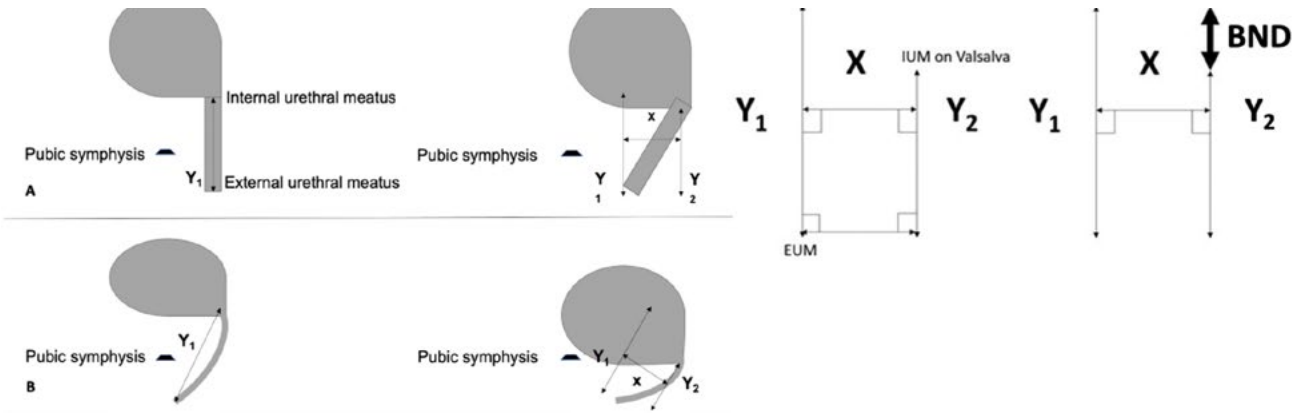

Figure 5. Diagram representation of urethral descent assessment technique. (A) The urethral at rest is uncurved and upright. (B) The urethra at rest is curved and tilted. Y1 is the length of the urethra when the urethra is straight. IUM: Internal urethral meatus; EUM: External urethral meatus; BND: bladder neck descent (116).

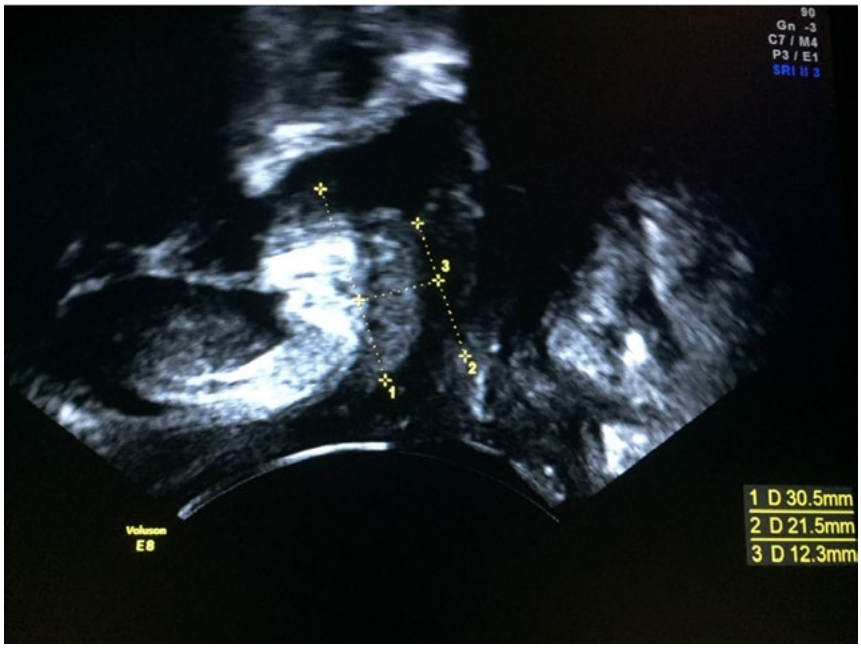

Figure 6. Urethral descent assessment in a healthy nulliparous volunteer without prolapse. The urethral length at rest was 30.5mm, the bladder neck moved forward 12.3mm. The bladder neck descent was 9mm (30.5-21.5 = 9).

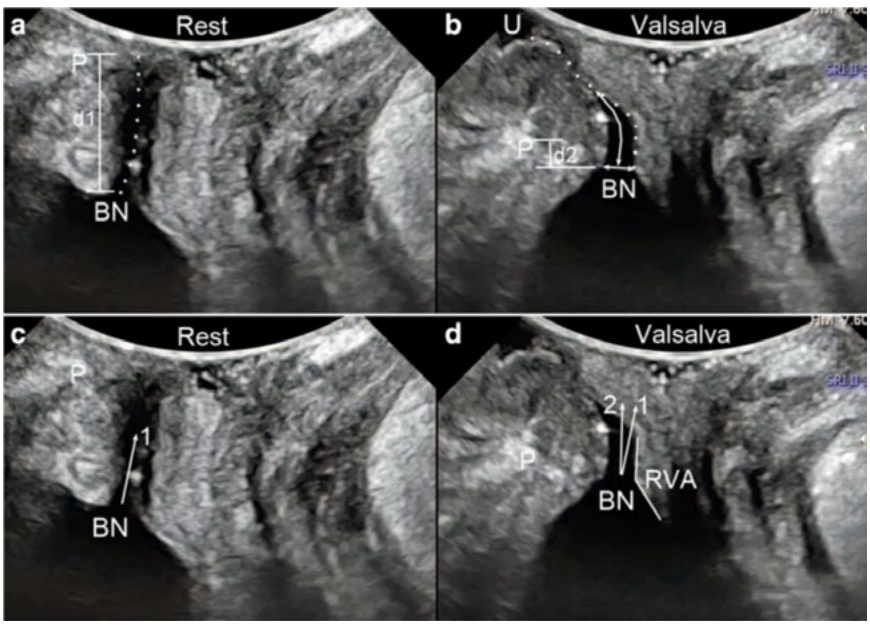

Figure 7. Transperineal ultrasound images in the mid-sagittal plane during real-time leaking. A and C were taken at rest, B and D during the Valsalva manoeuvre. A and b Urethral movement during the Valsalva manoeuvre; the dotted line in A shows the urethra at rest while in B it shows the urethra during the Valsalva manoeuvre. The length of the dotted line is equal to the urethral length. B Funnelling measurements (the long arrow shows the funnelling length and the short arrow shows the funnelling width) and urine leakage, seen as fluid (urine) between the external urethral orifice and the probe surface. A and b Measurement of the position of the bladder neck relative to the posterior inferior margin of the pubic symphysis (P); the difference between these measurements during the peak of the Valsalva manoeuvre and at rest (d1–d2) produces the value for bladder neck descent (BND). C and d Measurement of the urethral rotation angle (URA), which is the angle between the proximal urethra at rest (arrow 1) and during the Valsalva manoeuvre (arrow 2). D The retrovesical angle (RVA) during the Valsalva manoeuvre, which is measured between the proximal urethra and the trigone. P: symphysis pubis, BN: bladder neck, URA: urethral rotation angle, RVA: retrovesical angle, U: urine. (140)

A randomised controlled trial in primigravidae suggested that PFMT can play a preventative role in reducing the risk for SUI despite not conveying a significant change in bladder neck descent (141).

One research group has specifically investigated simultaneous perineal ultrasonography and urethrometry. They demonstrated that the variations in urethral pressure were caused by the activity of the urethral sphincter as well the pelvic floor muscles (142). The contractions from the urethral sphincter during acute stress events such as coughing are thought to be due to fast contractions. Some studies have used ultrasonography to optimise patient management, but despite the abundant literature on the use of ultrasonography in the investigation of women with urinary incontinence, disappointedly, a clinical advantage in terms of patient outcome has not been reported until now (143, 144).

Urethral funnelling can be observed on ultrasonography (**Figure 7**) particularly with the use of contrast agents. It is a typical finding in women with stress urinary incontinence but can be seen in asymptomatic women as well (145, 146). In a study on stress incontinent women, funnelling was found to be present in nearly all women (147). Urinary incontinence can be demonstrated by the use of colour Doppler of the urethra (148, 149). Colour Doppler has, furthermore, been used to visualise the periurethral vasculature in nulliparous women (150) and differences have been described between continent and incontinent women (151, 152) and before and after oestrogen supplementation in postmenopausal women. Data with the use of high frequency endovaginal ultrasonography have highlighted differences in urethral vascularity amongst continent women with parity (153). Doppler velocimetry has been used in a study on the vascularisation of the levator ani musculature and a correlation has been found between the absence of an end-diastolic flow and the presence of stress urinary incontinence (154). The blood flow around the urethra and bladder has been studied with Doppler before and after insertion of tension free vaginal tape and the transobturator tape. The blood flow decreases only after insertion of the tensional free vaginal tape whereas the blood flow was unchanged after insertion of the transobturator tape which may relate to the direction of urethral compression (155). Data showed no difference in urethral vascular indices measured by endovaginal ultrasound between women with SUI who were managed surgically or conservatively (156).

2.2.5. Determination of the Post Void Residual Urine and Bladder Wall Thickness

Ultrasonography is the gold standard technique for measuring bladder volume and post-void residual urine (157-161). Ultrasonographic data have been compared with residual volumes obtained by in and out catheterisation under ultrasound control and were found satisfactory. Although there is no universally accepted definition of high urine residual volume, there is consensus on the need for a short interval between voiding and post-void residual (PVR) measurement and the preference of ultrasound bladder volume measurement over urethral catheterization (162). However, Khan et al. have challenged the methodology of some studies and found deficiencies in all reports on the topic (163). A simple formula often used is (Height * Width* Depth cm) * 0.7= Volume (ml) in which the factor 0.7 is the correction for the non-spherical shape of the bladder. Automated ultrasound systems for measuring bladder volume and post-void residual have been developed and found to be more accurate than standard ultrasound measurements, furthermore they can be used by health care providers with no training in ultrasound imaging (164). However, measurement of bladder volume can easily and accurately be facilitated by use of cheap, standard 2D ultrasound machines, irrespective of the calculation formula used, even in women with severe pelvic organ prolapse (165). Automated bladder scanners are widely used and are, in general, experienced as reliable enough for clinical use, however, in the case of ascites (166) or an ovarian cyst (167) for example, the estimated urinary volumes can be incorrect, and in post partum women.

Normal values for the post void residual urinary volumes in asymptomatic women have been presented; in 60 year-old women, the median residual volume was 19 ml, and 95% of women had a post void residual volume of less than 100 ml (158). The ICS Urodynamics Committee has published its Good Urodynamic Practice recommendations regarding PVR measurement suggesting that for clinical practice a PVR <30 ml can be considered insignificant, while residual volumes persistently >50 ml could be regarded as important. They also suggested that large PVR (>200–300 ml) often indicates LUTD, acknowledging however that no level of residual urine, of itself, mandates invasive therapy and no PVR threshold is yet established for decision-making (162).

Ultrasound measurement of bladder wall thickness (BWT). Ultrasound measurement of BWT was first proposed as a non-invasive method for diagnosing infravesical obstruction in children (168). BWT was validated by measuring the thickness of the bladder by ultrasound and with microcalipers (80). Higher frequency ultrasound yielded measurements the closest to the microcliper measurements. BWT has been used to predict the outcome of children with primary nocturnal enuresis (168-170). BWT has also been proposed as a risk factor for upper urinary tract deterioration in children with myelodysplasia (171). Measurement of BWT was also proposed to diagnose bladder dysfunction (detrusor overactivity and detrusor hypocontractility versus normal detrusor function) in children with urinary tract infections (172, 173). Additional parameters such as the bladder wall thickness index (length x width x depth of the bladder at full bladder/average BWT) were proposed and a nomogram for the paediatric population provided (174).

In the adult population, higher BWT values have been measured in men than in women. Thickness may certainly differ depending the measurement technique; values of 3.3 +/- 1.1 mm and 3.0 +/- 1.0 mm, respectively were reported by Hackenberg and co-workers (175). Oelke confirmed a significant difference between male and female detrusor thickness (1.4 versus 1.2 mm, respectively) (176). A small increase of detrusor hypertrophy with age has been reported in both genders (174). In men, measurement of bladder wall thickness proved to be the most sensitive parameter (outperforming uroflowmetry) to diagnose BOO in patients suffering LUTS (177, 178). These findings were corroborated by the results of more ultrasonographic studies by use of automated bladder scanners (179).

Transvaginal ultrasound was first proposed in 1994 for the measurement of BWT in women with bladder volume of less than 20 ml. A large review of all studies on BWT with all three modes of imaging (transvaginal, transperineal and transabdominal) showed that the measurement is best measured by the transvaginal route (180). See Figure BWT. A significant difference was shown in patients with DO and USI (6.7 +/- 0.6 versus 3.5 +/- 0.6 mm, respectively). Low intraobserver and interobserver variability were measured: 0.02 mm in both with a 95% confidence interval of -0.22 to 0.18 and -0.32 to 0.35 mm, respectively (181). In 1996, Khullar and co-workers showed how ultrasound measurement of BWT is a sensitive method for diagnosing DO in symptomatic women without bladder outlet obstruction with 94% of women with BWT greater than 5 mm having involuntary detrusor contractions on videocystourethrography or ambulatory urodynamics (182). In 2002, the same group showed no overlap in the 95% confidence intervals of BWT between pa-

tients with DO and USI in women with storage symptoms, confirming the potential of this parameter for diagnosing DO (183). More data on the diagnostic value of transvaginal ultrasound in patients with overactive bladder symptoms confirmed a sensitivity of 90 % and specificity of 78 % for predicting OAB, when a cut off value of 4.78 mm was used (AUC = 0.905) (184). Conversely, a large UK-based cross-sectional test accuracy study found no evidence that BWT had any relationship with DO, regardless of the cut-off point, nor any relationship to symptoms as measured by the ICIQ-OAB; the authors concluded that despite patients' wide acceptability of the method BWT measurement was not sufficiently reliable or reproducible to predict DO (185).

In 2003, a study on ultrasound cystourethrography in women confirmed a significant association between age and intravesical pressure at maximum flow with BWT (186). Researchers have also demonstrated reduction in BWT following urethrolysis in women with bladder outlet obstruction resulting form anti-incontinence surgery (81). Methodological and technical issues in the ultrasound measurement of bladder wall thickness and weight remain open and constitute a major limitation for a more widespread use of these parameters. In 2005 Chalana and co-workers published an early report on automatic measurement of the ultrasound estimated bladder weight from three-dimensional ultrasound (187). An average value of 42 +/- 6 g was measured in healthy male subjects. A standard deviation of 4 g was seen among measurements performed in the same subject at different bladder volumes (200 to 400 ml). Normative values for UEBW and BWT in healthy female volunteers were calculated by another group by use of an automated bladder scan device showing mean values of 32.23g (SD +/- 4.9) and 1.62 (SD +/- 0.34), respectively (188). Further research in this area is certainly needed and further improvement in the accuracy of automated systems is eagerly awaited.

Although data published in the peer review literature on this subject are quite consistent, two discordant papers were published from Australia. Blatt and co-worker showed uniform values of BWT measured using an abdominal approach among men and women with non-neurogenic voiding dysfunction suggesting this parameter cannot be used to diagnose storage or voiding dysfunction; this may reflect the thinning of the bladder wall with increasing bladder volume (176, 189, 190). A retrospective study on women undergoing translabial ultrasonography suggests a significant association between BWT and DO although a low diagnostic accuracy was shown for the diagnosis of DO (191), which could be due to translabial ultrasound being a less reliable technique (192).

The association between detrusor hypertrophy and bladder dysfunction (DO and BOO) is a well established fact in Urology. Reduction in bladder wall thickness is observed after the relief of bladder outlet obstruction (81). The development of automated ultrasound systems for measuring UEBW is instrumental to foster further research in this area, particularly in the management of patients with LUTS (193) and in the evaluation of bladder response to pharmacological treatment (177).

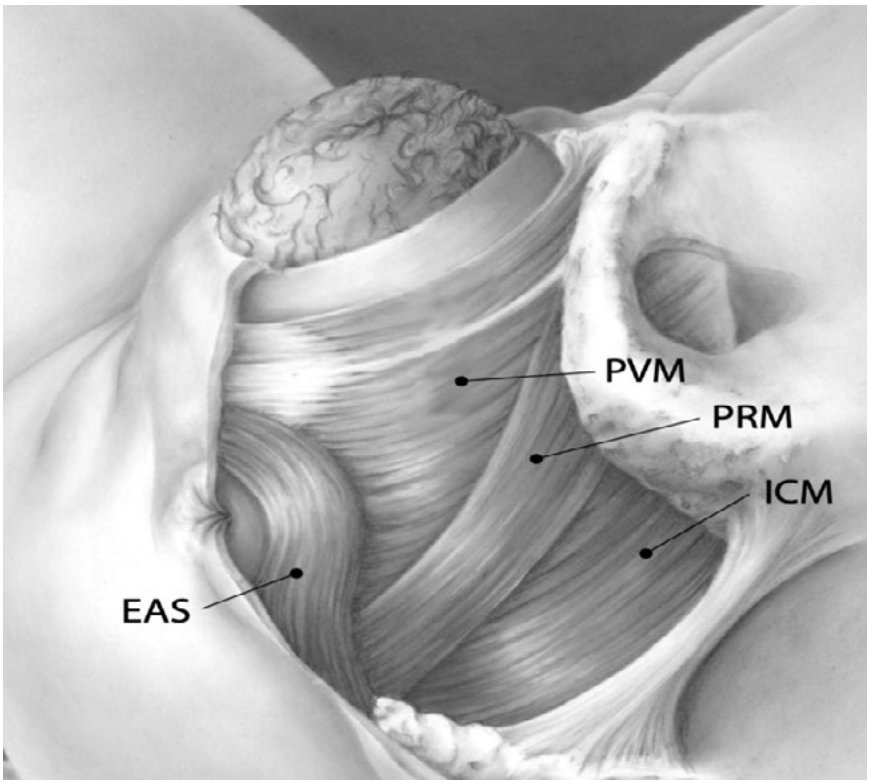

Figure 9: A left inferior view illustrating the pubovisceral muscle (PVM), which originates behind the pubic bone and forms the most distal portion of the levator ani muscle. It is particularly stretched late in the second stage of labor as the fetal head is driven by stron 2-maternal pushes, at 3-minute intervals, through the birth canal to crown. EAS: external anal sphincter, ICM: iliococcygeal muscle, PRM: puborectal muscle. (194) © DeLancey

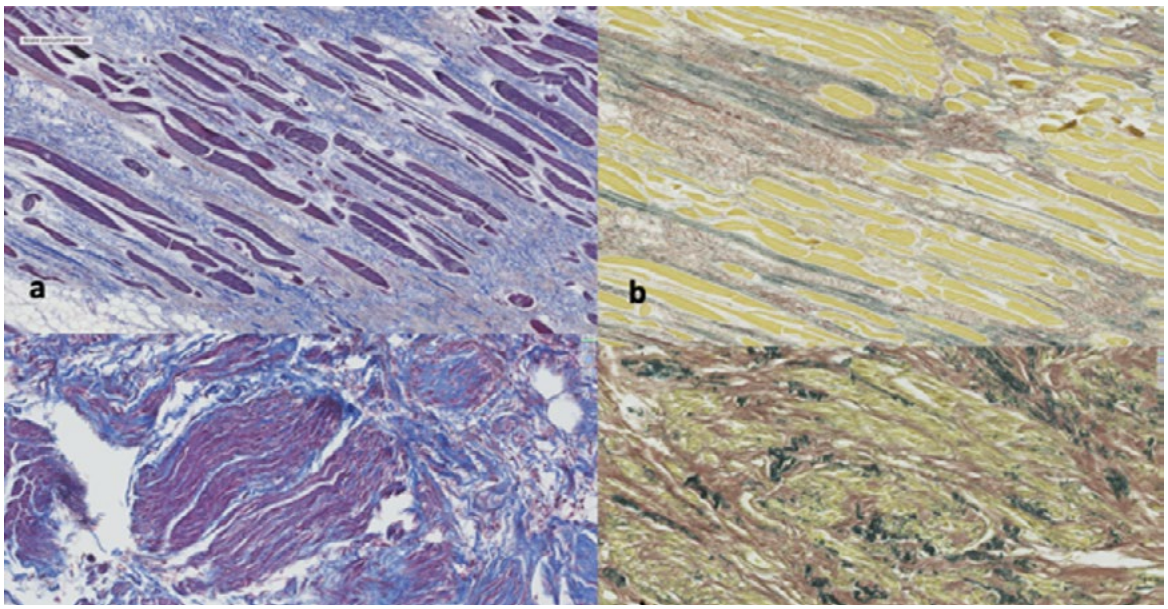

Figure 10. Pubovisceral enthesis muscle in cadavers; a. Masson Trichrome stain in normal enthesis; b. Van Gieson stain in intact enthesis; c. Masson Trichrome in cadavers with appearance of avulsion on ultrasound; d. Van Gieson stain in cadavers with appearance of avulsion on ultrasound. (195)

2.3. Ultrasound techniques for assessing the pelvic floor

A wide range of techniques that may be clinically applied have been described. The pelvic floor has been assessed with a wide variety of ultrasound machines and probes. The technology used is important because it can change the appearance of the image obtained. See Figure 11 for an example of the same image taken in 2D with three different ultrasound probes on a Voluson E8. See Table 3 for a summary of different pelvic floor techniques that have been described for the assessment of the pelvic floor.

The most established technique in clinical practice is endoanal ultrasound for the assessment of obstetric anal sphincter injuries (OASI). The clinical application

of these ultrasound techniques peri-operatively is not fully established (153). Ultrasound in not routinely recommended in current clinical guidelines for neither the assessment or the management of incontinence or prolapse.

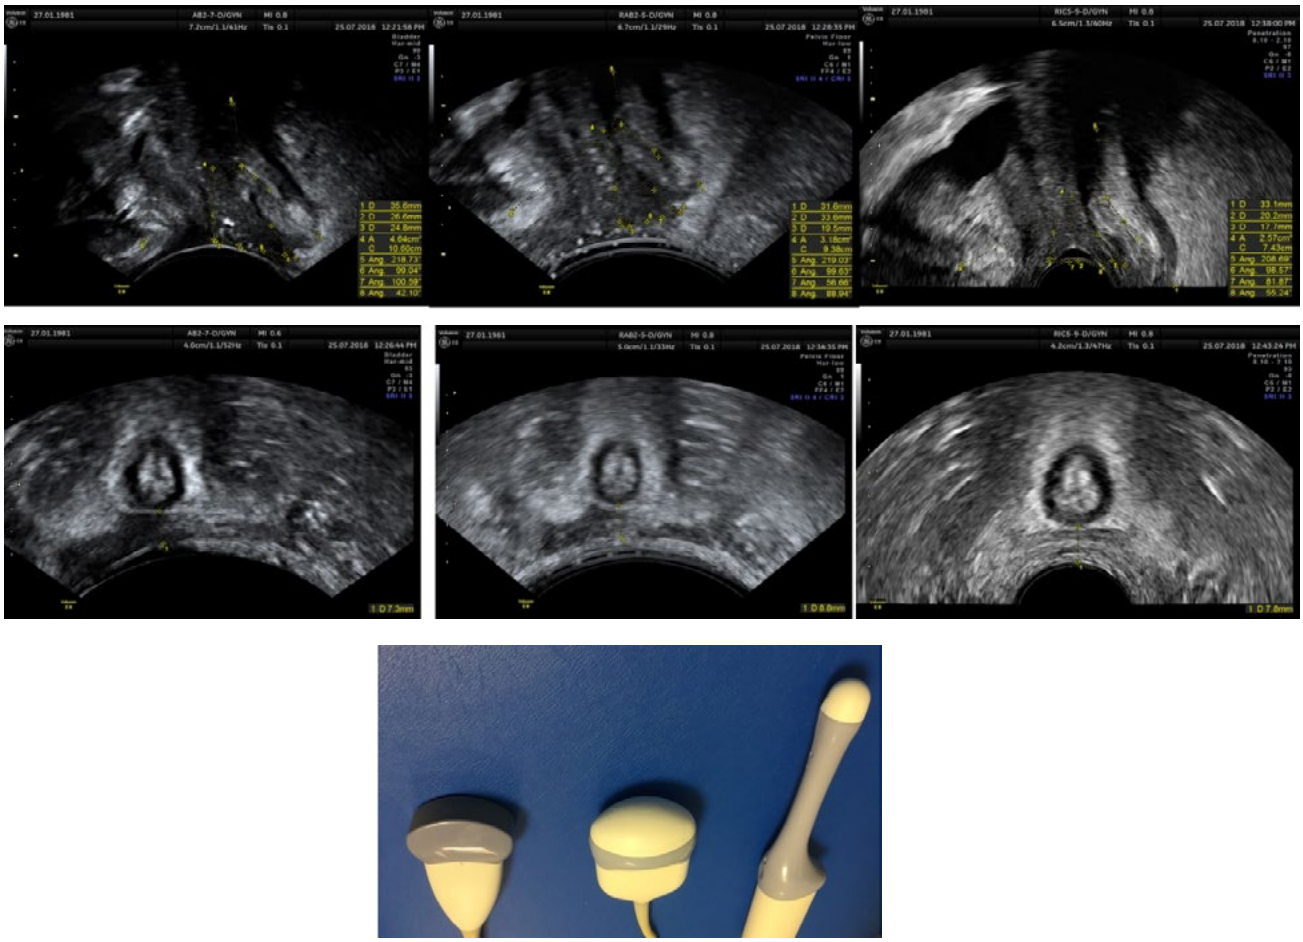

Figure 11. Pelvic floor ultrasound in 2D. The top row of images are mid-sagittal, the 2nd row of images are coronal angled downwards towards the anal canal. The second image shows in order the probes with which these images were acquired: 7 MHz (AB27D); 5 MHz (RAB25D); 9 MHz (RIC50D)

2.4. Perineal body

The perineal body fuses with the anal sphincter, anterior to the anal canal. The perineal body is where the muscles of the pelvic floor from both sides fuse together (puborectalis, transverse peronei and the bulbospongiosus muscles). The perineal body used to be called the 'central tendon' of the perineum (196). Histological studies have shown that the perineal body is entirely made out of striated muscle (197). Therefore, it may be more appropriate to refer to it as the central confluence of the pelvic floor muscles (not a tendon). The perineal body size can be evaluated in the mid-sagittal plane on 2D transperineal ultrasound (198). Prolapse is associated with a smaller perineal body. Perineal body mobility can be assessed with 3D transperineal ultrasound (199). Increased perineal body mobility has been demonstrated after vaginal birth (199).

The perineal body can be visualised and accurately measured in the midsagittal plane by transperineal 2D ultrasound (198). The legth, width (height), perimeter and area can be measured. The area is the most representative measurement as this measurement is less likely to be skewed by an irregular shape. The perineal body area in nulliparous women is 2.8+/-0.38cm2, compared with 2.1+/-0.5cm2 in women with prolapse (paired t-test, p<0.0001) (198). The prolapse patients were also observed to have a wider POP-Q GH (paired t-test, p=0.0003). Interestingly the POP-Q PB was not different (198).

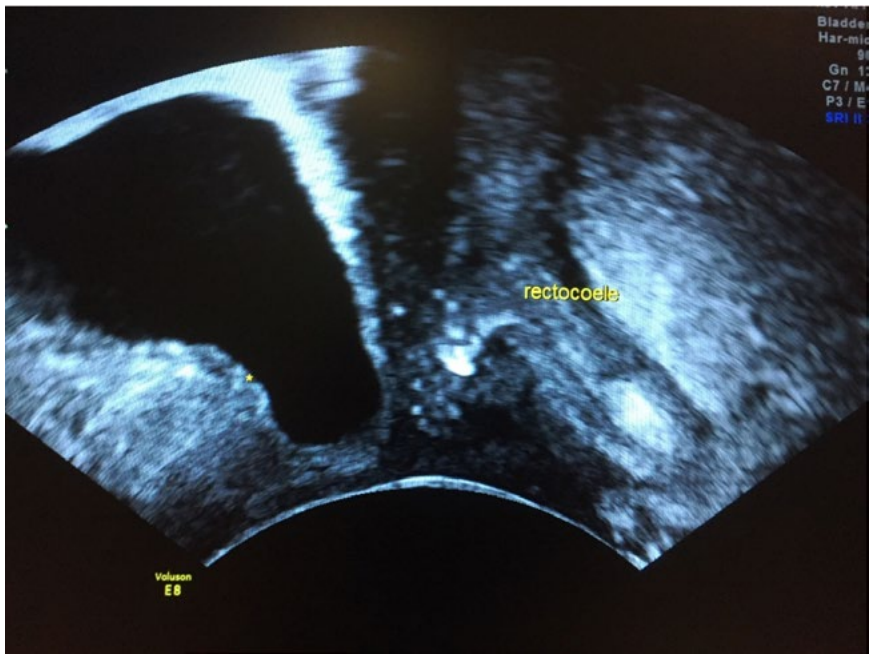

Figure 12. Midsagittal 2D image of a large cystocoele and rectocoele at maximal Valsalva.

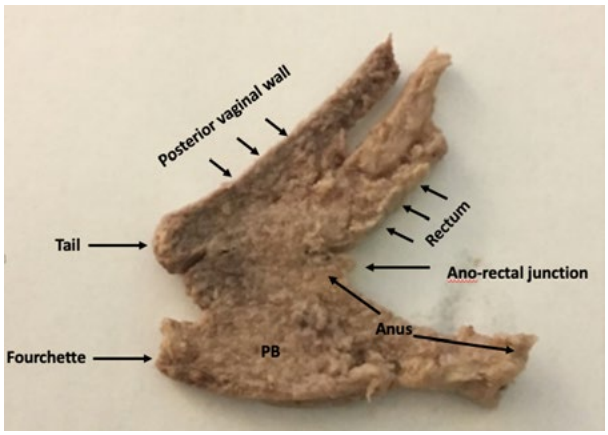

Figure 13a. Cadaver midsagittal section of the Perineal body. The perineal body is fused with the anal sphincter in the midline. The pointy part on the posterior vaginal wall is at the same level as the anorectal junction.

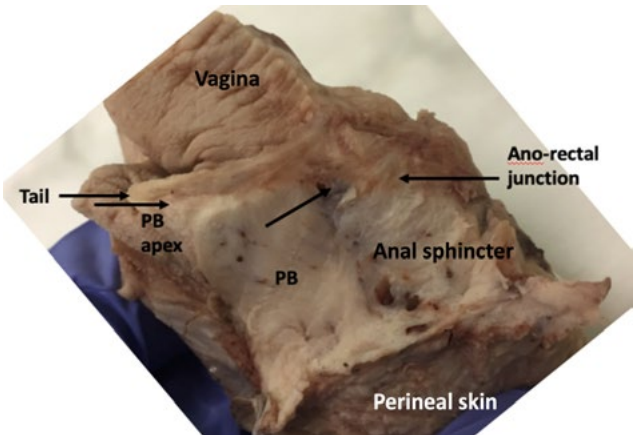

Figure 13b. Cadaver parasagittal section of the perineal body and anal sphincter.

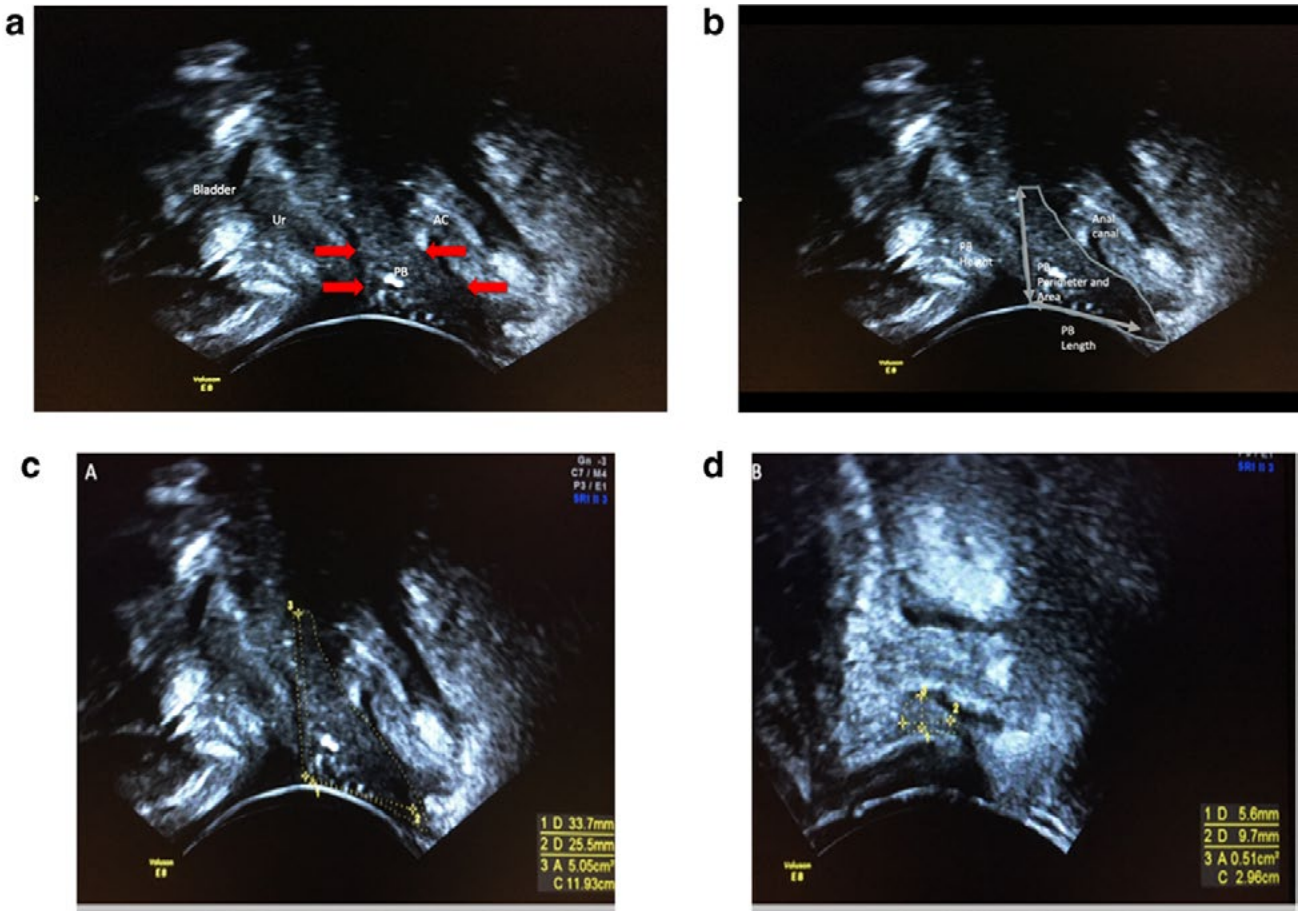

Figure 14. Perineal body on 2D midsagittal ultrasound. A. perineal body shown by the red arrows. B. perineal body width, legth and perimeter demonstrated. C. perineal body measurements done on Voluson E8, showing area 11.93cm2 that is derived from tracing the perimeter with the roller ball. D. small perineal body in the presence of a large rectocoele showing area 2.96cm2. (198)

2.5. Anal Axis (Anal Canal to Pubis Angle)

The anal axis can be assessed in the mid-sagittal plane with 2D ultrasound by measuring the angle between the anal canal and the Pubis, by pivoting on the ano-rectal junction (200). The angle is wider in prolapse patients 122.9° (SD 15.6°) compared to 98.2° (SD 15.9°) (two-sample t-test, $p<0.001$)(200). In children with congenital anomalies of the anorectal region, the anorectal axis has been assessed with MRI, as it is associated with obstructive defaecation (201).

Further work should be focused on assessing the clinical usefulness of the wide variety of ultrasound techniques described.

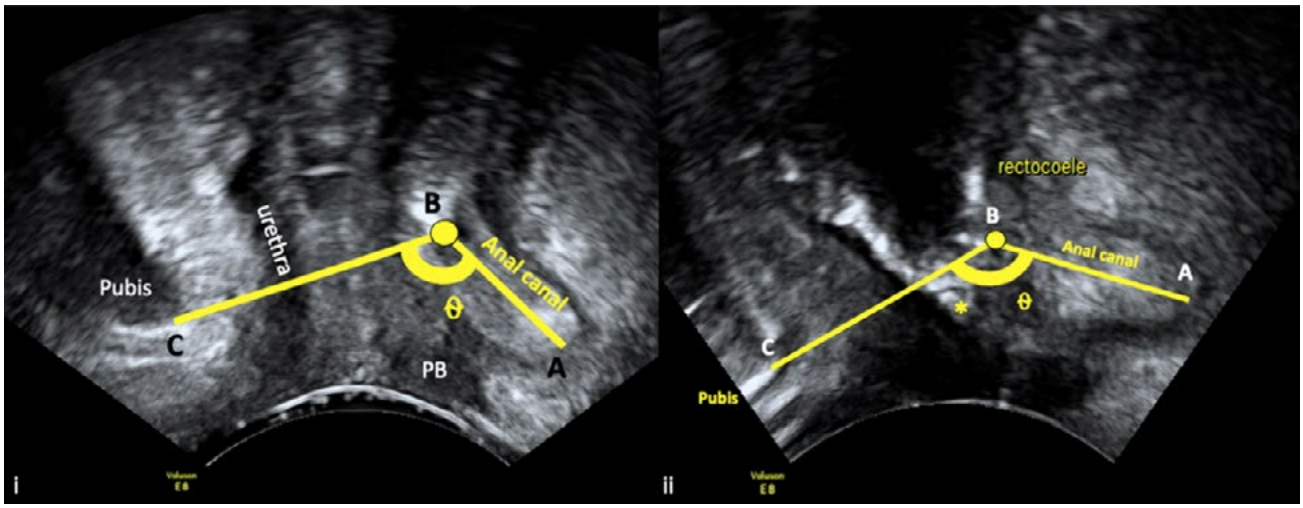

Figure 15. Anal axis in control and prolapse patients (200).

Acronyms used in this table: BWT: bladder wall thickness, VWT: vaginal wall thickness, OASI: Obstetric anal sphincter injury, LAM: Levator ani muscle injury, TA: transabdominal, TVS: transvaginal, TP: transperineal, EVUS: endovaginal, EAUS: endoanal, TUI: tomographic ultrasound imaging

2.5.1. Pelvic Floor Muscles

Ultrasonography can be used to assess pelvic floor muscles and their function. Contraction of the pelvic floor results in displacement of pelvic structures that can easily be imaged on ultrasound (**Figure 17**) such as the cranial lift of the urethra in relation to the symphysis pubis during a maximal squeeze (91, 229) but also the dimensions of the genital hiatus or the posterior ano-rectal angle can serve this purpose (230). Comparison with traditional measurements of pelvic floor muscle strength has been performed (229), and good correlations with palpation and perineometry have been found (231, 232). Ultrasonography has been used to evaluate the effects of pelvic floor muscle training. A higher resting position of the bladder neck and a reduction in the rotational excursion of the urethra during Valsalva manoeuvre have been found with pelvic floor training (233). Another research group has reported that the thickness of pelvic floor muscles increased after training (234). A number of studies have assessed healthy female volunteers to establish normal values (126, 234) and one study has specifically compared elite athletes with normal volunteers (235). One study has compared three-dimensional ultrasound of the levator ani hiatus at rest and during contraction in a number of different groups of women with prolapse, urodynamic stress incontinence and asymptomatic women suggesting that these measurements are not sensitive enough to discriminate between different groups (236).

Almost half of women are unable to perform an optimal contraction of the pelvic floor muscles. Ultrasonography can be used in pelvic floor training to provide women with a visual feedback of their exercise (91, 237). In one study, 57% of the women who were not able to perform a proper pelvic floor contraction, were able to do so with the help of visual biofeedback of ultrasonography to observe bladder neck movement (91). This does not appear to produce better outcomes of changes with pelvic floor physiotherapy (206). Another prospective study in women receiving physiotherapist-guided PFMT due to pelvic floor dysfunction, however, did demonstrate that the vast majority of patients would improve muscle contractility after the programme; amongst the non responders (“non-contractors”) almost 67% were found to have levator ani defects on transperineal ultrasound (238). The contraction of the pelvic floor muscle just before and during a cough, “the knack”, can also be visualised (239). It has been demonstrated that the knack can significantly reduce urethral mobility during a cough.

Direct measurement of the pelvic floor muscles is possible with the use of two and three-dimensional perineal ultrasonography. An alternative technique makes use of a 360 degree rectal probe intravaginally (**Figure 18**) (240). Most studies, however, have used three-dimensional perineal ultrasonography for this purpose (92, 230, 235, 241, 242). The thickness of the pelvic floor muscles as well as the hiatal area can be measured. Hiatal dimensions and pelvic floor muscle thickness have been extensively validated and have good test retest and inter observer characteristics (92). There is a learning curve to measurement of the levator ani hiatus needing over ten sets of scans to perform the measurement. However, measurements of the pubic arch were not accurate suggesting that measurements of levator avulsion may require more training (243).

The pelvic floor muscles were thinner in women with pelvic organ prolapse (90, 240, 244) and with urinary incontinence (245), whereas their genital hiatus was larger (73); interestingly this finding does not produce a significantly reduced maximal voluntary contraction even with pubovisceral muscle defects (246). Well trained women have thicker pelvic floor muscles compared with controls (234), and Chinese women had thinner muscles compared with Caucasian women (136). In nulliparous Chinese women, the anterior/posterior hiatal diameter was significantly increased in women with a higher body mass index (242).

A RCT in 140 incontinent women demonstrated that TAUS was accurate in detecting even minor differences in pelvic floor muscle strength between the PFMT and non-intervention groups and this correlated very well with assessment by digital palpation (247). By using this imaging modality as biofeedback, another research group from Japan established that women with postpartum SUI were less successful in achieving good pelvic floor muscle strength following an intensive PFMT in comparison to their continent counterparts, despite no morphological differences in the LAM between the groups before and after intervention (248).

Pelvic floor biomechanics were investigated with ultrasound using the position of the bladder neck in combination with continuous vaginal pressure measurements (249, 250). A novel biosensor was used to measure the force as well as the displacement of the pelvic floor during contraction (251). Another research group has inserted a water filled plastic bag to study the shape of the vagina during contraction (252). Others have assessed elasticity by means of the correlation of the dynamic dimensions of the hiatal circumferences and direct palpation of the muscles (253). Real time biomechanics of the pelvic floor have been compared between women with and without pelvic organ prolapse with the use of translabial 3D ultrasound and standardised Valsalva effort; significant pelvic organ prolapse was associated with a less compliant levator ani muscle close to its origin from the pubic ramus (median maximum strain 26% vs 32%, respectively, P=0.03) (254).

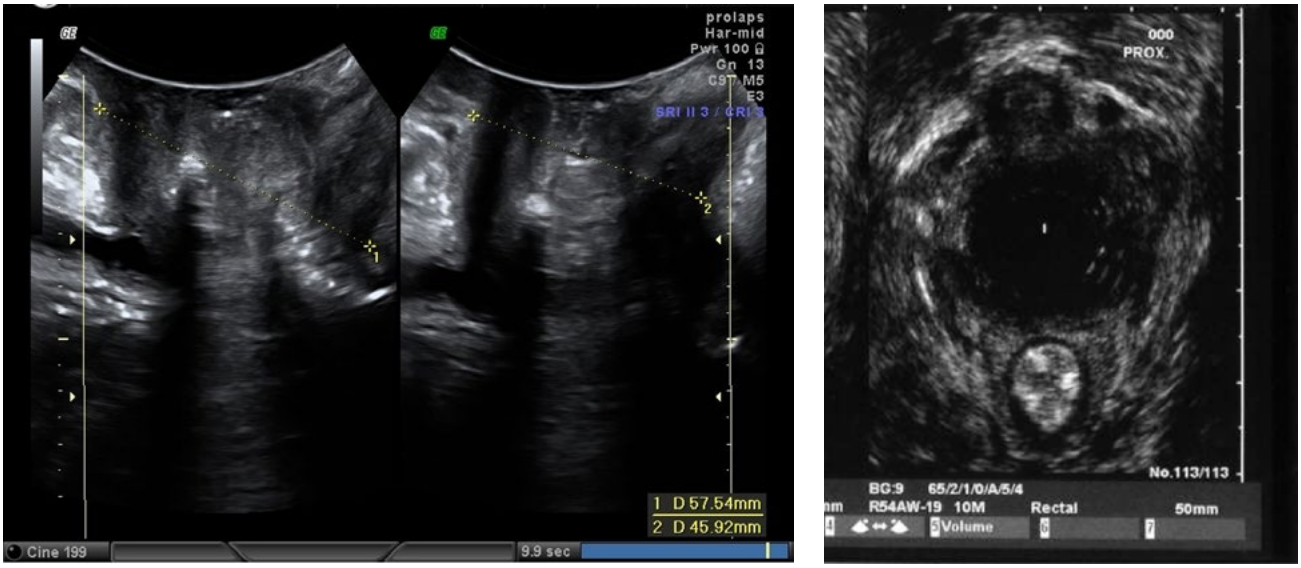

Figure 17: Perineal midsagittal two-dimensional view at rest and on contraction. Levator contraction with ventro-cranial displacement of the urethra. Measurement of minimal dimension of genital hiatus (from symphysis pubis to levator ani muscle)

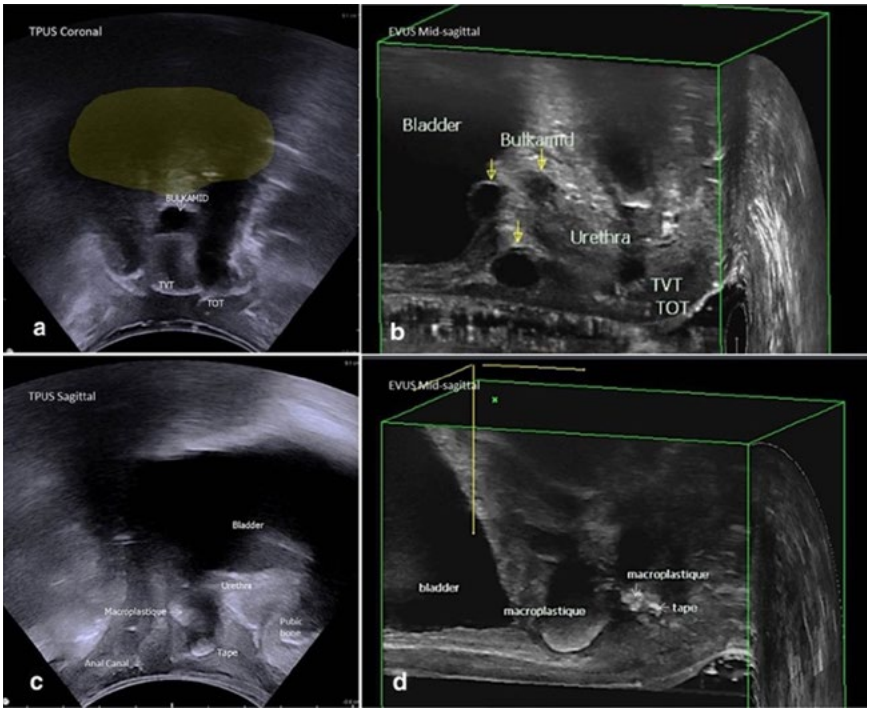

Figure 18: Urethral bulking agents. a Perineal pelvic floor ultrasound coronal view showing Bulkamid® as a hypoechoic area by the bladder neck as labelled (bladder highlighted in yellow). This patient presented with de novo urgency and reported to have undergone a transobturator tape (TOT) insertion that was partially excised owing to voiding dysfunction, followed by a tension-free vaginal tape (TVT) insertion (as labelled). Evidence of material used for Bulkamid® injections was also seen (unknown to the patient). b Mid-sagittal view on endovaginal ultrasound of the anterior compartment demonstrating the bulking agent (arrows) bulg- ing into the bladder and bladder neck. The two MUSs can also be seen the distal urethra. c Mid-sagittal view on perineal ultrasound. Macroplastique® is seen with higher echogenicity compared with Bulkamid® injections allowing differentiation, but may obscure sur- rounding pelvic structures. This patient presented with a history of having had three MUSs inserted; on ultrasound it was discovered that she in fact had Macroplastique® with only one MUS, which is seen very close to the urethral lumen (labelled tape). d Mid-sagittal view on endovaginal ultra- sound of the anterior compartment demonstrating the high echogenicity of the Macroplastique® compared with Bulkamid® . (210)

3. ENDOVAGINAL ULTRASOUND (EBUS) THE EMERGENCE OF HIGH FREQUENCY, HIGH DEFINITION POINT OF CARE ULTRASOUND

3.1. Introduction

Based on the practice parameters published by the American Institute of Ultrasound in Medicine (AIUM), in collaboration with the American College of Radiology (ACR), the American Urogynecologic Society (AUGS), the American Urological Association (AUA), the International Urogynecologic Association (IUGA), and the Society of Radiologists in Ultrasound (SRU),

Endovaginal Ultrasonography ultrasonography (EVUS), Perineal Pelvic Floor Ultrasound (pPFUS) and Introital Pelvic Floor Ultrasound (iPFUS) indications include but are not limited to the following:

Urinary incontinence;
- Recurrent urinary tract infections;
- Persistent dysuria;
- Symptoms of voiding dysfunction;
- Symptoms of pelvic organ prolapse;
- Obstructed defecation;
- Anal incontinence;
- Vaginal discharge or bleeding after pelvic floor surgery;
- Pelvic or vaginal pain after pelvic floor surgery;
- Dyspareunia;
- Vaginal cyst or mass;
- Synthetic implant visualizations (slings, meshes, and bulking agents);
- Levator ani muscle assessment after childbirth;
- Obstetric perineal injury;
- Obstetric Anal Sphincter Injury (OASIs);
- Perineal cyst or mass.

There are no contraindications except where patients are unable to consent to the procedure and in situations that would breach infection control guidelines, such as the presence of an open wound or severe vulvovaginal pain and discomfort.

3.2. Anterior and Posterior Endovaginal Ultrasonography

Anterior and posterior dynamic imaging may be performed using EVUS. In a study of nullipara correlated with the histology of the anterior and posterior compartment, the following measurements were found: urethral length 36 mm (±5); striated urogenital sphincter area 0.6 cm^2 (±0.16); longitudinal and circular smooth muscle area 1.1 cm^2 (±0.4); urethral complex width 14 mm (±2); urethral complex area 1.3 cm^2 (±0.4); internal anal sphincter length 26 mm (±4); internal anal sphincter thickness 3.2 mm (±0.8); and rectovaginal septum length 31 mm (±5). The agreement for visualization of structures was as follows: vesical trigone 96% ($\kappa = 0.65$), trigonal ring 94% ($\kappa = 0.8$), trigonal plate 84% ($\kappa = 0.6$); longitudinal and circular smooth muscle 100%; compressor urethra 97% ($\kappa = 0.85$); striated urogenital sphincter 97% ($\kappa = 0.85$); rectovaginal septum 100%; internal anal sphincter 100%; external anal sphincter subdivisions 100% (2).

To visualize the anterior compartment, introduce the transducer into the vagina until the vesicourethral junction is visualized. During anterior compartment imaging, the details of the urethral anatomy along with any sling or mesh present can be visualized (3-7). Levator ani deficiency (LAD) and urethral sphincter complex status, as visualized on 3D ultrasonography, are independent factors. Moderate to severe LAD is more prevalent in patients with SUI (8). Smaller rhabdomyosphincter length and area on 3D EVUS are associated with x-ray funneling. Ultrasound urethral volume of 3.5 cm^3 as a cutoff provides the same reliability as x-ray funneling for the diagnosis of ISD (4). During posterior compartment imaging, any mesh present can be visualized (5). Cough, Valsalva and

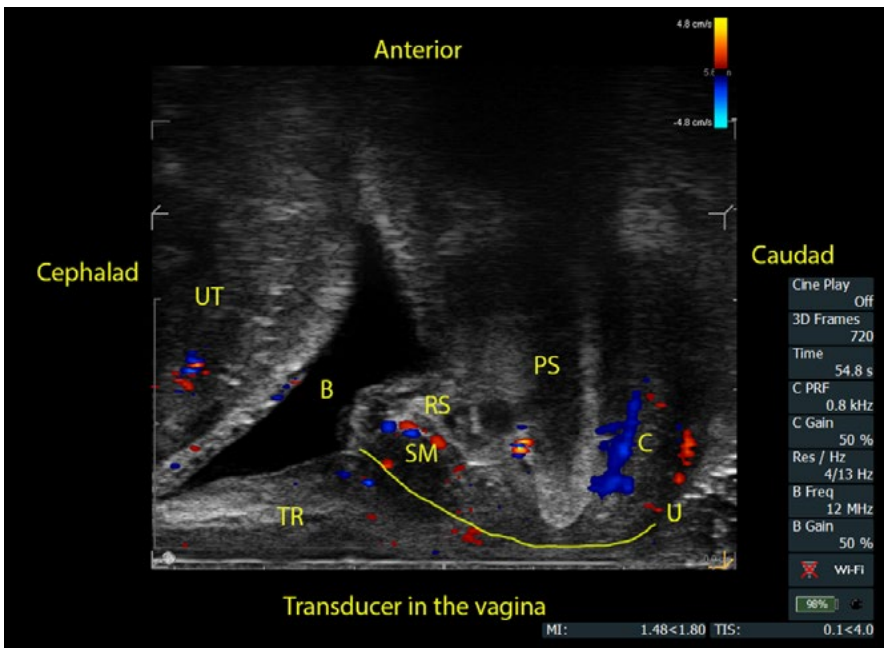

Figure 19: Anterior compartment with doppler flow view of the urethra and the bladder. B= bladder, C= Clitoris, PS= pubic symphysis, RS= rhabdomyosphincter, SM=Smooth muscle, TR= trigone, U=Urethra delineated by the yellow line, UT=Uterus (anterior edge of the uterus is seen cephalad to the bladder).

contraction maneuvers can be performed by the patient to improve visualization of high rectocele, enterocele, sigmoidocele, or intussusception. Visualization of a low rectocele may be impeded by the presence of the transducer in the vagina. Pelvic floor dyssynergia can also be noted during the maneuvers. Measure the distance from the transducer to the levator plate with the patient at rest. Then direct the patient to contract her pelvic floor muscles, and measure the distance at maximal contraction of pelvic floor muscles (9, 10) (*Figure 20*).

The visualization of correct pelvic floor lift is an important clue to the patient's pelvic floor function. This measurement has a good correlation with the Oxford scale in measuring pelvic floor lift. If the patient has defecatory dysfunction, she may, at this time, be asked to perform the Valsalva maneuver. Women with obstructive defecatory symptoms have wider rectum and descendent levator plate regardless of the prolapse stage as measured by POPQ or the severity of rectocele (11).

3.3. 3D Endovaginal Ultrasonography (3D EVUS)

Once the transducer is advanced to visualize the anterior compartment as in Figure 19, the 3D volume is obtained. The scan starts from the vesicourethral junction and will continue 6 cm caudal to include the perineal body (12). The 3D volume clearly demonstrates the levator ani muscle subdivisions and defects, vaginal masses and cysts, slings, and mesh. The levator ani muscle integrity, minimal levator hiatus area, anteroposterior diameter, urethral length, and sling and mesh position and dimensions, along with the levator plate descent angle, should be documented (*Fig 21).*

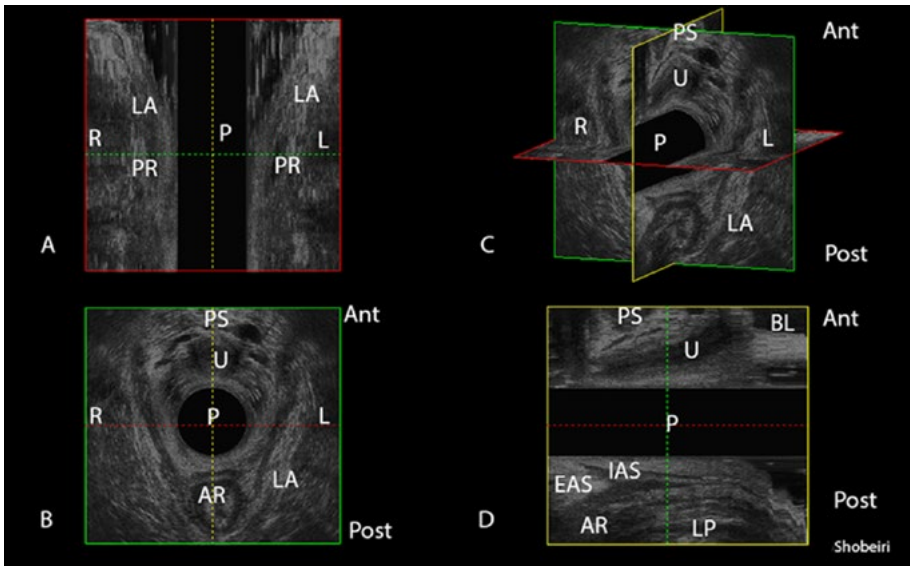

Figure 21: Endovaginal 3D volume as seen on workstation.

B in green frame is the axial view of the minimal levator hiatus.
D in yellow frame is the right midsagittal view of the pelvic floor.
C is the 3D volume with all three planes in yellow, red and green colors

3.3.1. 3D Endovaginal Ultrasonography: Levator Ani

The location of the puboperinealis, puboanalis, puborectalis, pubococcygeus and iliococcygeus as seen by three-dimensional endovaginal ultrasonography has been confirmed through anatomic dissection of fresh-frozen pelves. Subdivisions of the levator ani muscle can be visualized reliably with three-dimensional ultrasonography due to a high frequency of the probe placed directly adjacent to the muscles in the vagina (13, 14). In nulliparous women, Anterior and lateral borders of the minimal levator hiatus are formed mostly by pubococcygeus (Fig 22). The puborectalis, pubococcygeus, and iliococcygeus form the bulk of the levator plate (Fig 23). The mean of minimal levator hiatus and puborectalis hiatus areas are 13.4 cm^2 (±1.89 cm^2 SD) and 14.8 cm^2 (±2.16 cm^2 SD). The mean levator plate descent angles is -15.9° (±8.28° SD) (Fig 22) (1).

The levator ani subdivisions can be individually scored (0=no defect, 1=50% or less defect, 2=more than 50% defect, 3=total absence of the muscle) on each side. A levator ani deficiency score is categorized as mild (score 0–6), moderate (score 7–12), and severe (score more than 13). Score distribution significantly differs by prolapse stage (*P*<.001). No patients with stage 3 prolapse had a levator ani score less than 6, and no patients with stage 4 prolapse had a levator ani score less than 9. In patients with prolapse, those with moderate levator ani deficiency have 3.2 times the odds of POP compared with patients with a minimal defect; those with severe levator ani deficiency have 6.4 times the odds of prolapse than those with minimal deficiency (15). Furthermore, Worsening LAD score is associated with levator plate descensus and decreasing levator plate descent angle (10).

Childbirth causes overstretching of the levator ani muscle (LAM), predisposing to avulsion. 24% of women after delivery have well-delineated, hypoechoic areas consistent with hematomas. Hematomas away from the attachment zone of the LAM to the pubic bone resolve. Hematomas at the site of LAM attachment to the pubic bone always result in avulsion diagnosed three months postpartum. However, 1/3 of avulsions are not preceded by a hematoma at the site of LAM attachment to the pubic bone (16). Although the prevalence of pelvic floor hematoma is higher in vaginal-primiparous women than vaginal-multiparous women after vaginal delivery, hematomas are present in both groups, pointing to the fact that the cycle of LAM overdistention, injury, and recovery is persistent with each additional pregnancy and vaginal birth (17). From the time of injury to the LAM that goes unrecognized to the development of prolapse may

take up to 18 years (18). Aging is also a strong risk factors for pelvic floor prolapse, and urinary incontinence. Levator ani muscle hiatus changes to a more oval form in older nulliparous postmenopausal women, and this change in shape is associated with increased pelvic floor symptoms (19).

3.3.2. 3D Endovaginal Ultrasonography: Mesh and sling imaging

Three-dimensional endovaginal sonography allows for more detailed imaging compared to computed tomography and magnetic resonance imaging of the female pelvic floor, in that each plane can be manipulated to show unique images of synthetic implanted materials (20). The EVUS easily distinguishes any type of sling with mesh.

tomography and magnetic resonance imaging of the female pelvic floor, in that each plane can be manipulated to show unique images of synthetic implanted materials (20). The EVUS easily distinguishes any type of sling with mesh.

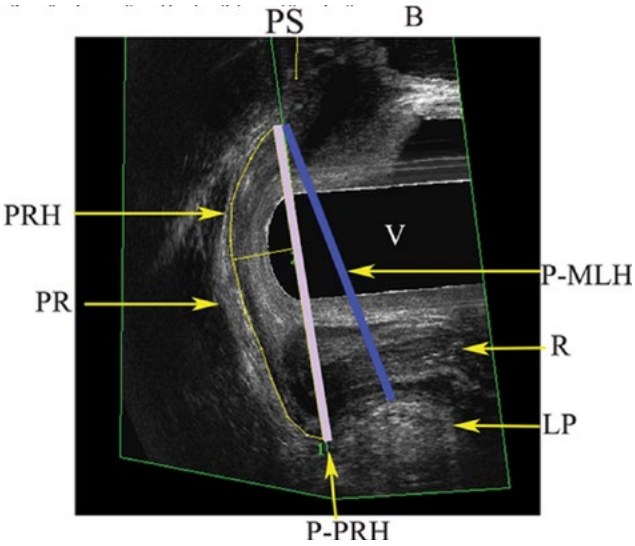

Figure 22. Ultrasound showing plane of MLH and PRH in the right sagittal view. Abbreviations: B, bladder; LP, levator plate; P–MLH, plane of MLH (blue line); P–PRH, plane of puborectalis hiatus (purple line); PR, puborectalis; PS, pubic symphysis; R, rectum; V, vagina (1).

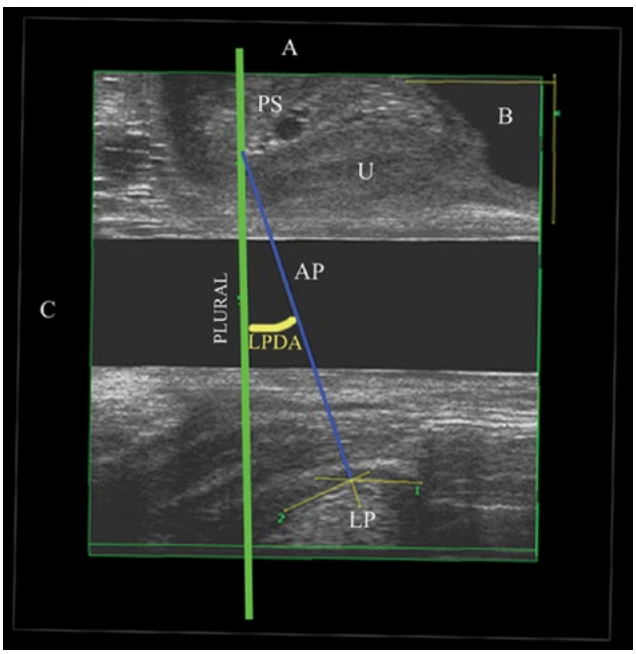

Figure 23: Levator plate descent angle (LPDA) in mid-sagittal view by transvaginal 360° ultrasound. Abbreviations: A, anterior; B, bladder; C, caudad; LP, levator plate; LPDA, levator plate descent angle; PLURAL, pubic levator ultrasound reference assessment line (green line); PS, pubic symphysis; U, urethra (1).

The most common complaints of vaginal mesh complications are pain and dyspareunia. EVUS helps assess mesh presence, location, and extent, including planning for surgical intervention (7). Anterior and posterior vaginal mesh have distinct patterns on 3D EVUS. In patients presenting with mesh complications, the posterior meshes are more often visualized as a "flat" pattern with a higher frequency of pain. Mesh complications of the anterior compartment have a higher frequency of folding and shrinkage (5).

3.3.3. 3D Endovaginal Ultrasonography: Urethral bulking agents

The ultrasound signal produced by the bulking agents varies depending on the makeup of the agent. Collagen-based bulking agents vary between hypoechoic, isoechoic, and hyperechoic. The signal from a calcium-based agent will produce a hyperechoic structure on the image near the urethra (Fig 24). Bulking deposits vary in size and shape. A well-placed bulking agent should appear round or oval in shape, whereas a poorly distributed bulking agent may track along the urethra. An agent tracking along the urethra will have the same echotexture but will appear elongated (21). Although the bulking agent is most often found at 3- and 9-o'clock positions as intended, the distance from the UVJ is highly variable after an uncomplicated office-based transurethral injection. The bulking material does not form the distinct spheres in 41% of cases and tracks toward the bladder neck or the distal urethra (22).

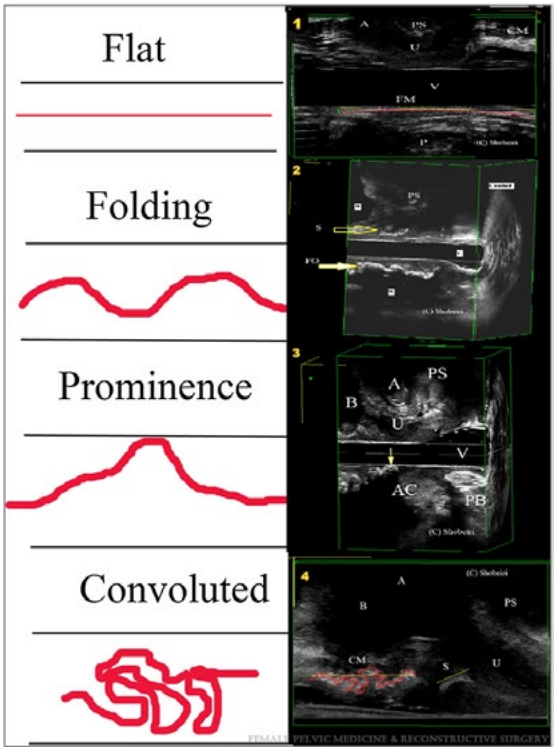

Fig 24b: Three-dimensional ultrasound images depicting vaginal mesh location and patterns based on their US manifestation: (1) flat posterior mesh in the same patient as convoluted anterior mesh, (2) left lateral view of folded mesh and anterior sling, (3) mesh prominence posterior mesh, and (4) convoluted anterior vagina mesh and sling. Arrows indicate mesh location. 3.3.4. 3D Endovaginal Ultrasonography: Cysts and Masses

The utility of 3D EVUS in evaluating Gartner duct cysts, solid masses, urethral diverticula, and Bartholin glands is well established. Most urethral diverticula are located in the middle of the urethra and involve the posterolateral wall facing the vagina. Sonography shows a relatively anechoic cavity adjacent to the urethra and may show an orifice that communicates with the urethral lumen; it also may show inflammatory debris or surrounding inflammatory edema (Fig 26) (23).

3.4. Consensus Statement

3D EVUS has been shown to be in correlation with tissue characterstics as validated by histologic and cadaveric studies and has been shown to have good intra and interobserver reproduceability. **[Level of evidence 2, Grade of Recommendation B].**

3D EVUS enables imaging of the levator ani muscle subdivisions and allows for quantification of muscle injury. **[Level of evidence 2, Grade of Recommendation B].**

3D EVUS enables direct visualization implanted mesh, slings, implanted urethral bulking agents, vaginal cysts and masses including the urethral diverticulum and should be considered as first line of investigation where the technology is available. **[Level of evidence 2, Grade of Recommendation B]**

3.5. Future Research Areas

- Examining the utility of 3D EVUS during surgery to assess surgery outcomes.
- Examining the utility of 3D EVUS to assess surgery outcomes and correlate with recurrence rates.
- Comparing 3D EVUS pre and post surgical to assess surgical outcomes
- Evaluate advance ultrasound technologies such as shear wave elastography (SWE) for the assessment of tissue characteristics.
- In general there is a lack of core competency in EVUS and there is a need for widespread education for full adaptation of point of care ultrasound.

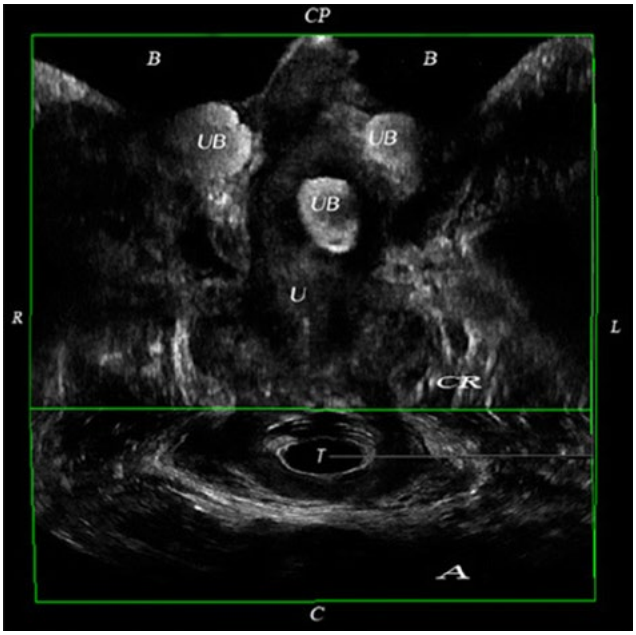

Fig 25: Coronal view obtained using an endovaginal transducer of a 3D volume demonstrating a urethral bulking agent. B, bladder; UB, urethral bulking agent; U, urethra; T, transducer; C, caudad; CP, cephalad; R, right; L, left; CR, coronal view; A, axial view.

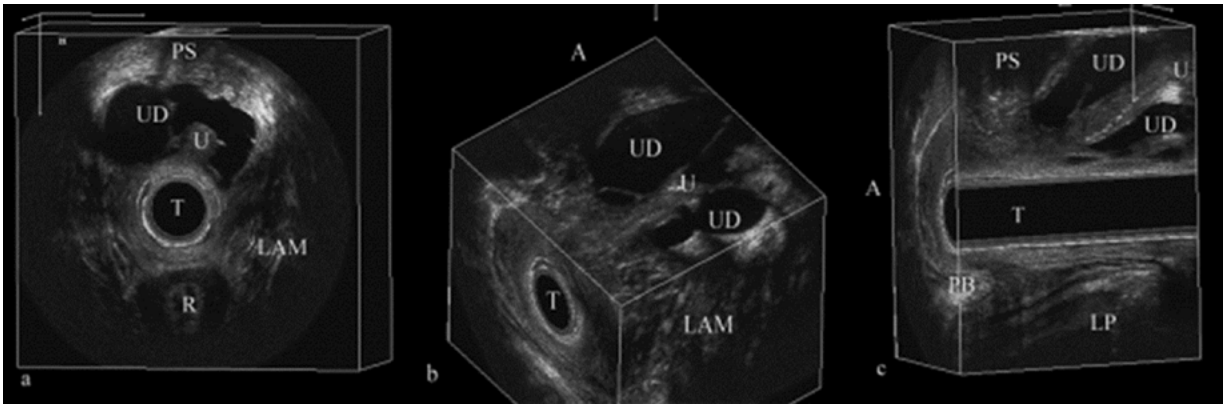

Fig 26. A: Axial view of the urethral diverticulum. The urethra is surrounded by the diverticulum. Anatomic landmarks are the pubic symphysis and pubic ramus superiorly, urethra medially, and vagina inferiorly.

4. THE ROLE OF MRI IN THE ASSESSMENT OF THE FEMALE PELVIC FLOOR

4.1. Introduction

The role of magnetic resonance imaging (1) in evaluating pelvic floor disorders has been established in recent years and continues to evolve. This technique provides unparalleled images of pelvic floor muscles, connective tissue, and organs. In addition to the detailed static picture of the pelvic organ support system anatomy, MR can also reveal the downward movement of each pelvic compartment during increases in abdominal pressure. Advances in MR imaging, equipment and software have significantly improved image quality and now MRI provides ever more detailed pictures of anatomy and function. At present active investigation is ongoing to see how this imaging might result in a better understanding of these diseases and improve their diagnosis and management.

Although women might present with symptoms isolated to one of the pelvic compartments, they often have concomitant defects in other compartments or pelvic structures. In these women, imaging can provide information to extend what can be determined on physical examination (2). Furthermore, surgical failures could result from lack of a thorough preoperative evaluation of the female pelvis and inadequate diagnosis and staging of pelvic floor deformation and dysfunction (3). Accurate diagnosis of coexisting abnormalities is therefore essential in planning reconstructive and anti-incontinence procedures. Although most diagnoses of pelvic floor prolapse are made on detailed physical exam, the sensitivity and specificity of the pelvic exam in diagnosing various forms of pelvic floor prolapse is low (4-6) . Ultrasound and fluoroscopy have been used to improve diagnosis (7, 8) and the role of MRI in pelvic floor dysfunction is rapidly developing. A systematic review suggests that prolapse assessment on dynamic MR imaging may be useful in the posterior compartment, although clinical assessment and dynamic MR imaging seem interchangeable in the anterior and central compartment (9).

MRI provides detailed images of bladder neck and urethral mobility, rectocele, cystocele, enterocele and uterine prolapse, in a single non-invasive study without exposing the patient to ionizing radiation (10-20). MRI also provides a multiplanar thorough evaluation of pelvic organs including the uterus, ovaries, ureters, kidneys, and levator muscles, as well as the urethra, that is unavailable by any other imaging modality (12, 14-18, 21, 22). MRI can identify ureteral obstruction, hydronephrosis, and uterine and ovarian pathology. In addition, MRI remains the study of choice for the evaluation of urethral diverticula.

The following measurements using MRI in urogynecology and female urology have been highlighted in the IUGA/ICS Joint Report on the Terminology for Female Pelvic Floor Dysfunction (23):

a) Bladder neck and cervical descent/mobility:

   1. Position of bladder neck and cervix at rest and on Valsalva.
   2. Pubo-coccygeal line: A line extending from the inferior border of the pubic symphysis to the last joint of the coccyx. Bladder neck or cervical descent >2 cm below this line with straining indicates weakness of the pelvic floor. If alternative landmarks are used in scientific papers they should be clearly described.

b) Intercurrent pelvic pathology: For example, fibroids, ovarian pathology.
c) Uterine version: Anteverted or retroverted; flexion at the isthmus.
d) Bladder abnormalities: For example, tumor; foreign body.
e) Urethral abnormality: For example, diverticulum.
f) Postoperative findings: For example, bladder neck mobility.
g) Pelvic floor measurements/levator defects: Assessment of the configuration of pelvic floor muscles, in particular, the levator ani.
h) Descent of pelvic organs.

This article is an update to the ICI article on the role of MRI in assessing the female pelvic floor (2012) and provides a current review of the role of MRI in understanding the causes and treatment of pelvic floor disorders.

4.2. Technique

4.2.1. Conventional MRI

Standard MRI consists of two-dimensional image acquisitions. In contrast to tumor diagnostics, MRI for urogynecological investigations can be performed without contrast media. The examination parameters are chosen organ- and examination-specific (T1, T2, proton density weighting)(24). The T2-weighted multiplanar slices are particularly suitable for visualizing the fine anatomical layers and structures, which allows, for example, the assessment of the layering of the vagina (mucosa, musculature and adventitia), urethra and its sphincters, different uterine structures, but also for the assessment of levator ani muscle fibers or ligaments **(Figure 27).** The T1 weighted sequences are ideal for the detection of fat, blood (for example hematocolpos/-metra in malformations), gas in infectious disease or metal (25). With technological advances, dynamic examinations of Valsalva maneuvers lasting 14 to 16 seconds can be recorded, which is reasonable in terms of time for the patient. Thus, MRI may become more widely used for functional assessment in the future, especially due to advances in technology and lower costs of the MRI examination. Contraindications for the use of MRI are non-MRI capable pacemakers and implants as well as severe claustrophobia. History of brain or heart surgery might also be a contraindication due to the use of potentially non-MRI-suitable clips or prostheses.

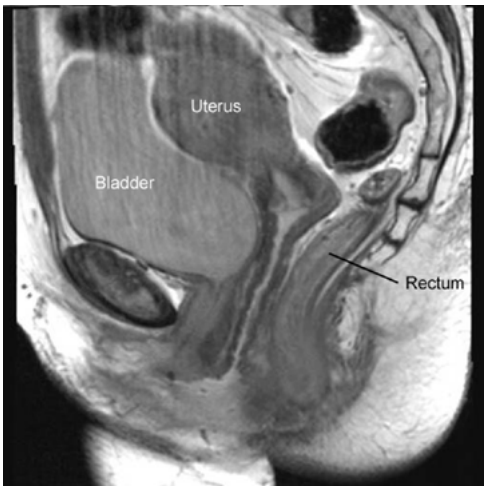

Figure 27: Sagittal mid pelvic section showing anatomical detail visible in static images made with Proton Density sequence.

4.2.2. Ultra fast image acquisition and MR sequences

Pelvic organ movement during Valsalva is identifiable using very fast single-shot MR sequences and the technical aspects have been summarized in a previous report **(Figure 28)** (ICI 2016) (16, 17, 26, 27). These sequential images are obtained approximately once per second, either as a series of images covering the entire pelvis (static imaging) or repetitively in one plane while the patient is straining (dynamic imaging). The patients are placed in the supine position with legs slightly spread apart, and knees bent and supported by a pillow. Most pelvic floor details can be seen without the need for bowel preparation, premedication, instrumentation or contrast medium but often, especially with MR defecography, ultrasound gel or other suitable agents are used to enhance visibility of the rectum and vagina. The MRI torso coil is centered at the symphysis pubis. Images are acquired in the sagittal plane using single-shot fast spin echo (SSFSE) or half Fourier acquisition, single shot turbo spin echo (HASTE) sequences. Single, mid sagittal views are obtained during 3 seconds of apnea with the patient relaxed and during various degrees of progressive abdominal straining.

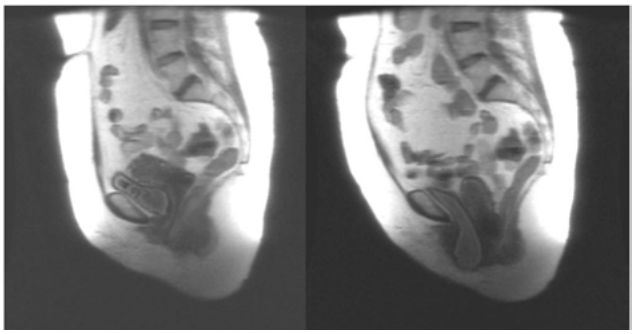

Figure 28: The rest and strain image taken from a mid-sagittal dynamic MR sequence revealing cystocele and uterine descent using SSFSE sequence.

Steady-state free precession gradient-echo imaging provides an alternative T2-like imaging contrast (T2- and T1-weighted imaging) with robust signal and a rapid acquisition time of less than 1 second, thereby permitting near real-time continuous imaging. This is an improvement on the HASTE approach that requires 1–2 seconds between acquisitions to allow T1 recovery; therefore, real-time imaging is not possible. Comparisons of the degree of POP shown on dynamic true fast imaging with steady-state precession (FISP) versus HASTE sequences in symptomatic patients reveal a greater degree of prolapse in all three compartments with a dynamic true FISP sequence. Near real-time continuous imaging with a dynamic true FISP sequence may therefore be useful to evaluate pelvic floor dysfunction in addition to dynamic multiplanar HASTE sequences (28).

During a typical study of pelvic organ movement two sets of images are obtained. The first set consists of static sagittal and para-sagittal images covering the pelvis from left to right sidewall. These images are used to select the mid-sagittal plane for the dynamic second set of images. This static sequence also allows for anatomic delineation of the pelvic sidewalls and muscular and fascial components of the pelvic floor (16, 17, 26, 27). The perineal membrane and the levator ani musculature, as well as the anal sphincter anatomy, are also clearly demonstrated (29, 30). The static set consists of 17-20 sequential images independently acquired in a total of about 18 seconds.

The second set of images consists of relaxed and straining mid-sagittal images used to assess the degree of pelvic floor relaxation and organ prolapse. Images can then be looped for viewing on a digital station as a cine stack.

Dynamic MRI allows detection of POP that may not be evident on conventional static sequences, as it permits both structural and functional evaluation. For example, in women with lower urinary tract symptoms, evaluation of the urethra may be of added value (31).

The first time a woman performs a Valsalva maneuver, she may not get the prolapse to protrude to its maximal extent. Forty per cent of women have a greater than 2cm increase in prolapse size from their first to third Valsalva attempt and 95% of women extend their prolapse further with a third Valsalva (32). As with clinical examination, several attempts may therefore be required to have maximal anterior compartment prolapse present during dynamic MRI of the pelvic floor. Delaney et al evaluated whether the use of a speculum blade modifies the evaluation of pelvic organ prolapse (POP) as assessed by dynamic MRI. Twenty-seven women with POP Quantification (POPQ) stage II or greater, scheduled for POP surgery, were evaluated using MRI. The procedure was repeated using the posterior blade of a standard plastic Grave's speculum to successively retract the anterior and posterior vaginal walls. Standard POPQ was 15% stage II (n =4), 59% stage III (n =16) and 26% stage IV (n =7). The use of a blade evidenced hidden pelvic prolapsed compartments in 59% (n =16) of cases. For 48% of patients (n =13), the variation of the leading edge of at least one additional prolapsed compartment was diagnosed as more than 20 mm. In this series, the use of a speculum blade during dynamic MRI modified the POP evaluation in a large proportion of patients with POP stage > or =II (33).

More recently, open magnetic resonance imaging (MRO) with vertical magnets, has allowed imaging in a variety of upright postures (34). A pilot study compared distances between the lowest point of the bladder to the pubococcygeal (35) and pubopromontoreal (PP) lines as well as the ratio of bladder area under the PC and PP lines to the total bladder area. Significant elongation between the PC line and lowest point of the bladder was evident in women with POP comparing supine and standing images ($p = 0.03$), but not controls ($p = 0.07$). Similarly, this axis was significantly longer in women with cystocele versus controls only in the standing position. Bladder area under the PC line was significantly increased between supine and standing positions only among women with cystocele ($p < 0.01$), and significantly larger among the study group in the standing position ($p < 0.005$), less significant in the supine position ($p = 0.015$), and not significant in the sitting position ($p = 0.3$) (36).

4.2.3. Three dimensional MRI

Three dimensional (3-D) MRI provides precise detail of the bony and muscular pelvic structures **(Figure 29)** so that 3D models can be constructed based on these detailed images. In this technique, static or dynamic images are reconstructed using consecutive planes in the axial, sagittal and coronal dimensions. Anatomic variations of the insertion and path of the pubococcygeus and iliococcygeus muscles can be seen. Fielding et al. made 3D models of the pelvic viscera and supporting muscles and bones with the marching-cubes algorithm and a surface-rendering method in nulliparous continent female volunteers and found that the muscle morphology, signal intensity and volume are relatively uniform (29). They described an average volume of the levator ani of 46.6 cc, width of the levator hiatus of 41.7 mm and an average posterior urethrovesical angle of 143.5°. In addition, these 3D models made

from multi-slice scans during a maximal Valsalva have allowed direct measurements of changes in the relationship between the vagina and pelvic walls.

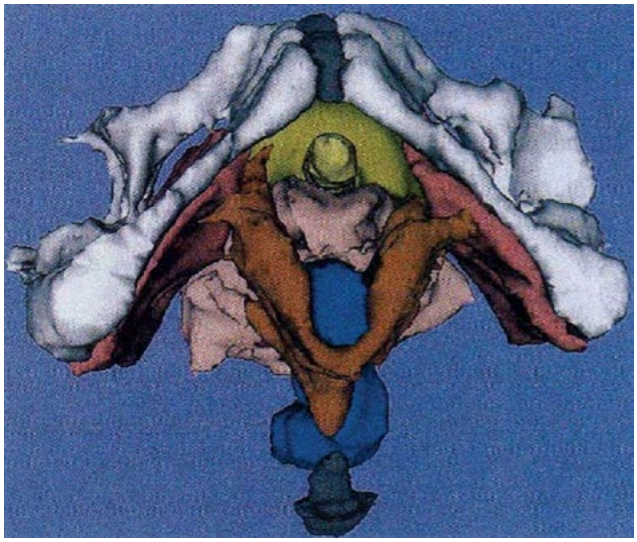

Figure 29: Pelvic Organs as seen from caudal on a three-dimensional reconstruction from Magnetic resonance images. Copyright Mosby Inc.

3D MRI enables evaluation of paravaginal defects, apical descent and vaginal widening. Larson et al (37) studied the relative contributions of "midline defects" (widening of the vagina) and "paravaginal defects" (separation of the lateral vagina from the pelvic sidewall) in women with anterior prolapse using 3D MRI models of the anterior vaginal wall and found that changes in lateral anterior vaginal wall were considerably greater than changes in vaginal width in cases vs controls. These "paravaginal defects" were also highly correlated with apical descent.

The geometry of the arcus tendineus fascia pelvis (ATFP) and arcus tendineus levator ani (38) in women with unilateral levator ani muscle defects and associated "architectural distortion" has been studied using 3D MRI. In those women, the ventral arcus anatomy is significantly altered in the presence of levator defects as well as architectural distortion, resulting in change of the supportive force direction along the lateral anterior vaginal wall, thus increasing the risk for anterior vaginal wall prolapse (39).

Luo et al (40) developed a method to evaluate changes in apical ligament lengths and lines of action from rest to maximal Valsalva using 3D stress magnetic resonance imaging (MRI). In a case-control study, 3D reconstructions of the uterus and vagina, cardinal ligament (CL), deep uterosacral ligament (USL(d)), and pelvic bones were created using 3D Slicer software. At maximal Valsalva, CL elongation was greater in cases than controls, whereas USL(d) was not; CL also exhibited greater changes in ligament length, and USL(d) exhibited greater changes in ligament inclination angle.

Following studies that reported diffusion tensor imaging (DTI) as a method for detecting alterations in tissue organisation of injured striated skeletal muscles, the clinical application of DTI and fibre tractography in pelvic floor imaging was assessed by Zijta et al (41). A two-dimensional (2D) spin-echo (SE) echo-planar imaging (EPI) sequence of the pelvic floor was acquired. Offline fibre tractography and morphological analysis of pelvic magnetic resonance imaging (MRI) were performed. Inter-rater agreement for quality assessment of fibre tracking results was evaluated. DTI with fibre tractography seems to enable 3D visualisation and quantification of elements of the female pelvic floor.

The first models of the pelvis, pelvic muscles and ligaments reconstructed in 3D from tracing a magnetic resonance imaging (MRI) were built from a female pelvis from a cadaver (42) and from a 45-year-old multiparous woman. The models were obtained with the aid of the Slicer® software an open source software platform for medical image informatics, image processing, and three-dimensional visualization (43).

4.2.4. Reference Lines and quantification of POP

As POP is a downward movement, quantification of this movement is of major importance to classify the descent in imaging. A number of studies have described reference values for grading POP (16, 17, 19). Traditional reference lines are drawn in the midsagittal plane and are based on certain anatomic landmarks. The pubococcygeal line (PCL) marks the distance from the pubis to the coccyx and serves as a fixed anatomical reference. In the nomenclature used by Comiter et al. (16), Gousse et al. (17), and Barbaric (27), the width of the levator hiatus is measured as the distance from the pubis to the pubococcygeus muscle (H-line). The hiatus is formed by the puborectalis muscle and encompasses urethra, vagina, and rectum. The M-line depicts the relaxation of the muscular pelvic floor by measuring the descent of the levator plate from the PCL. Using these three simple measurements, an MRI classification of the degree of POP has been described (16, 27). In the normal population, during straining, the hiatus (H-line) is less than 6 cm long and does not descend (M-line) more than 2 cm below the PCL. The upper urethra, urethrovesical junction, bladder, upper vagina, uterus, small bowel, sigmoid colon, mesenteric fat and rectum are all above the H-line. A combination of hiatal enlargement and pelvic floor descent constitutes relaxation. As the pelvic floor descends, so do the organs above it. The grading system for prolapse of any pelvic organ is based on 2 cm increments below the H-line. By determining the degree of visceral prolapse beyond the H-line, the degree of rectocele, enterocele, cystocele, and uterine descent can be graded in a 0 to 3 scale as follows: 0=none, 1=minimal, 2=moderate, and 3=severe. Other similar systems have been described (19) highlighting the need for standardization of nomenclature and grading of organ prolapse using MRI. In a small study, Ginath et al showed that MRI measurements of pelvic landmark angles can differentiate between women with and without uterine prolapse and correlate best with POPQ point C (44).

Novellas and colleagues evaluated two classification systems using the PCL and the midpubic line, (MPL) in 30 patients with symptoms of POP. For prolapse detection, the correlation between clinical examination and MRI ranged between 74 and 89%. For prolapse staging, the correlation was poor to moderate. Inter-observer agreement was good to very good (kappa between 0.67 and 0.95). It was slightly better at the mid stage, with both systems (kappa between 0.83 and 0.97). Comparison of the inter-observer agreement between both MRI classification systems showed better results for the system using the pubococcygeal line ($p<0.005$). The classification system based on the pubococcygeal line appeared more reliable and simple for the evaluation of pelvic prolapse on MRI (45). In another study, agreement between clinical and PCL staging was fair in the anterior (kappa = 0.29) and poor in the apical (kappa = 0.03) and posterior (kappa = 0.08) compartments. Agreement between clinical and MPL staging was fair in the anterior (kappa = 0.37), apical (kappa = 0.31), and posterior (kappa = 0.25) compartments. The MPL had higher agreement with clinical staging than the PCL

in this study. However, neither reference line had good agreement with clinical staging (46). The intra- and interobserver reliability of dynamic MR staging in POP patients has also been evaluated using various anatomical landmarks in relation to the PCL, H-line, and MPL. Clinical measurement points were assessed in relation to the mid-pubic line. Overall, the intra- and interobserver reliability of MR imaging measurements was excellent to good. The PCL showed superior reliability (intraclass correlation coefficients-ICC range 0.70-0.99). The reliability of clinical measurement points, however, were only moderate (ICC range 0.20-0.96). The intra- and interobserver reliability of quantitative prolapse staging on dynamic MR imaging were good to excellent. The PCL appeared the most reliable to use (47).

The sacrococcygeal-sacrospinous inferior pubic point (SCIPP) line is another widely used reference line, first introduced for measurements in the lateral cystourethrogram later applied in MRI (48). In pelvic floor imaging there have been used several reference lines, however there is no consensus yet, which reference line should be used in the clinical practice.

Singh et al (49) compared a new technique of grading POP by using dynamic MRI with the clinical staging proposed by the POP-Q system (50). A new reference line, the mid-pubic line, was drawn on the MR image to correspond to the hymenal ring marker used in the clinical staging. The proposed staging by MRI showed good correlation with the clinical staging (kappa = 0.61). Torricelli (51) also used MRI to evaluate functional disorders of female pelvic floor. In symptomatic women MRI confirmed the pelvic examination findings in all cases; MRI also detected additional alterations (4 cases of uterine prolapse and 3 of enterocele) that had been missed at clinical evaluation. Deval (52) compared dynamic MR imaging with physical examination as an alternative to dynamic cystoproctography for the evaluation of POP. PCL and puborectalis muscle were the reference points. The grading system is based on degree of organ prolapse through the hiatus and the degree of puborectalis descent and hiatal enlargement. They also used, the mid pubic line, which was drawn on the MR image to correspond to the hymenal ring marker used in clinical staging. Intra-operative findings were considered the gold standard against which physical examination, dynamic colpocystodefecography and MRI were compared. The sensitivity, specificity and positive predictive value of MRI were 70%, 100%, 100% for cystocele; 42%, 81%, 60% for vaginal vault or uterine prolapse; 100%, 83%, 75% for enterocele; 87%, 72% and 66% for rectocele. More recently Etlik (53) found physical examination and MR findings to be very concordant in the diagnosis of pelvic prolapse. Statistical correlations in the stages of prolapse between both of the methods were significant for anterior and middle compartment ($P<0.01$), as well as for posterior compartment ($P<0.05$).

Rosenkrantz et al evaluated the prevalence of pelvic organ prolapse as an incidental finding on dynamic magnetic resonance imaging (MRI) using the pubococcygeal line (PCL) and mid-pubic line (MPL) to diagnose and grade prolapse in all three pelvic compartments. Sixty women with symptoms unrelated to pelvic floor dysfunction who underwent dynamic MRI were included. In asymptomatic women, dynamic MRI identified the greatest degrees of prolapse in the posterior compartment. The MPL consistently yielded greater frequency of prolapse than the PCL. These findings however are of uncertain significance, requiring correlation with clinical examination (54).

Semiautomated pelvic floor measurement algorithmic models on dynamic MRI images have been developed and compared with manual pelvic floor measurements for pelvic organ prolapse (POP) evaluation. These models were shown to provide highly consistent and accurate locations for all reference points on MRI. The reference points can also be identified faster compared to manual-point identification (55). A fully automated localization method for multiple pelvic bone structures on magnetic resonance images (MRI) has been developed by the same group. Identifying structures of interest such as the pubic bone, sacral promontory, and coccyx correctly, by a fully automated identification method may result in improved diagnosis of female pelvic organ prolapse according to the authors (56).

Many different reference lines in relation to a wide variety of reference points have been used in different kind of studies. The definition of reference lines can be imprecise and interchangeable, such as the PCL and the SCIPP line. In 2013 Tunn and Rizk stated in an Editorial comment that a proper validation system for interpreting MRI measurements of POP is lacking and we urgently need to reach a consensus on a more standardized and scientifically robust MRI protocol for examination of the pelvis (57).

As a further advancement the Pelvic Inclination Correction System (PICS) line was introduced in 2013 by Betschart et al. It allowed the determination of descent of any pelvic organ in a standardized way, independent of the location of the pelvis in the scanner, whether it is tilted, flexed or extended, independent of the size or shape of the pelvis, and the orientation between different examinations or individuals (58). As the structures involved in prolapse, like the

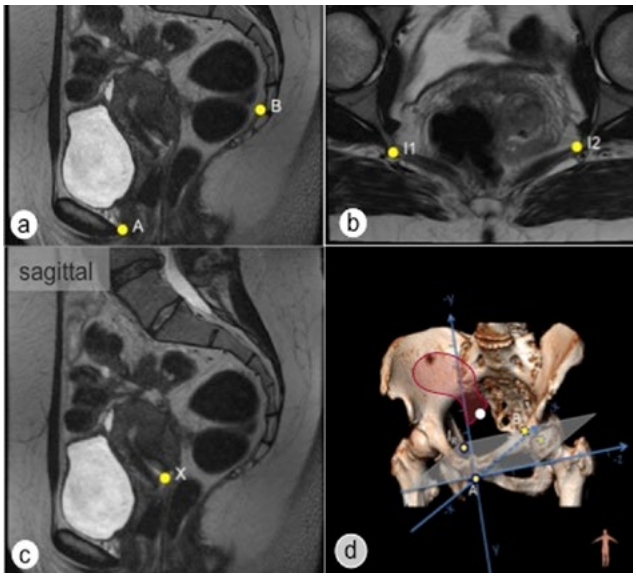

Figure 30: 3D PICS system to localize the cervix. To establish the 3D PICS coordinate system four bony landymark points are needed: a) symphysis (A), sacrococcygeal joint (B) in the midsagittal plane, b) ischial spines on the left and right side in the axial plane. c) localization of the cervix (x). d) Vector geometry can now be used to calculate the position of the cervix that is expressed with three coordinates (x/y/z, x=47, y=-54 and z=-9mm). The coordinates x means that the cervix is located 47mm from the symphysis on the antero-posterior x-axis, -54mm (y-value) means that the point lies cranially in the standardized PICS plane about 5cm above the introitus in the middle of the pelvis, and -9mm in the z-axis equals in a right-handed coordinate system 9mm to the left from the midline (59).

levator ani muscle and pelvic floor ligaments, are dispersed in the 3D space, a universally applicable 3D coordinate system was proposed that allows the measurement of any point, attachment or organ in the pelvis independent of the patient's position in the scanner, at rest or strain (59) **(Figure 30)**. Within this 3D measurement system defect localization of any point within the 3D space of the pelvis can be done. As it is based on bony landmarks in two perpendicular planes it not only allows spatial localization but also the comparison of outcomes between different surgical collectives independent of the actual position or time of the recording in the scanner and allows longitudinal studies before and after an event like a prolapse surgery or a delivery.

4.3. Normal Pelvic Floor Functional Anatomy

4.3.1. MR imaging of normal pelvic support structures

MRI studies of normal subjects have improved our understanding of normal pelvic anatomy, its variations (29) (30, 60) as well as anatomic changes in pelvic floor dysfunction (22, 61, 62).

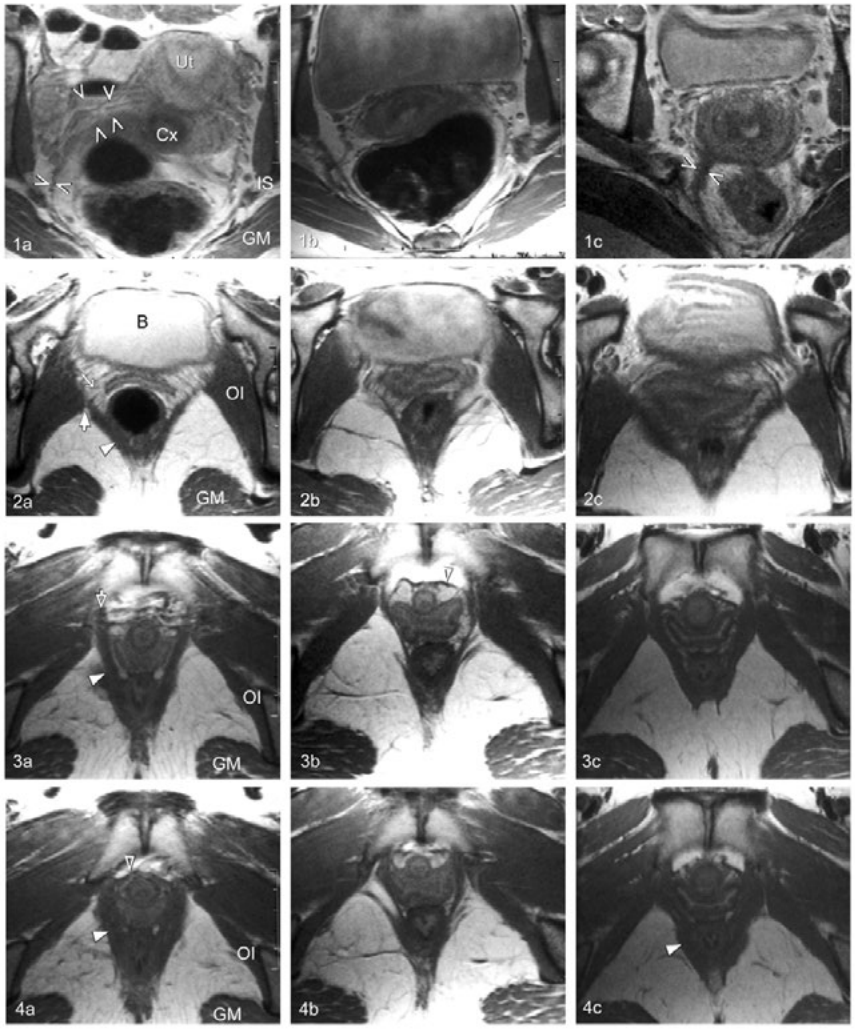

Figure 31: Axial images according , in 22-year-old (A, D, G, and J), 24-year-old (B, E, H, and K), and 34- year-old (C, F, I, and L) nulliparous women without urogynecologic problems. A-C, Level of cervix (Cx) and ischial spine (IS); uterus (Ut) with bright endometrium is also seen. Paracolpium and parametrium suspend (open tips) vagina and cervix from lateral and posterior pelvic sidewall. Smooth muscle of uterosacral ligament (open tips) is best seen in C. GM, Gluteus maximus muscle. D-F, Level of bladder (B) base. Upper vagina between bladder and rectum (R) and its attachment to pelvic sidewall by vascular and connective tissue mesentery (small arrow) are seen. Levator ani muscle (iliococcygeal part, filled arrowhead) arises from arcus tendineus of levator ani muscle (filled arrow). OI, Obturator internus muscle. G-I, At level of proximal urethra, levator ani muscle (pubovisceralis part, filled arrowhead) arises from pubic bone (open arrow). Pubovesicalis muscle (open arrowhead) is clearly seen in H. Vessels (white gap) are visualized between smooth muscle layer of lateral vaginal wall and levator ani muscle at this level. J-L, At level of middle urethra, pubovesicalis muscle is seen as shown in J (open arrowhead). Vessel layer (white gap) between lateral vaginal wall and levator ani muscle (filled arrowhead) has disappeared; direct connection between vagina and levator ani muscle is seen at this level. Small white gap in levator ani suggests fascia between puborectalis and pubococcygeal muscles (especially in J and L)(179).

In the supine position the female pelvic floor is dome-shaped at rest (62, 63). During voluntary pelvic floor contractions, the levator musculature straightens and becomes more horizontal. With bearing down the muscle descends, the pelvic floor becomes basin-shaped, and the width of the genital hiatus widens.

With MRI the specific structures are identified and their normal variations described (**Figure 31**). Tan (61) demonstrated the anatomy of the female pelvic floor with MRI. The pelvic and the urogenital diaphragm were well depicted as were urethral supporting structures—the peri-urethral and paraurethral ligaments, the pubovesical muscle, the lateral vesical ligament and the zonal anatomy of the urethra (64). The MRI findings in volunteers correlated with the endovaginal MR findings and gross anatomy in cadavers. Chou (65) studied the urethral support structures relative to the arcuate pubic ligament including the arcus tendineus fasciae pelvis, the perineal membrane, the pubococcygeal levator ani muscle and its vaginal and bony attachments, and the pubovesical muscle. Tunn et al (66) showed that 2- to 3-fold differences occur in distance, area, or volume measures of continence system morphologic features in continent nulliparous women with normal pelvic organ support and urodynamics. Sekhar et al described female urethral pathology including benign lesions, malignancy and post-intervention appearance (67).

The uterosacral ligaments also exhibit greater anatomic variation than their name would imply (68). A first quantitative analysis of uterosacral ligament origin and insertion points was done by Umek et al. This study remains unsurpassed to date in its morphometric accuracy and size of study collective (68).

Three dimensional simplified biomechanical models constructed from MRI scans showed that the CL is parallel to the body axis. The US ligament is dorsally directed. The tensions on these ligaments seem to be affected by their orientations according to this study (69). Luo et al performed stress MRI to analyze the 3D changes in apical ligament geometry within the uterosacral – cardinal ligament complex. At maximal Valsalva the CL elongation was greater in women with prolapse then in controls, whereas the USL exhibited a greater change in the ligament inclination angle downwards (40).

Kaniewska et al described the female pelvic anatomy with special focus on the suspensory ligaments of the female genital organs as depicted with MRI. They also proposed a checklist for structured reporting of the MRI findings in the female pelvis (70).

Characteristic anatomic features of the posterior compartment and perineal body have been studied with MR cross-sectional anatomy and can be further elucidated and integrated with 3-D anatomy. In nulliparous asymptomatic women the posterior compartment's upper, mid, and lower segments are best visualized in MRI in the axial plane. It is bounded inferiorly by the perineal body, ventrally by the posterior vaginal wall, and dorsally by the levator ani muscles and coccyx. In the upper portion, the compartment is bordered laterally by the uterosacral ligaments, whereas in the middle portion, there is more direct contact with the lateral levator ani muscles. In the lower portion, the contact becomes obliterated because the vagina and levator ani muscles become fused to each another and to the perineal body (71) (**Figure 32**). The perineal body anatomy has been possible to study using 2mm MR images. Visualization of perineal body anatomy in living women and development of 3-D models enhanced our understanding of its 3 different regions: superficial, mid, and deep (72). The three distinct perineal body regions (73) are a superficial region at the level of the vestibular bulb, a midregion at the proximal end of the superficial transverse perineal muscle, and a deep region at the level of the midurethra and puborectalis muscle. Structures are best visualized on axial scans, whereas craniocaudal relationships are appreciated on sagittal scans. In the superficial portion at the level of the vestibular bulb (VB), the bulbospongiosus (BS) inserts into the lateral margins of the perineal body, whereas the superficial transverse perineal muscle (STP) and external anal sphincter (EAS) traverse the region. In the perineal body's midregion at the proximal end of the superficial transverse perineal muscle, the puboperinealis muscle inserts into the lateral margins of the perineal body and in some individuals can be seen to cross the midline. This region also contains the distal internal anal sphincter. The puboanalis muscle is also visible as it inserts in the intersphincteric groove between internal and external anal sphincters. The puboanalis muscle and internal anal sphincter extend into the perineal body's most deep region at the level of the midurethra. Here the pubovaginalis muscle also becomes visible as it fuses with

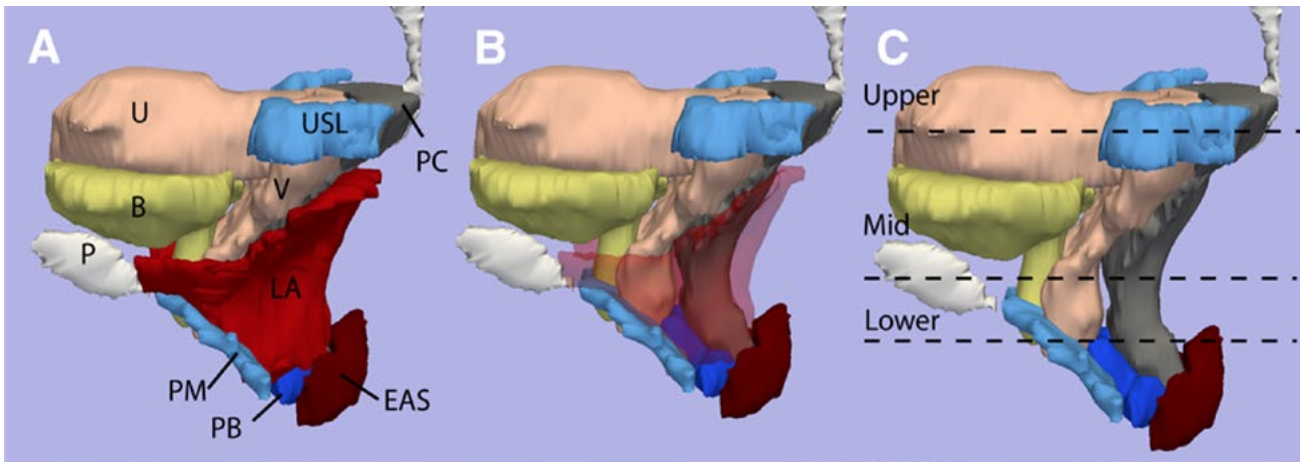

Figure 32: The outline of the midsagittal pubic bone (P) is shown. The bladder (B) is yellow; the uterus (U) and vagina (V) are pink; the uterosacral ligament (USL) and perineal membrane (PM) are turquoise blue; the levator ani muscle (LA) is red; the perineal body (PB) is royal blue; the external anal sphincter (EAS) is dark red; and the posterior compartment (35) is gray. Image A, All organs are shown. B, Levator ani muscles have been faded to show the underlying structures. C, Levator ani muscles have been removed. Figure 33: 3D Model of the perineal body (72).

the vaginal side wall, sending fibers posteriorly to the perineal body. In this location, the longitudinal muscle of the rectum may be visible in the midline. The puborectalis muscle forms a loop behind the rectum at this level but does not contribute fibers to the perineal body (**Figures 33 & 34**).

One of the key anatomical contributions MRI has made to the understanding of normal pelvic floor structure, regards the ability to make images of a wide variety of normal living women. The pelvic floor is greatly distorted in cadavers due to loss of muscle tone and pressures during embalming. Otcenasek et al have used MR images of a normal nulliparous woman to establish geometry and then added details from dissection to produce an anatomically based topographically normal 3-D model that displays the features of pelvic floor anatomy (**Figure 35**)(74).

Nardos et al (75) compared levator hiatus measurements between pelvic magnetic resonance imaging (MRI) and 3-dimensional pelvic ultrasound (US) in 37 asymptomatic nulliparous women. They found that the MRI measurements obtained from the sagittal images were consistently greater than the ones obtained by US. However, there was no such difference between MRI and US for the axial images. The authors attributed this observation to acquisition planes for axial images or interpretation of landmarks for the sagittal images.

4.3.2. Levator Ani Muscle Functional Anatomy

Evidence from MR and CT images in volunteers and cadavers shows that the anterior transverse portion of the levator muscle is basin-shaped; the middle transverse portion funnel-shaped, while the posterior transverse portion dome-shaped. The puborectalis appears u-shaped outside the vertical portion (76). On MR images of the five Terminologia Anatomica-listed levator ani components: pubovisceral (pubovaginal, puboperineal, and puboanal), puborectal and iliococcygeal portions of the levator ani muscle muscles in women with normal pelvic support., the puborectal muscle can be seen lateral to the pubovisceral muscle and decussating dorsal to the rectum in the axial plane. The course of the puboperineal mus-

cle near the perineal body is also seen best in the axial plane. The coronal view is perpendicular to the fiber direction of the puborectal and pubovisceral muscles and shows them as “clusters” of muscle on either side of the vagina. The sagittal plane consistently demonstrates the puborectal muscle passing dorsal to the rectum to form a sling that can be seen as a “bump”. This plane is also parallel to the pubovisceral muscle fiber direction and shows the puboperineal muscle (77)(**Figure 36**).

Betschart et al (78) described a technique to quantify muscle fascicle directions in the levator ani (LA): Among levator subdivisions, significant angle differences were observed between PVM and PRM (60 degrees), and between ICM and PRM (52 degrees). An 84 degrees difference was observed between PVM and EAS. The smallest angle difference was between PVM and ICM (8 degrees). The difference between PRM and EAS was 24 degrees.

Recent studies looked at the levator ani muscle volume in relation to BMI or age. In two studies by Morris and levator ani muscle did not show evidence of significant age- or body-weight related levator ani muscle atrophy (79, 80). Contradictory results and an age-dependent thinning of the levator ani muscle showed a study by Komemushi and colleagues: for patients aged ≤65 years, both men and women significant differences in the median muscle thickness (men: 3.8 mm vs 3.1 mm, P ≤ 0.0001; women: 4.1 mm vs 2.6 mm, P ≤ 0.0001) were shown (81). Swenson and colleagues showed also an increase of the levator bowl volume with aging and a more posterior distension of the muscle, independent of childbirth changes to the genital hiatus (82).

4.4. Pathophysiology of Pelvic Floor Disorders

4.4.1. Levator Ani (LA) Muscle Defects

Lammers et al (83) assessed the inter- and intraobserver reliability of the diagnosis of pubovisceral muscle avulsions and measurements of the levator hiatus on MRI and confirmed that pubovisceral muscle avulsions and levator hiatus measurements can be assessed with good to excellent reliability on MRI.

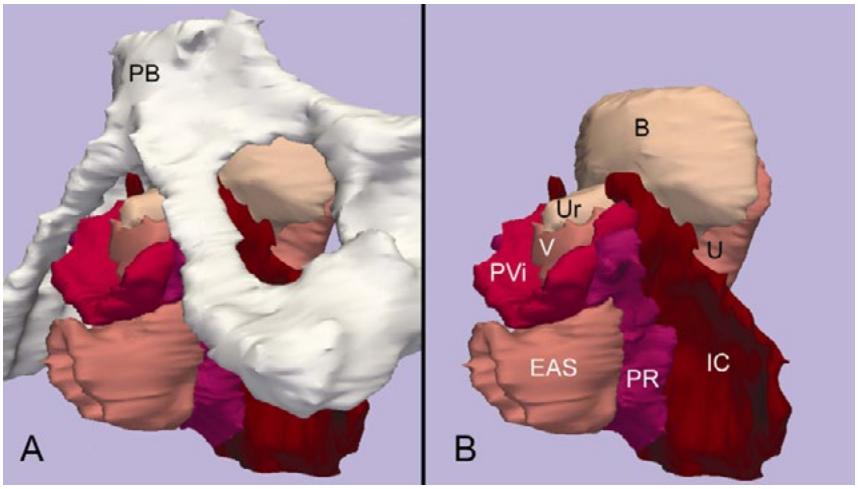

Figure 36: Three-dimensional model of levator ani subdivisions including the pubic bone and pelvic viscera. This model was created by using the magnetic resonance images shown in Figures 2, 3, and 4. The pubovaginal, puboperineal, and puboanal muscles are all combined into a single structure, the pubovisceral muscle. Inferior, left 3-quarter view. B. The same model without the pubic bone. Figure 37: Examples of grades of defects in the pubovisceral portion of the levator ani muscle in axial magnetic resonance images at the level of the mid urethra. These were selected to illustrate degrees of defects in individuals with a normal contralateral pubovisceral muscle. The score for each side is indicated on the figure, and the black arrows indicate the location of the missing muscle. A. A grade 1 defect; B. A grade 2 defect; and C. A grade 3 defect. © DeLancey 2006 (84).

In a case control study with group matching for age, race, and hysterectomy status (84), women with prolapse (cases) were compared to those with normal support (controls). Major defects were those that lost more than 50% of the muscle bulk. Cases were more likely to have major levator ani defects than controls (55% compared with 16%), but equally likely to have minor defects (16% compared with 22%) **(Figures 37 & 38).** Women with defects generated less vaginal closure force during a pelvic muscle contraction than women without defects (2.0 Newtons compared with 3.1 Newtons) and women with prolapse also generated less vaginal closure force during pelvic muscle contraction than controls (2.0 Newtons compared with 3.2 Newtons). This confirmed earlier uncontrolled observations with ultrasound (85).

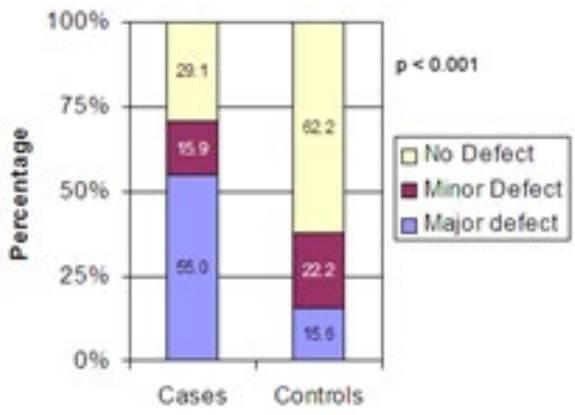

Figure 38: Percentages of cases and controls with no defects, minor defects, and major defects; P_.001. © DeLancey 2006 (84).

It is important to distinguish between muscle thickness and muscle damage. A woman with a normally thin but intact muscle may have less muscle substance than a woman with naturally bulky muscles who has a defect that has involved 25% of her muscle bulk. The issue of muscle damage is relevant to seeing who is injured, while that of muscle bulk, with the capability of the muscle to close the hiatus. Hoyte et al (86) examined 10 women with prolapse, 10 with urodynamic stress incontinence, and 10 asymptomatic volunteers. Mean 3-dimensional parameters in the 3 groups showed levator volumes of 32.2, 23.3, and 18.4 cm^3 (P <0.005); hiatus widths of 25.7, 34.7, and 40.3 mm (P <0.005); left levator sling muscle gaps of 15.6, 20.3, and 23.8 mm (P =0.03), right levator sling muscle gaps of 15.6, 22.5, and 30.8 mm, (P =.003), and levator shape (90%, 40%, and 20% dome shaped; P <0.005). Subsequently, using a novel thickness mapping (87), they found thicker, bulkier anterior portions of the levators in asymptomatic women, compared with women with prolapse or urodynamic stress incontinence while the more posterior portions of the muscle were not affected.

Hsu and colleagues quantified levator ani muscle cross-sectional area as a function of prolapse and muscle defect status (88). Using muscle cross-sections from 3-D reconstructions they found that women with visible levator ani defects on MR have less muscle ventrally compared with women with intact muscles. Women with major levator ani defects had larger cross-sectional areas in the dorsal component than women with minor or no defects indicating a compensatory hypertrophy in this area. Furthermore, after controlling for prolapse, women with levator defects appear to have a more caudal location of their perineal structures and larger hiatuses at rest, maximum contraction, and maximum Valsalva maneuver (89).

Among women with POP, those with major LAD appear less likely to experience stress incontinence when “coughing, laughing, or sneezing” (odds ratio (OR) 0.27) and when “twisting, reaching, lifting, or bending over” (OR 0.26) than women with normal muscles. They are less likely to have obstructive symptoms characterized by assuming an “unusual toileting position” or “changing positions... to start or complete urination” (OR 0.27). Women with minor LAD appear more likely to experience stress incontinence with exercise (OR 3.1) and urge incontinence (OR 4.0) than those with normal muscles. Lower urinary tract symptoms are therefore less common among women with prolapse and major levator ani defects and more common among those with minor defects (90). This may be explained by the fact that the women with major LA defects have larger prolapses than those who do not have major LA defects. It is a clinical observation that prolapse often reduces the occurrence of stress incontinence (urethral kinking?) and this hypothesis is consistent with the observations mentioned above.

Cai et al (91) evaluated levator ani morphology and function in healthy nulliparous women using static and dynamic MRI. They found no morphologic abnormality in healthy nulliparous women. However, in 15% (12/80) of women, pelvic organ descent below the pubococcygeal line was observed. In these women, the width of the pubic portion of the levator ani was significantly reduced during straining, whereas the levator plate angle, the levator hiatus area, and the H and M line lengths were enlarged. These changes were associated with weakened levator ani function and pelvic floor laxity.

Longitudinal studies on the changes of the pelvic floor before, during and after pregnancy are scarce. In one study, 19 subjects seeking assisted reproductive medicine underwent a pre-pregnancy pelvic MRI and 10 of the women underwent a post-pregnancy pelvic MRI 6 months after delivery. Pregnancy and delivery resulted in increased pelvic mobility in both vaginal delivery and elective cesarean delivery patients and in 20% of the women a levator injury was described (92).

Not only birth-related injuries have been addressed by MRI, also pregnancy-related USL and LA changes were subject of imaging research. In a sequential MRI exam three time points during pregnancy and two times postpartum (at 6 weeks and 12 months), the levator ani muscle and the uterosacral ligament after a c-section were still longer postpartum at 12 weeks than at week 16 of gestational age (93).

4.4.2. Identifying the Injury Zone within the Levator Ani

Muscle most often involved by Injury

MRI based 3D models show that in women with bilateral puborectal muscle avulsion after vaginal delivery, the damage affects the pubic origin of the muscle. This structural change alters the support to the whole endopelvic fascia and destabilizes both the anterior and the posterior vaginal walls (94). In women with significant muscle on one side and damaged muscle in the same individual (95) the injury involves the muscle's origin from the posterior pubic bone **(Figure 39).** Distortion of the surrounding connective tissue with lateral spilling of the vagina towards the obturator internus muscle is observed in 50% of women. The defect is right sided in 71% of patients. The average difference of the amount of muscle lost in these types of injury between the normal side and the defective side is up to 81% at locations nearest the pubic origin (96). Almost all of the volume difference (13.7%, P=0.0004) is attributable to a reduction in the pubic portion (24.6%), not the iliococcygeal portion of the muscle.

An estimate of levator ani muscle stretch during delivery was published using MRI of a live childbirth. Three-dimensional magnetic resonance image sequences were obtained from coronal and axial planes before the expulsion phase without pushing and during the expulsion phase, occurring over 2 contractions. A maximum circumferential stretch of 248% on the posterior-medial portion of the levator ani muscle was shown (97).

4.4.3. Changes in the Hiatus Size and Levator Plate Angle with Prolapse

The levator ani muscle's constant activity closes the genital hiatus. In addition to evaluating defect status and muscle bulk, MRI has revealed changes to the levator hiatus and angle of the levator plate (that midline portion of the muscle between the anus and the coccyx) which is presumed to be influenced by muscle action. Hsu and colleagues (98) studied 68 women with pelvic organ prolapse and 74 normal controls. During Valsalva, controls had a mean levator plate angle of 44.3 degrees. Cases had 9.1 degrees (21%) more caudally directed levator plate angle compared to controls (53.4 degrees vs. 44.3 degrees), 15% larger levator hiatus length (7.8 cm vs 6.8 cm), and 24% more caudal perineal body location (6.8 cm vs 5.5 cm). Increases in levator plate angle were correlated with increased levator hiatus length (r = 0.42) and perineal body location (r =.51). The bladder neck descent at straining is also correlated with the levator plate angle at rest, hiatus length at rest and at straining (99). Uterine cervix descent at straining is correlated with increased hiatus length and width at straining, and greater levator plate angle (p=0.007) at straining. Paradoxically anterior rectal

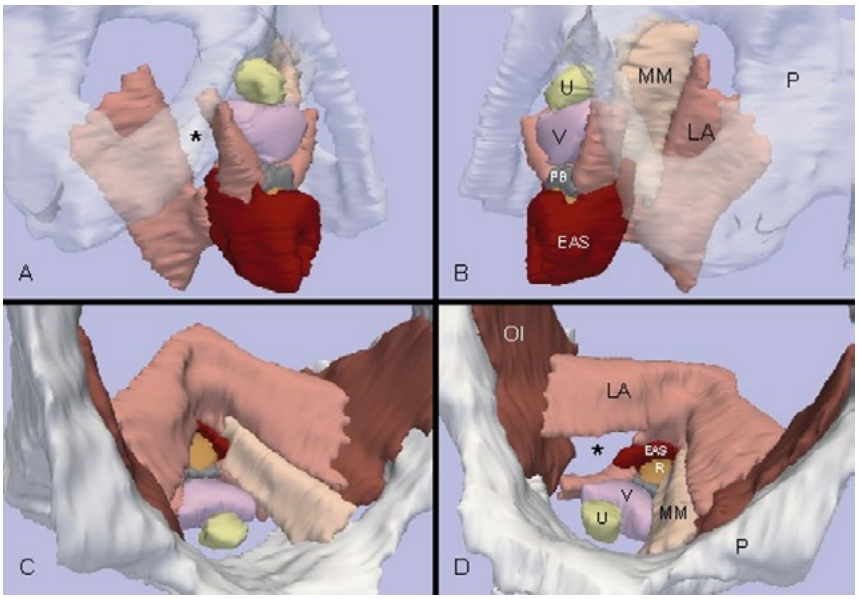

Figure 39: Three-dimensional model generated from the axial MR scans shown in Figure 1. A, and B, Oblique right and left inferolateral views, similar to the dorsal lithotomy position, are shown. In these panels the pubic bone is semitransparent and the obturator internus muscle is not shown. C, and D, Oblique right and left views peering over the pubic bone and down to the pelvic floor are shown. The urethra, vagina, and rectum have been truncated so as not to obscure the views of the levator muscles. EAS, external anal sphincter; LA, levator ani; MM, mirror image of the missing muscle; P, pubis; PB, perineal body; U, urethra; V, vagina. The missing muscle in A and D is denoted (asterisk). © DeLancey 2006 (95) .

bulging at straining is inversely correlated with the hiatus width at rest (p = 0.04).

Perineal descent and localized outward bulging of the levator ani during Valsalva was evaluated by Gearhart and colleagues (100). In this study, dynamic MRI of symptomatic patients with pelvic floor prolapse demonstrated unsuspected levator ani hernia. Patients with POP, fecal and/or urinary incontinence, or chronic constipation were evaluated. Fifteen percent of patients (12/80) had unilateral (n = 8) or bilateral (n = 4) levator ani hernias on MRI. Perineal descent on physical examination was associated with a levator ani hernia in nine patients.

4.4.4. MRI and the Bony Pelvis

Studies of the bony pelvis dimensions and their associations with POP, levator ani defects and stress incontinence have recently been undertaken. Stein et al showed that bony pelvis dimensions are similar at the level of the muscular pelvic floor in white women with and without POP (101). Further evaluation of the bony pelvis using MRI scans has also improved our understanding of the natural history of stress urinary incontinence as well as the associations of the bony pelvis dimensions with the prevalence of levator defects (102). Other studies investigating the role that different pelvis shapes play for specific diseases will be described in subsequent sections of this review.

Pipitone and colleagues analyzed musculoskeletal findings in 18 women with postpartum pelvic pain. They found a high number of musculoskeletal abnormalities 4.5 months after vaginal deliveries. In 94.4% lesions were found with MRI and they correlated highly with the symptoms. Most prevalent chronic injuries were bone oedema, pelvic bone fractures and levator ani injuries (103).

4.4.5. MRI of Pelvic Floor After Vaginal Delivery

There are changes observed in the levator ani and pelvic floor musculature immediately after delivery, which change over time. Boreham (104) evaluated the normal visibility of the levator in post term nulliparas using 3-dimensional (3-D) MRI. LA insertion into the symphysis was visible in 93%, and the iliococcygeus muscle assumed a convex shape (arch) in 92% of 84 nulliparas. Mean LA volume was 13.5 (3.7) cm^3. Interestingly there was a positive association between LA volume and higher fetal station with increasing BMI. The muscle signal intensity appears increased at 1 day postpartum on T2 weighted images, but normal by 6 months. The urogenital and levator hiatus decreases significantly by 2 weeks postpartum (105). Lienemann (106) found thinning of the puborectal muscle in primiparous women after vaginal delivery (0.6 cm vs. 0.8 cm) and increased descent of the bladder, vaginal fornix, and anorectal junction during straining compared to healthy asymptomatic nulliparous volunteers.

The descent of the bladder and cervix on straining appears greater in women who delivered vaginally compared to those who had cesarean delivery and to nulliparous women. There is a positive correlation between the duration of labor and the area of the levator sling and also between birthweight and the descent of the cervix on straining (107).

The role of levator ani muscle damage and stress soon after birth has also been studied. An investigation of 80 nulliparous asymptomatic women and 160 vaginally primiparous women half of whom had new stress incontinence after their first birth was conducted 9 months after delivery. A visible defect in the levator ani muscle was identified in 32 primiparous. Twenty-nine of these 32 defects were in the pubovisceral portion of the levator and three were in the iliococcygeal portion. None of the nulliparous women showed these abnormalities (108). In a further study of this cohort (109) evaluation of obstetric factors associated with levator ani injury after first vaginal birth showed increased odds ratios for levator defect: forceps use 14.7, anal sphincter rupture 8.1 and episiotomy 3.1 but not vacuum delivery (0.9) epidural use (0.9) or oxytocin use (0.8). Women with levator injury were 3.5 years older and had a 78-minute longer second stage of labor. Differences in gestational age, birth weight, and head circumference were not statistically significant.

Dannecker (110) compared women after spontaneous vaginal delivery to those delivered by vacuum extraction and a control group of healthy nulliparous volunteers. Significant differences for individual POPQ component measurements were noted for points Aa and Ba, TVL, and GH (spontaneous delivery versus control) and in addition for Ap, Bp, and D (vacuum extraction versus control). Significant differences were observed for the position of bladder base, bladder neck, posterior vaginal fornix, anorectal junction, hiatus perimeter and depth of rectocele. Looking into comparisons with the spontaneous vaginal delivery group, on clinical examination, there was more evidence of anterior vaginal wall descent after vaginal delivery, and TVL and GH. Differences between the groups with regard to points Ap and Bp reached only marginal significance. With MRI measurements primiparous women who underwent spontaneous vaginal delivery as compared to nulliparous women showed considerable and statistically significant descent of almost all assessed structures at rest and on straining. Bladder base, bladder neck and the anorectal junction descended even below the respective reference lines. The bladder neck showed considerably increased mobility, and the genital hiatus showed an increased change on straining. The depth of rectocele increased more than three times. One of 26 women (4%) had a rectocele >3 cm. POPQ measurements that differed significantly between primiparous women after vacuum extraction and nulliparous women of the control group indicated more evidence of anterior and posterior vaginal wall descent after vacuum extraction. In addition TVL and GH was increased and PB was decreased after vacuum extraction. MRI measurements after vacuum extraction, showed considerably increased descent and mobility of the bladder base and bladder neck on straining, and descent of the anorectal junction was prominent. The mean depth of rectocele was four times bigger than in the nulliparous group. Four of 49 women (9%) had a rectocele >3 cm.

Branham and colleagues (111) evaluated postpartum changes in the levator ani muscle in relation to obstetric events. In those subjects recovering to normal MR by 6 months an average of nearly 60% increase in right puborectalis muscle thickness compared with that seen at 6 weeks indicated the extent of the injury. Younger white primiparous women had a better recovery at 6 months than older white women. Subjects experiencing more global injury, in particular to the iliococcygeous, tended not to recover muscle bulk.

Heilbrun and colleagues investigated the correlation between the presence of major LAM injuries on MRI with fecal incontinence (FI), POP, and urinary incontinence (UI) in primiparous women 6-12 months postpartum using a scoring system to characterize LAM injuries on MRI. Major LAM injuries were observed in 19.1% women who delivered vaginally with external anal sphincter (EAS) injuries, 3.5% who delivered vaginally without EAS injury, and 0% who delivered by cesarean section before labor (P=.0005). Among women with EAS injuries, those with major LAM injuries trended toward more FI, 35.3% vs. 16.7% (P=.10) and POP, 35.3% vs 15.5% (P=.09), but not UI (P=1.0). These data confirm that both EAS and LAM are important for fecal continence and that multiple injuries contribute to pelvic floor dysfunction (112) .

Handa and colleagues used MRI to measure bony and soft tissue pelvic dimensions in 246 primiparas, 6-12-months postpartum. A deeper sacral hollow was significantly associated with fecal incontinence (P = 0.005). Urinary incontinence was marginally associated with a wider intertuberous diameter (P = 0.017) and pelvic arch (P = 0.017). There were no significant differences in pelvimetry measures between women with and without prolapse in this study (113).

In another prospective study, 51 primiparous women (vaginal delivery group: 30 women; elective caesarean delivery group: 21 women) underwent static and dynamic MRI at 1 week, 6 weeks, 3 months, and 6 months postpartum to measure pelvic floor MRI values. Pelvic floor recovery primarily occurred during the early phase after delivery in both groups. Elective caesarean delivery had a non-significant protective effect on postpartum pelvic floor structure and function compared to vaginal delivery (114).

4.4.6. MRI and Biomechanical Investigation of the Pelvic Floor

MRI has allowed anatomically based biomechanical models to be constructed. Simulations have demonstrated important interactions between muscle and connective tissue in providing anterior vaginal wall support (115). MRI has enabled construction of finite element analysis (116, 117). It has also allowed for capture of 3D shape variation of the levator ani during straining where complete volumetric imaging is prohibited by the inherent temporal resolution of the scanning technique (118).

Chen developed and validated recently a 3D finite element computer model of the anterior vaginal wall and its supports based on spatial data from MR scans of normal women. They determined the combinations of muscle and connective tissue impairments that result in cystocele formation, as observed on dynamic MRI geometry from a healthy nulliparous woman. It included simplified representations of the anterior vaginal wall, levator muscle, cardinal and uterosacral ligaments, arcus tendineus fascia pelvis and levator ani, paravaginal attachments, and the posterior compartment. The authors found that development of a cystocele requires a levator muscle impairment, an increase in abdominal pressure, and weakening of apical and paravaginal support (119). These simulations provide a way to see what specific changes in structural components do to pelvic organ support in ways that would be impossible to study in living women.

Peng et al (120) assessed urethral support by developing a pelvic model from an asymptomatic female patient's MR images using the finite element method. Weakening the vaginal walls, puborectalis muscle, and pubococcygeus muscle generated the top three largest urethral excursion angles. Weakening all three levator ani components together caused a larger weakening effect than the sum of each individually weakened component, indicating a nonlinearly additive pattern. The authors concluded that the vaginal walls, puborectalis, and pubococcygeus are the most important individual structures in providing urethral support. The levator ani muscle group therefore provides urethral support in a well-coordinated way with a nonlinearly additive pattern according to the authors of this study.

A recent study by Sheng et al on urethral closure pressure 8 months after a vaginal delivery with risk factors for a levator avulsion revealed that the presence of a pubovisceral muscle tear did not influence resting urethral closure. However, women with a pubovisceral muscle tear achieved a 25% lower urethral closure pressure during an attempted pelvic muscle contraction than those without a pubovisceral muscle tear (121). Levator ani muscle integrity and pelvic floor function are interrelated in this pressure analysis.

4.4.7. Racial Differences in Pelvic Dimensions

There are differences that exist in the occurrence of women from different racial backgrounds. Several groups have evaluated racial differences in the bony pelvis and the levator ani muscles (122-124). In a study by Handa et al (122), a wider transverse diameter (odds ratio 3.4) and a shorter obstetrical conjugate (odds ratio 0.2) were associated with pelvic floor dysfunction after controlling for age, race, and parity. Hoyte and colleagues found that levator ani volume was significantly greater in African-American (AA) asymptomatic nulliparous women without pelvic floor dysfunction compared to white American (WA) ones (mean = 26.8 vs. 19.8 cm3, P = .002). The levator-symphysis gap was smaller in the AA (left-18.2, right-18.8 mm) versus the WA group (22.4, 22.6 mm, P = .003, .048) on the left and right. Significant differences were also seen in bladder neck position, urethral angle, and the pubic arch angle (123). In another study with 3D MRI levator thickness was significantly greater bilaterally in black nulliparas compared to white ones, yet obturator internus muscle thicknesses were similar (124).

Handa found that the pelvic inlet was wider among white women than African-American women (10.7+/-0.7 cm compared with 10.0.+0.7 cm, P<.001). The outlet was also wider (mean intertuberous diameter 12.3+/-1.0 cm compared with 11.8+/-0.9 cm, P<.001). There were no significant differences between racial groups in interspinous diameter, angle of the subpubic arch, anteroposterior conjugate, levator thickness, or levator hiatus (125).

A broader group of races was studied by Rizk et al with MR in asymptomatic multiethnic nulliparous young volunteers from 5 ethnic groups (Emirati, other Arab, Filipino, Indian/Pakistani, and European/white volunteers), with the white volunteers as the reference group (126). The white volunteers were taller (P <.0001) than the other women. Their levator hiatus was longer than the Emirati women (P=.03) and wider than the Filipino women (P=.04). The bladder neck descent on straining was also greater than the other groups (P <.00001). The white women also had the longest transverse diameter of the pelvic inlet (P=.002). Their sagittal outlet diameter was longer than the Emirati and Arab women (P=.02), and their interspinous diameter was longer than the Arab women (P=.002).

4.5. Pelvic Organ Prolapse

MRI has proven to be a key assessment for understanding pelvic organ prolapse; a problem that arises from damage to connective tissue, muscles, and nerves that are invisible on standard radiography. With the advent of 3D ultrasound and MRI, the actual structures involved in the cause of prolapse can be seen and examined. This is possible not only in static scans that reveal morphological details of the pelvic structure, but also in dynamic scans where the movements of the various organs can be studied.

Evaluation of the degree of anterior compartment (bladder) and apical compartment (cervix) prolapse at maximal Valsalva using dynamic MRI showed a strong correlation between how far the bladder base and uterine cervix were below normal with $r^2 = 0.53$ indicating that slightly over half of the observed variation in anterior compartment support may be explained by apical support (127). Further analysis in the same patients showed that vaginal length was the strongest secondary factor determining 30% of the variation after apical descent was taken into account. This finding that a longer vaginal wall was associated with increasing cystocele size was unexpected, but seems consistent with clinical observations (128).

Hsu et al found that vaginal thickness is similar in women with and those without pelvic organ prolapse. However, in prolapse patients the vaginal perimeter and cross-sectional areas are 11% and 20% larger respectively (129).

Broekhuis et al studied the relationship between patient symptoms using questionnaires' domain scores and the perineal position on dynamic MR imaging of 69 women. They found that POP symptoms were associated with the degree of descent of the perineum but perineal descent was not related to anorectal and/or urinary incontinence symptoms (130).

In another study examining correlations of patients' symptoms with findings on clinical examination and dynamic MR imaging of the pelvic floor, only the domain score genital prolapse was significantly correlated in the positive direction with the degree of POP as assessed by POP-Q and dynamic MR imaging (r(s) = 0.64 and 0.27, respectively), whereas the domain score urinary incontinence was inversely correlated (r(s) = -0.32 and -0.35, respectively). The sensation or visualization of a bulge in the vagina was the only symptom which correlated positively with the degree of POP, with clinical examination and dynamic MR imaging showing similar correlation in this respect (131).

Broekhuis et al concluded that correlations for the POP staging with the use of POP-Q, dynamic MR imaging, and perineal ultrasonography are only observed in the anterior compartment (132).

4.6. MRI for Clinical Evaluation of Prolapse

4.6.1. Enterocele

In the past, enteroceles were usually only appreciated on radiographic examination after repeated straining after evacuation and usually required opacification of the vagina in order to demonstrate the insinuation of small bowel loops between the rectum and vagina (133). MRI has proven to be a much simpler and less invasive technique for the evaluation of enteroceles. In comparisons between physical examination, intraoperative findings and MR images in women with and without prolapse. MRI was significantly superior in detecting enterocele when compared to physical examinations with a sensitivity of 87%, specificity of 80%, and positive predictive value of 91% (17)(**Figure 40**). Similarly, MRI had a much higher sensitivity for detection of enteroceles when compared to physical exam and dynamic cystoproctography (134). Whether or not this technique alters clinical outcome remains to be seen.

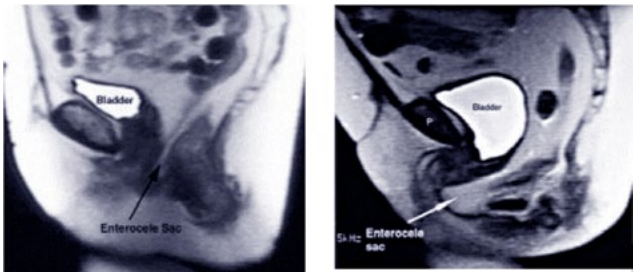

Figure 40: Pelvic floor MRI: Enterocele at rest a) and during Valsalva b).

4.6.2. Cystocele

MRI has a sensitivity of 100%, specificity of 83%, and positive predictive value of 97% when evaluating for cystocele compared to intraoperative findings. In addition, urethral hypermobility and postvoid urine residual can be documented, as well as evaluation of ureteral obstruction, hydroureteronephrosis and other pelvic abnormalities **(Figures 41 a, b).**

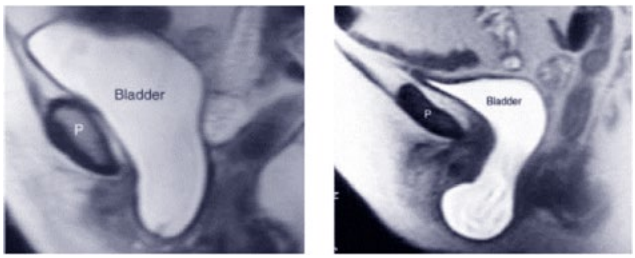

Figure 41: Pelvic floor MRI: grade 2 (a) and grade 3 (b) cystocele.

MRI can also be helpful in documenting the status of pelvic organ support as part of a program to assess operative efficacy (135, 136) and differentiating such problems as Müllerian remnant cysts from cystocele (137).

Larson et al showed that in women with anterior wall prolapse, Valsalva causes downward translation of the vagina along its length. A transition point separates a proximal region supported by levator muscles and a distal, unsupported region no longer in contact with the perineal body. In this latter region, sagittal and frontal plane

Uterovaginal junction shown with dark pink square. c Addition of midsagittal pelvic bones (white) and anterior vaginal wall model. d Powerpoint image of both resting and straining anterior vaginal wall models and their relationship to the normalized ATFP, shown here as green line extending from the pubic symphysis to the ischial spines (green square), or the P-IS line. © DeLancey 2009 (138).

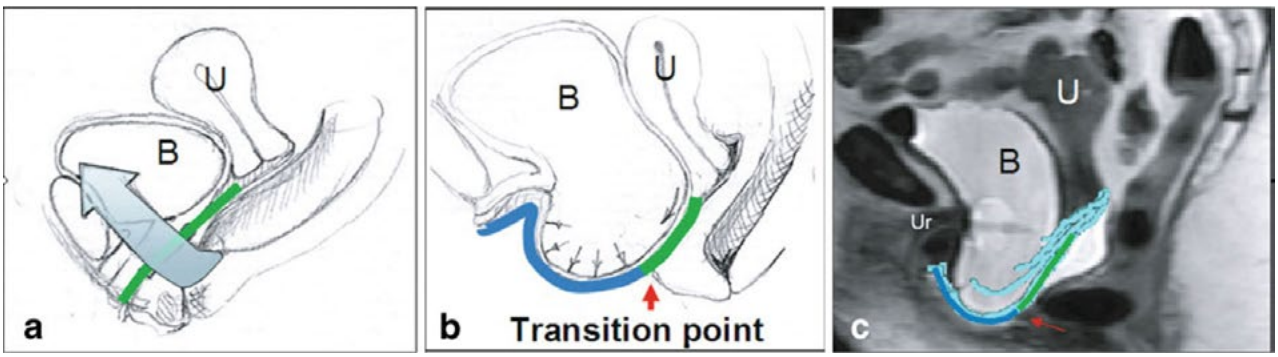

Figure 43: Midsagittal view of pelvis with normal support (a) and with prolapse (b). Green represents area where levators (blue arrow) provide cranial reaction forces to counteract the action of intraabdominal pressure and caudal movement of the anterior wall. The red arrow delineates the transition to unsupported region lacking this opposing set of reaction forces (blue line), thereby creating a pressure differential acting caudally on that region. c Red arrow illustrates this point on midsagittal MRI with modeled anterior vaginal wall. U uterus, B bladder, Ur urethra. © DeLancey 2009 (138).

"cupping" occurs. The distal vagina rotates inferiorly along an arc centered on the inferior pubis. Downward translation, cupping, and distal rotation are therefore novel characteristics of cystocele demonstrated by 3-D MR imaging (138)(**Figures 42 & 43).**

In cystoceles, the distal anterior vaginal wall (AVW) may no longer be in contact with the posterior vaginal wall or perineal body as it bulges through the introitus. The exposed vaginal wall length has been quantified using dynamic MR imaging. The authors found a bilinear relationship between exposed vaginal wall length and most dependent bladder location as well as apical location. It is when the bladder descent is beyond the inflection point that exposed vaginal wall length increases significantly (139).

4.6.3. Rectocele

The reported sensitivity of pelvic examination for diagnosis of rectocele ranges from 31% to 80% (4, 5, 7, 140, 141). This is usually secondary to organ competition for space in the vagina with other significant prolapse (8). In addition, it is often difficult to reliably distinguish an enterocele from a high rectocele. **Figure 44** shows a rectocele diagnosed by dynamic MRI. A rectocele is easily seen when filled with gas, fluid, or gel. Although highly specific, when no rectal or vaginal opacification is used, MRI can miss up to 24% or rectoceles (17). When rectal opacification is used, a correct diagnosis of rectocele can be made in 100% of patients studied when compared to intraoperative findings (21). Rectal opacification by introducing sonographic transmission gel or gadolinium into the rectum is therefore necessary to increase MRI's ability to diagnose rectocele.. In complex situations such as rectal intussusception (142) MR can provide important information by distinguishing mucosal from full-thickness descent. MR defecography also shows movements of the whole pelvic floor. In this study, 30% of the patients studied were found to have associated abnormal anterior and/or middle pelvic organ descent that would not necessarily be seen in traditional evacuation proctography (unless opacification of vaginal, bladder and intestine are carried out).

Quite important and not replaceable by any other imaging is the diagnosis of intussuception in MR defecography (143). Intussuception has therapeutic consequences as the symptoms and intestinal problem would not be resolved by colpoperineoplasty.

At maximal Valsalva on MRI, structures are more caudal and the hiatus longer in women with posterior prolapse. The posterior vaginal wall is longer; this length and point Bp strongly correlate with MRI prolapse size (r=0.5; P=.002; r=0.7; P<.001, respectively) (144).

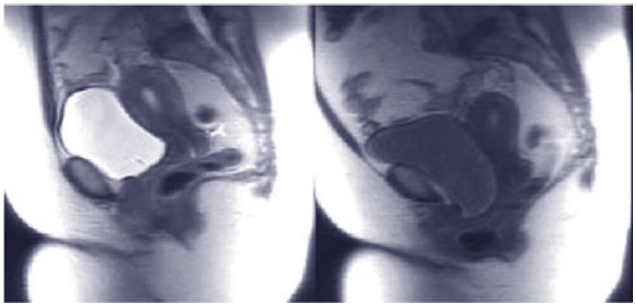

Figure 44: Resting (a) and straining (b) midline sagittal section showing a rectocele that traps intestinal contents.

What remains unclear is the relationship between anatomical findings and functional problems. The diagnosis of an anatomical abnormality does not mandate surgery. Simply identifying a rectocele on an imaging study based on the location of the intestinal lumen to a reference line does not mean that correction of the rectocele will cure defecation problems. Rectocele surgery is not without complications and the risk of dyspareunia after posterior colporrhaphy is real. Attention should be paid to make sure that symptoms are truly depending on stool trapping and the condition must be shown on imaging.

4.6.4. Uterine Prolapse

Although uterine prolapse is easily diagnosed on physical examination MRI is an excellent modality to record the structural relationships with the bladder and rectum in patients with uterine prolapse **(Figure 45).** In addition to depicting the position of the uterus and adjacent organs, it has the ancillary benefits of evaluating uterine size, position, orientation (retroversion) and pathology (fibroids, tumors, Nabothian cysts. etc.), but also ovarian pathology (cyst or mass) which may sometimes prove useful if these problems have not been picked up on physical examination. This is helpful information in determining the route of hysterectomy. Furthermore, MR imaging provides information on the presence or absence of cystocele, rectocele, urethral hypermobility and urethral diverticula, and evaluates for ureteral obstruction (11, 12, 15-17, 145). Gousse et al. report a sensitivity of 83%, a specificity of 100% and a positive predictive value of 100% when comparing dynamic MR imaging to

Figure 45: Pelvic Floor MRI: Uterine Prolapse.

intraoperative findings. These numbers were similar when compared to physical examination alone (17). More importantly, MRI was able to clearly define the other compartments of the pelvic floor and diagnose uterine and/or ovarian disorders in 30 of 100 patients evaluated (17).

4.7. Assessing Treatment Outcome

4.7.1. Pelvic Organ Prolapse Operations

Several studies have evaluated the anatomic changes seen after surgical procedures using MRI to better understand how surgical therapies affect pelvic support and structures. Lienemann et al. (146) evaluated women after abdominal sacrocolpopexy and found that functional MRI identified the exact sacral fixation points after the procedure and easily identified the axis of the vagina and the exact position of the synthetic material used for the repairs. Shatkin-Margolis et al. reported a significant improvement of the length of the M- and H-line, the anorectal angle, cystocele and vaginal prolapse after native-tissue fixation of the vaginal apex to the uterosacral ligaments, bilaterally and concurrent anterior and posterior colporrhaphies along with a perineorrhaphy (147). Sze (148) used MRI to study vaginal configuration on MR after abdominal sacrocolpopexy and sacrospinous ligament suspension. This study demonstrated the differences in the geometry of these two operations and should prove helpful in establishing outcome variables for different surgical procedures. Similarly Rane (149) used MRI to compare the vaginal configuration following transvaginal sacrospinous fixation, posterior intravaginal slingplasty (PIVS) (infracoccygeal sacropexy) and sacrocolpopexy (SCP) and demonstrated improvements in the restoration of vaginal configuration and differences between the procedures in final anatomy. Boukerrou (150) compared outcomes of 1) abdominal sacral cervicopexy, 2) vaginal hysterectomy with paravaginal repair, sacrospinous suspension and posterior colporrhaphy and 3) sacrospinous suspension and posterior repair without paravaginal suspension with MRI. The correction provided by vaginal route was found to result in a return of the bladder and the vaginal apex to their normal positions. In addition, vaginal shortening and postoperative change in vaginal orientation were not present postoperatively.

Nicolau-Toulouse et al (151) evaluated the anatomic outcomes of bilateral sacrospinous vault fixation (BSSVF) with synthetic, polypropylene mesh arms using MRI in a small case series of women with symptomatic pelvic organ prolapse (POP) with and without uterus. They confirmed that BSSVF with synthetic mesh restores the anatomy between the vagina and the ischial spines.

Relationships between assessment of surgical correction studied with MR imaging and symptoms have been studied. Gufler (152) compared preoperative evaluations with those two to four months after surgery. Of the seven patients who had symptoms postoperatively, only two had abnormal findings on physical examination but MRI showed pathologic findings in five of the seven patients. Huebner et al assessed symptomatic changes after anterior levatorplasty with morphologic changes visualized by MR defecography (153). Anterior levatorplasty improved quality of life in patients with symptomatic rectocele and correction of rectocele is accurately documented by MR defecography, however only moderate correlation between morphologic and clinical improvements was observed.

MRI has also been used for the evaluation of the effectiveness of POP surgical mesh procedures.

Dynamic MRI may evaluate the support of anterior and posterior pelvic floor structures by anterior and posterior polypropylene implant respectively. But dynamic MRI evaluations in a small series by Siegmann and colleagues suggest that if one compartment of the pelvic floor is repaired another compartment frequently (73.3%) develops dysfunction. These results did not correspond to clinical symptoms on short-term follow-up (3 months) indicating the need for long-term follow-up studies to prove if dynamic MRI can reliably identify significant POP after surgery and before the onset of symptoms (154). In another small series of ten women by Kasturi et al (155) undergoing intervention for POP with Prolift, postoperative MRIs supported the inert nature of polypropylene mesh.

Larson et al examined structural relationships between anterior mesh kit suspension points and the upper vagina in women with normal support. Using MRI generated 3D models, they found that the anterior vagina extended above superior attachment points in 100% of women at rest and in 73% during Valsalva. It extended posterior to them in 82% and 100% (rest and Valsalva, respectively). The mean percentage of anterior vaginal length above superior anchoring sites was 40 +/- 14% at rest and 29 +/- 12% during Valsalva. The upper vagina was therefore found to lie above and posterior to superior suspension points in the majority of women with normal support (156).

In an observational study, the 1-year outcomes after mesh repair in patients with POP were evaluated using clinical examination (CE), dynamic magnetic resonance imaging (dMRI), and the prolapse quality-of-life (P-QOL) questionnaire. Sixty-nine women were treated with Seratom(R) or Perigee mesh implants. Advanced cystoceles and enteroceles were underestimated by CE using the POP-Q system compared to dMRI ($P = 0.003$ and $P < 0.001$), vice versa dMRI overestimated POP compared to CE (157).

4.7.2. Visualisation of Implants

In case of mesh and sling complications, MRI might be a useful tool to localize the mesh material in T2-weighted sequences. The polypropylene material will be visualized as a hypointense structure (158). A study by Brocker et al. demonstrated that vaginally inserted Fe3O4- polypropylene implants were shrinking for at least 40% in length (159). The location and dimension of the implanted mesh could be well visualized. Mesh placement variations might be important in the diagnosis and illustration of postoperative complications (159). Another study with a MR-visible polyvinylidene fluoride mesh containing paramagnetic Fe3O4 microparticles did not show

a significant deformation of the mesh material at two time points (6 weeks and 8 months) after insertion (160).

4.7.3. Pelvic Muscle Exercises

Studies on the effects of pelvic muscle training on the pelvic floor (161) demonstrate reduced levator ani surface area and volume encircled by the levator ani muscle during contraction. When elite athletes are compared to normal women significant differences appear in the cross-sectional area and width of the pelvic floor muscles, (162). These types of studies are being facilitated by improved techniques of aligning contracted and non-contracted muscle (163).

The effect of pelvic muscle training with or without instrumentation was assessed by a study of Dierick and colleagues. The impact of a 3-week period of intensive pelvic floor muscles training (PFMT) on the puborectalis (PR) and iliococcygeus (IL) muscles showed on static MRI a decrease in muscle volumes on both sides of the iliococcygeus muscle ($p = 0.040$, $p = 0.045$) as well as a decrease in signal intensities of right and left puborectalis muscle ($p = 0.040$, $p = 0.021$). These morphological changes after PFMT suggest a decrease in adipose content of PR (164).

Whether pelvic floor morphometry predicts the success of pelvic floor muscle training or not was the aim of a study by Dumoulin et al (165). In the MRI morphometry a urethrovesical junction height at rest of 11.4mm appeared to be predictive for a response to PFMT (165).

4.7.4. Comparison of MRI with other examinations and assessment of reliability

Dynamic contrast roentography and multiphasic fluoroscopic cystocolpoproctography (CCP) have previously been considered the best radiological studies for detecting POP. These studies rely on the opacification with contrast material of the bladder, vagina, small bowel, and rectum with all organs opacified together or in phases with each organ opacified individually prior to each straining phase (5, 149) (153, 161). These studies fail to detect up to 20 percent of all enteroceles (145, 166-168). Therefore, MRI has proven to be a much simpler and less invasive technique for the evaluation of enteroceles. In addition, MRI is able to differentiate the enteroceles according to their contents (small bowel, large bowel, rectosigmoidocele or mesenteric fat). MRI is also an excellent study to differentiate high rectoceles from enteroceles, thus allowing adequate surgical planning and safer planes of dissection (16, 17, 21, 134). Although multiphasic MRI with opacification of organs and multiphasic fluoroscopic cystocolpoproctography have similar detection rates for enterocele (166), excellent images can be obtained from dynamic MRI without contrast for opacification of the small bowel or rectal contrast. Thus the minimal added information obtained by contrast administration does not seem to warrant the invasiveness of organ opacification at this time (17, 133, 167). However, MRI without rectal contrast shows statistically fewer pelvic floor abnormalities than CCP. Except for enteroceles, MRI with rectal contrast shows statistically similar frequency of POP as CCP (169).

Evacuation proctography has been used to diagnose enterocele, rectoceles, perineal descent and rectal intussusception. Dynamic contrast roentography or fluoroscopic cystocolpoproctography have also been used (5, 140, 141, 166, 170) to diagnose rectoceles. The disadvantages of these techniques are the inability to visualize the soft tissue planes comprising the pelvic floor, their invasiveness, and their use of significant levels of ionizing radiation. Without the use of rectal opacification, MRI appears to be a poor choice for the evaluation of rectoceles missing up to 25% of such defects. With rectal opacification a correct diagnosis of rectocele can be made in 100% of patients in comparison to intraoperative findings (21). Triphasic dynamic MRI and triphasic fluoroscopic cystocolpoproctography have similar detection rates for rectocele (166). Upright dynamic MR defecating proctography has been reported (171). Although these studies might prove to be more sensitive in detecting anorectal anomalies, their utility seems to be more pronounced in patients with disorders of defecation include anismus, intussusception, and others, and may be too invasive to justify their routine use in the evaluation of rectocele.

Kaufman (172) evaluated dynamic pelvic MRI and dynamic cystocolpoproctography in the surgical management of females with complex pelvic floor disorders. Physical examination, dynamic MRI, and dynamic cystocolpoproctography were concordant for rectocele, enterocele, cystocele, and perineal descent in only 41% of patients. Dynamic imaging lead to changes in the initial operative plan for 41% of patients. Dynamic MR was the only modality that identified levator ani hernias. Dynamic cystocolpoproctography identified sigmoidoceles and internal rectal prolapse more often than physical examination or dynamic MR. Whether this type of imaging creates measurably better outcomes remains to be seen. Singh et al (49) showed a reasonably good correlation between clinical staging and MRI staging (Kappa = 0.61) with the mid pubic line being used as a surrogate for the hymenal ring. In addition, specific features such as the levator-vaginal angle the area of the genital hiatus could be assessed quantitatively on MRI.

Torricelli (51) studied ten healthy volunteers and 30 patients with suspected pelvic floor deficiency with and without POP. They found good concordance between physical examination and MRI with four cases of uterine prolapse and three cases of enterocele seen on MRI that had not been suspected on pelvic examination. Whether these would have been detected at the time of surgery was not discussed. Deval (52) compared intraoperative findings as a gold standard for MRI based diagnosis. The sensitivity, specificity, and positive predictive value of MRI were 70%, 100%, 100% for cystoceles; 42%, 81%, 60% for vaginal vault or uterine prolapse; 100%, 83%, 75% for enteroceles; 87%, 72%, 66% for rectocele. Although all of these measurements are somewhat subjective, these figures show that it is possible to quantify the individual elements of pelvic floor dysfunction in reasonable parameters.

In a recent study, the value of dynamic pelvic floor MRI was assessed in comparison to standard clinical examination in treatment decisions made by an interdisciplinary team of specialists including a urologist, gynecologist, a proctological, and colorectal surgeon. The authors concluded that MRI has the advantage of allowing diagnosis of clinically occult enteroceles. In addition, in nearly half of cases, MRI changed management or the surgical approach relative to the clinical evaluation (173).

Different studies undertook comparisons or combinations of MRI and tomographic ultrasound imaging in the detection of pelvic floor muscle lesions (1, 174-177). Ultrasound and MRI depict puborectalis and pubovisceral avulsion both well and with a good consistency, however, iliococcygeus muscle avulsion as a sign of major levator trauma is diagnosed more accurately in MRI (174).

Whether a preoperative MRI results in a better surgical outcome was topic in a cost-effectiveness study by Wyman and colleagues. A preoperative MRI resulted in a 17% increased chance of successful initial surgery and a decreased risk of repeat surgery with an ICER of $2298 per avoided cost of surgical failure (178) and the authors concluded that MRI as an accurate preoperative diagnostic will reduce costs for repeat surgeries.

4.8. Conclusions

Proof that MR imaging has value will eventually need to come from increased operative success rates. Better documentation of preoperative and postoperative anatomy could allow us to seek reasons of operative failure. Because MR provides a detailed picture of a woman's pre-operative anatomy, once operative failures are discovered, it would be possible to look back at images from women with successful and unsuccessful operations to seek anatomical explanations for failure.

Advancements in MRI technology with the addition of 3D imaging as well as studies correlating imaging findings with clinical examination and symptom scores may establish further the clinical applications of these modalities.

III. IMAGING IN ANAL INCONTINENCE

1. BACKGROUND

Anal incontinence may result from anatomical and/or neurological disruption of the anal sphincter complex. Prior to the development of anorectal imagining techniques, anal sphincter disruption was detected by digital palpation supported by EMG needle mapping and ano-rectal manometry. Use of endoanal ultrasonograpghy (EAUS) for anal sphincter imaging was first described by Wild in 1956 (1), but remained neglected for many decades because of the limitation of technology then available (2). In 1989 Law and Bartum defined the technique of EAUS and endosonographic anatomy of the anal sphincter complex (3). Since then, EAUS has become the gold standard of imaging the anal sphincter complex.

Development of 3-D rendering technique over the last decade has enabled a better quality imaging of the anal sphincter complex using the EAUS. Recently other imaging modalities such as Transvaginal, transperineal and translabial ultrasonography, MRI, Defecaography and Sonoelastography have been described to assess the anal sphincter complex in patients with anal incontinence.

2. INDICATIONS

Anal sphincter imaging has become an integral part of the assessment of anal incontinence. Following detailed history and examination, the patient should be offered anal sphincter imaging (either 2D or 3D EAUS) depending on the availability of imaging modalities and the expertise. Even though ano-rectal physiological studies indicate dysfunction of the anal sphincter complex, they do not identify the anatomical site and the degree of anal sphincter disruption. EAUS has been the gold standard of detecting anal sphincter disruption or atrophy. EAUS is also used in the follow up of women after obstetric anal sphincter injuries to assess the success of the primary repair and to advice on subsequent delivery (4). EAUS has been used intra-operatively to identify the damaged EAS prior to secondary repair and also to identify the IAS defects prior to injecting bulking agents.

3. IMAGING MODALITIES

3.1. Ultrasonography

3.1.1. Endoanal Ultrasound (EAUS)

EAUS is performed using a 360^0 rotating rectal probe with a 7 - 10 MHz transducer (focal range 2-4.5cm) with minimum beam width of 1.1mm. Several systems are currently available, and recently integrated 3D systems are also available (B&K Medical, Sandoften 9, 2820 Gentofte, Denmark). Women should be examined prone with an endoanal system to minimise anatomical distortion. Figure 46 shows a schematic diagram of the anal sphincter complex in relation to the endoanal probe (4).

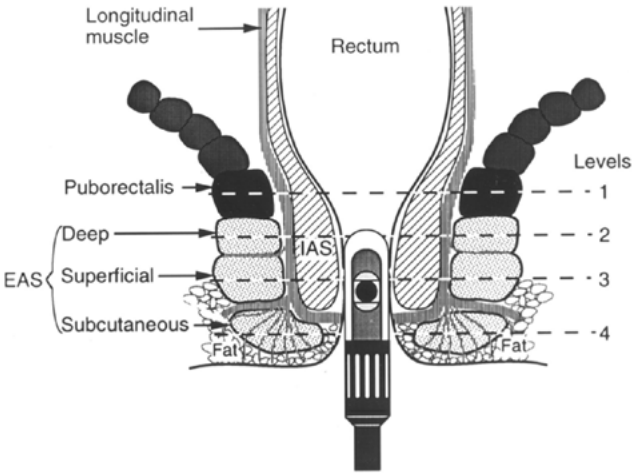

Figure 46: A schematic diagram of the anal sphincter complex in relation to endoanal probe.

The standard EAUS image of the anal canal is of 4 layers (Figure 47):

1. The subepithelial layer is moderately reflective.
2. The internal sphincter is the most obvious landmark and is a well-defined low reflective ring. The internal sphincter varies in thickness with age, being <1mm in neonate, 1-2mm in young adults, 2-3 in middle age and >3mm in the elderly.
3. The longitudinal layer is a complex structure with a large fibroelastic and muscle component, the latter formed from the puboanalis as well as the longitudinal muscle of the rectum (Figure 47).
4. The external sphincter is better defined in men than women, where it tends to be less hypoechoic. It is distinguished mainly by interface reflections between muscle/fat planes either side (Figure 47). In women the external sphincter is shorter anteriorly than posteriorly, which must not be misinterpreted as a tear. The transverse perineii muscles fuse anterior with the sphincter, whereas in men they remain separate.

With experience the examination can be performed in about 5 minutes and provides an ideal method for a rapid assessment of sphincter integrity and thickness.

A recent observational study showed a statistically significant correlation between decreased maximal resting pressure and decreased internal anal sphincter (IAS) thickness or an IAS defect. The correlation between Maximum Squeeze Pressure and external sphincter pathology was significantly less consistent (5).

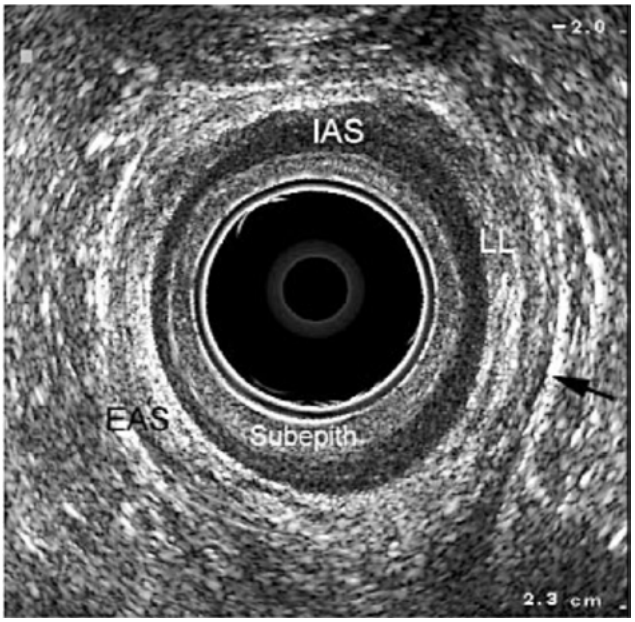

Figure 47 : Axial endosonography in the mid canal in a normal 38-year-old female. Subepith: subepithial layer; IAS: internal anal sphincter; LL: longitudinal layer; EAS: external anal sphincter. The outer border of the external sphincter is defined by an inter- face reflection at the fat/muscle boundary (arrow).

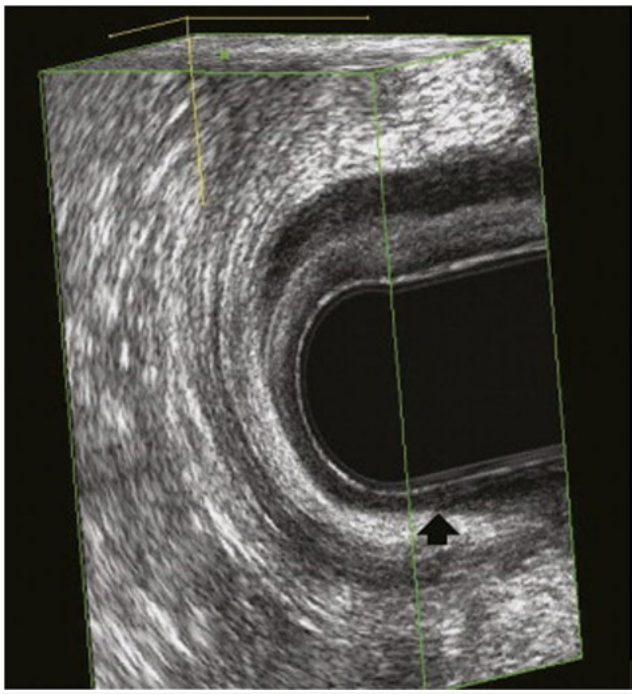

Figure 49: Complete defect of the internal anal sphincter (7).

3.1.2. Dimensional Endoanal Ultrasonography (3-D EAUS)

With 3D-EAUS, the anal canal is scanned in a conventional manner, and dedicated software provides a final 3D appearance (3D rendering). The data obtained from a series of closely spaced EUS images (0.25 mm) are combined to create a 3D volume displayed as a cube. The image can then be freely rotated and it is possible to visualize defects at different angles and to get the most information out of the data (6). The advent of 3D ultrasonographic multiplanar reconstruction of the anal canal has further improved the detection of anal sphincter injuries with nearly 95-100% sensitivity and specificity (7). With 3D-EAUS, the aspect, localization (circumference involved, height), size (in degrees or percentage of circumference) and number of sphincter defects can be described in detail, together with a calculation of the volume of such defects (8). Defects of the puborectalis fibers of the levator ani are less common and these can be seen as heterogeneous remodelling or shortening of the two bands is visible after episiotomy or pelvic floor injury during vaginal delivery. Its role in the development of AI is probably underestimated and characterization, particularly in terms of volume, would be of interest to assess the functional impact (7). Two scoring systems has been introduced to objectively evaluate the anal sphincter defects detected in 3D EAUS (9, 10), and both these scoring system have shown acceptable intra observer and inter observer agreement (10).

Although EAUS has been accepted as the gold standard of imaging anal sphincter complex, the equipment and the expertise may not be readily available in some centres. Some patients may find EAUS technique embarrassing and unacceptable. Hard endoanal cone of EAUS may cause the disruption of normal anal canal anatomy. Because of these drawbacks, other imaging modalities such as endovaginal, transperineal and translabial ultrasonography have been evaluated to assess the anal sphincter complex.

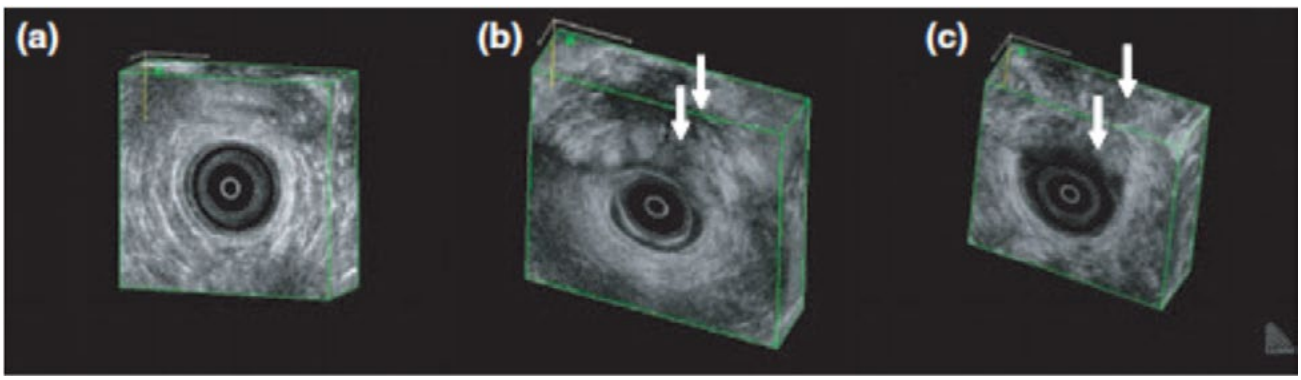

Figure 48: Three-dimensional endoanal ultrasound showing no (a), partial (b) or complete EAS defect (c). Arrows indicate an EAS defect in the sagittal view (11).

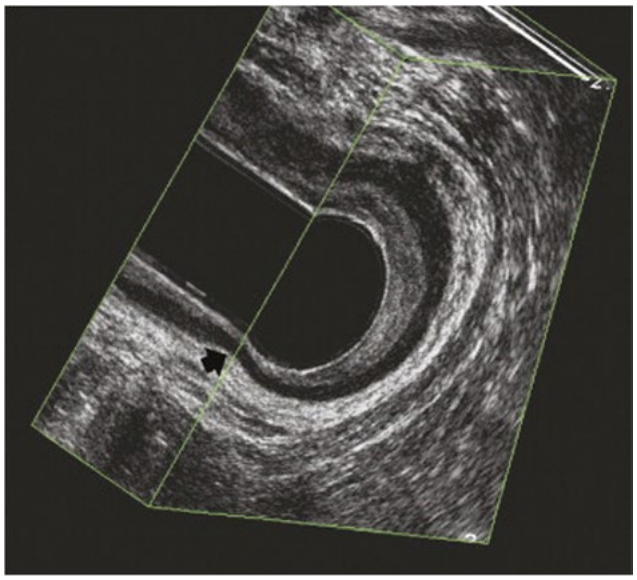

Figure 50: Partial defect of the internal anal sphincter (7).

3.1.3. Transvaginal Ultrasonography

Sultan et all first described the vaginal use of 360^0 rotating probe used for the EAUS and obtained clear images of anal sphincter complex (12). Since then different types of probes including side-fire transrectal probe, a standard transvaginal probe and modified vaginal probe has been used to evaluate the anal sphincter complex with variable sensitivity and specificity for detecting anal sphincter injury (13).

3.1.4. Transperineal ultrasonography

Transperineal ultrasonography (TPU) to image the anal sphincter complex was first described by Peschers et al (14) and found to have a good inter observer reliability in detecting IAS and EAS defects compared with EAUS (15). A recent study by Roos et al (13) comparing the endovaginal and transperineal ultrasonography to detect obstetric anal sphincter have concluded that both these modalities are not sensitive enough to detect anal sphincter defects.

3.1.5. Translabial ultrasonography

Translabial ultrasound (TLU) offers an alternative imaging modality of the anal sphincter complex and has proven to be well-tolerated by patients. It has been used to describe anal sphincter complex integrity (14, 16). Hall et all evaluated 60 women with TLU and reported that mean sphincter measurements are given for symptomatic and asymptomatic intact women and are comparable to previously reported endoanal MRI and endoanal ultrasound measurements (17). The advantages of TLU are that the equipment needed is readily available to all gynecology and radiology imaging laboratories.

3.1.6. Integrated Multicompartmental Pelvic Floor Ultrasonography

Pelvic organ dysfunction includes multiple conditions such as pelvic organ prolapse, urinary incontinence, anal incontinence, defecatory disorders and sexual dysfunction. Based on this concept, integrated multicompartmental Pelvic Floor imaging including two-dimensional (2D), three-dimensional (3D) and 4D pelvic floor ultrasonography as well as transvaginal, endoanal and transperineal techniques, has been described from a global and multicompartmental perspective (18). Value of this approach in routine assessment of pelvic floor dysfunction is yet to be evaluated.

3.1.7. Dynamic Anorectal Endosonography (DAE).

DAE uses a rigid biplane transrectal probe with a frequency of 7 MHz with the tip of the probe covered with a water-filled balloon to maintain the acoustic window for the ultrasound waves. By slowly and manually rotating the linear probe through 360°, various layers constituting the anal wall (mucosa, internal anal sphincter, and external anal sphincter), the layer forming the rectal wall, and the perirectal tissues (puborectalis muscle, bladder, and vagina, or prostate) has been demonstrated. After the initial examination, the patient makes a defecation effort with the probe left in the same position (19). Study 56 women using DAE and Dynamic MRI Defecography showed that a significantly more internal anal sphincter defects were found with DAE than with dynamic MRI defecography, but there was no significant difference for the diagnosis of external anal sphincter defects (19).

3.1.8. Sonoelastography

Sonoelastography is a new imaging technique based on differences in radiofrequency signals following endogenous/exogenous compression due to different elastic properties of the targeted tissues or organs (20). This technique has been evaluated in pathological conditions of breast, thyroid, pancreas and prostate. The elastographic pictures registered simultaneously with conventional gray-scale B-mode images during sonography or endosonography are assumed to distinguish malignant from inflamed areas and thus facilitate the diagnostic work-up. Based on this concept it is assumed that Sonoelastograhy is able to diagnose different condition causing anal incontinence. However there is only one published study comparing the conventional endoanal ultrasonography and elastography (21). This prospective study included 50 patients with fecal incontinence following ano-rectal surgery and Crohn's disease. Elastogram color distribution within the sphincter representing elastic properties was quantified using a visual analogue scale and an off-line computerized area calculation program. The IAS, a smooth muscle, and the EAS, a striated muscle, have different elastogram color distributions, probably reflecting their different elastic properties. The absence of significant correlations with the major clinical and functional parameters suggests that in routine clinical practice ultrasound real-time elastography may not yield additional information in patients with fecal incontinence except in patients who had radiation.

3.2. MRI

Anatomy of the anal sphincter complex has been redefined over the past 20 years by the use of body coil, endoanal coil and phased-array coil magnetic resonance imaging (MRI). However these different MRI techniques have led to conflicting anatomical descriptions of the anal sphincter complex (22). Endoanal coil MRI studies by Rociu et al (23, 24) have suggested that the levator ani muscle has only a transverse portion and that the EAS muscle is composed of only a subcutaneous and a superficial portion describing five image layers (Figure 51).

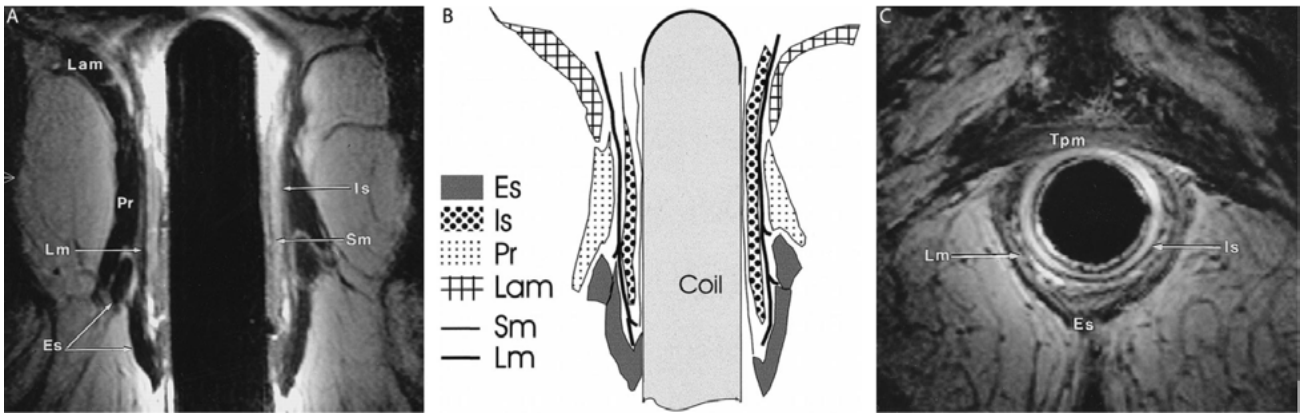

Figure 51: T2-weighted turbo spin-echo endoanal coil MRI studies by Rociu et al (23, 24).

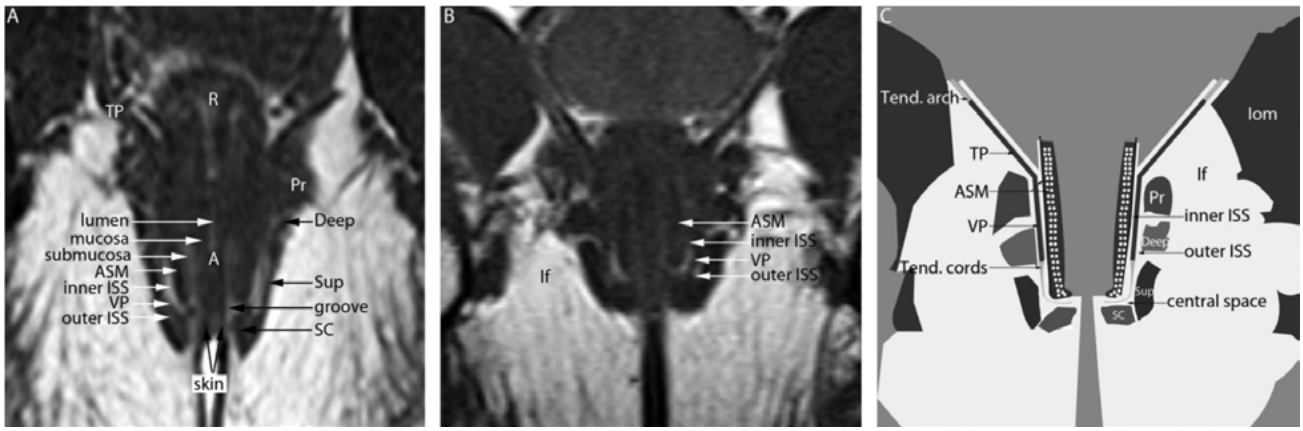

Figure 52: Midcoronal T1-weighted turbo spin-echo body coil MRI images (27).

However, body coil MRI studies by Guo and Li (25) suggested that the levator ani muscle also has a vertical portion (vertical levator), and separate body coil MRI studies by Hsu et al (26) suggested that the EAS muscle has 3 separate components which has been identified in EAUS as well.

A more recent study by Guo et al (27) using multiplanar body-coil MRI studies demonstrated that the anal region actually has 7 image layers: the mucosa, submucosa, anal smooth muscle, inner space, vertical levator, outer space, and the EAS muscle (Figure 52). The authors reported that endoanal MRI does not reliably outline the superficial layers of the anal region because a blind zone is created in the anal canal near the coil. This blind zone lead investigators to effectively ignore the mucosa, submucosa, anal smooth muscle, intersphincteric groove, and subcutaneous sphincter and thus accounts for the early endoanal MRI description of the anal region as comprising only 5 image layers.

Images of the anal sphincter complex obtained using endoanal MRI are thought to be superior to MRI performed with a body coil because of increased signal to noise ratio resulting in high spatial resolution images. Although the endoanal MRI allows the comprehensive assessment of atrophy and focal defects of the external canal, the internal sphincter is less well defined (28). A meta-analysis of nine studies, comparing endoanal MRI with endoanal ultrasound or surgical diagnosis in 157 patients by Tan et al (29) has shown that Endoanal MRI was sensitive and specific for the detection of external sphincter injury and especially sphincter atrophy. It may be useful as an alternative to endoanal ultrasound in patients presenting with fecal incontinence. However, the limited availability of dedicated endoanal coils outside specialist units has resulted in less widespread familiarity with this technique and further clinical studies are needed to identify its best application in clinical practice.

In addition to the damage to the anal sphincter complex, levator ani muscle (LAM) injury has also been postulated as a cause for anal incontinence especially after childbirth. A recent MRI study by Heilbrun et al (30) reported major LAM injuries in 19% of women who delivered vaginally with external anal sphincter (EAS) injuries compared to 3% delivered vaginally without EAS injury, and 0% delivered by caesarean section before labour. Among women with EAS injuries, those with major LAM injuries tend to have more anal incontinence symptoms than those who did not have LAM injury. These data suggests that both EAS and LAM are important to maintain faecal continence.

3.3. Evacuation Defecography (Proctography)

Evacuation defecography is indicated in patients with constipation, and in patients with obstructive defection associated with anal incontinence caused by overflow incontinence or post defecation leakage. In these patients, defecography is useful to visualise an outlet obstruction due to an anatomical (e.g. enterocele, rectocele, intussusception) or a functional (e.g. anismus) cause. Evacuation defecography is also useful to demonstrate bladder and uterovaginal prolapse as well as pelvic floor descent (Figure 53 a-b) but gives limited information as to rectal function. Evacuation defecography

Figure 53: Sagittal views from a dynamic MRI examination. The dotted line indicates the position of the pubococcygeal line. At rest (a) there is some descent as the anorectal junction (ARJ) is more than 1 cm below this. During pelvic stress (b) there is marked pelvic floor descent, with descent of the cervix (Cx) and bladder base (Bl).

has shown a good reproducibility of diagnosing enterocele, anterior rectocele and their grading in patients with faecal incontinence (31).

The rectum is opacified with 120ml of a barium paste and the small bowel with a dilute barium suspension given orally about 30mins before. The patient is seated sideways within the fluoroscopic unit on a radiolucent commode. Evacuation of the barium paste is recorded either on video or on cut film at 1 frame/sec using a low

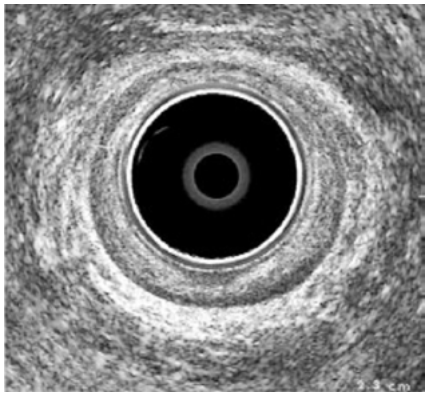

Figure 55: Endosonography with an axial image in the mid canal of an elderly patient, aged 73 years with passive faecal incontinence. The internal sphincter measures only 1.1mm (markers) indicative of internal sphincter degeneration.

dose protocol. At rest the anorectal junction is at the level of the ischial tuberosities and the anal canal closed. Evacuation is rapid (<30sec) and the rectum below the main fold should be emptied completely. During evacuation the anorectal angle widens as the anorectal junction descends and the anal canal opens. At the end of evacuation pelvic floor tone returns and the puborectalis pulls the anorectal junction upwards and forwards back to the resting position. Intra-anal intussusception creates a thick double fold of rectum, which impacts into the anal canal on straining at the end of rectal evacuation. Rectal prolapse represents an extension of this process, with passage of the intussusception through the anal canal and inversion of the rectum (Figure 54 a-c).

Compared to conventional evacuation defecography, Dynamic MR defecography at a vertical open magnet unit has become popular recently as it produces multiplanar images with increased soft tissue contrast and avoids radiation exposure. However, the comparative results between conventional defecography and dynamic MR defecography in patients with prolapse and anal incontinence are variable (32, 33). Some of these variations have been attributed to the difference in technique. The main drawback of MR defecography is the supine position required which causes sub optimal assessment of prolapse and evacation (32). Since vertical open-magnet MR imaging units are not widely available, the role of MR defecography in the diagnostic work-up of faecal incontinence is still limited.

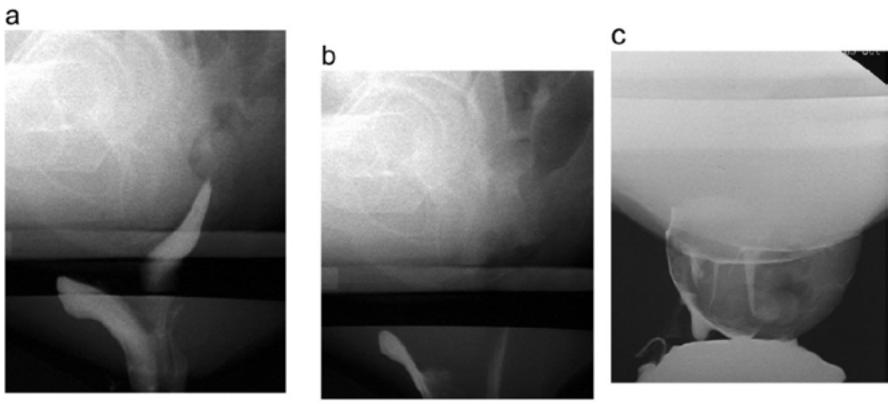

Figure 54: Evacuation proctogram showing the development of rectal prolapse. Intussusception starts at the end of rectal emptying (a) and rapidly passes through the anal canal (b) to form the external prolapse(c).

4. SPHINCTERIC DISORDERS

4.1. The Internal Anal Sphincter (IAS)

IAS is responsible for the maintenance of resting anal pressure and plays a vital role in maintaining anal continence. Isolated IAS defects are associated with surgery for ano-rectal malignancies, anal fissure and undetected obstetric anal sphincter injuries. These patients may present with passive faecal soiling and seepage rather than frank faecal incontinence.

Abnormalities of thickness are usually related to the patient's age. A sphincter less than 2mm thick in a patient more than 50 years of age is indicative of internal sphincter degeneration (Figure 55) and is associated with passive faecal incontinence.

Obstetric trauma to the internal sphincter parallels that of the external sphincter in extent, but should always be in the anterior half, so that any defect between 3 and 9 is due to some other cause.

Sphincterotomy may be more extensive than was planned, particularly in women, and 3D studies are especially helpful to assess the longitudinal extent of the defect. The length of the sphincter divided relates directly to the risk of incontinence (34). Dilatation procedures are hazardous and may completely fragment (Figure 56) the internal sphincter.

4.2. The External Anal Sphincter

When striated muscle is stretched beyond the limits of its elasticity fibres rupture and heal with granulation tissue and eventually fibrosis. Most chronic tears are seen with scar formation, and present as a uniform area of low reflectivity distorting and obliterating normal anatomical planes (Figure 54). A key to the diagnosis is lack of symmetry with the anterior part of the external sphincter not fusing at 12 o'clock as the probe is moved slowly down the canal. This may also be seen on 3D studies in the coronal plane (Figure 57). Other perineal structures, such as the puboanalis and transverse perineii are frequently torn and distinguishing these tears from external sphincter trauma requires experience, and again may be helped by 3D multiplanar imaging. The distinction is important as tears of the puboanalis or transverse perineii are not associated with a significant fall in squeeze pressure (35), and it is only damage to the external sphincter that results in a significant change. Childbirth damage to the puborectalis part of the levator ani muscle with intact EAS and IAS has been reported as a distinct cause for anal incontinence. 3-D EAUS is reported to be superior in detecting this type of injury (36).

In healthy young adults a good correlation has been found between measurements of layers thicknesses on endosonography and endocoil MRI, with an Ri of 0.96 for the external sphincter (37). The outer border of the external sphincter is easier to see on MRI, but fibrosis is not so markedly different in signal from normal muscle, so that the conspicuity of tears may not be as obvious as with endosonography.

Atrophy of EAS is a more difficult problem. Determining the thickness of the external sphincter on EAUS depends on visualising its borders from interface reflections between the longitudinal layer on the inside and subadventitial fat on the outer border. As atrophy involves a reduction of muscle fibres and an increase in fat, the outer interface reflection is lost and the thickness of the external sphincter cannot be measured. Such loss of definition of the outer border of the external sphincter on endosonography has a positive predictive value of 71% for atrophy (38). Using 3D EAUS and a grading system based on definition (Figure 56) and echogenicity of the external sphincter showed a comparable accuracy to endocoil MRI in detecting atrophy (39).

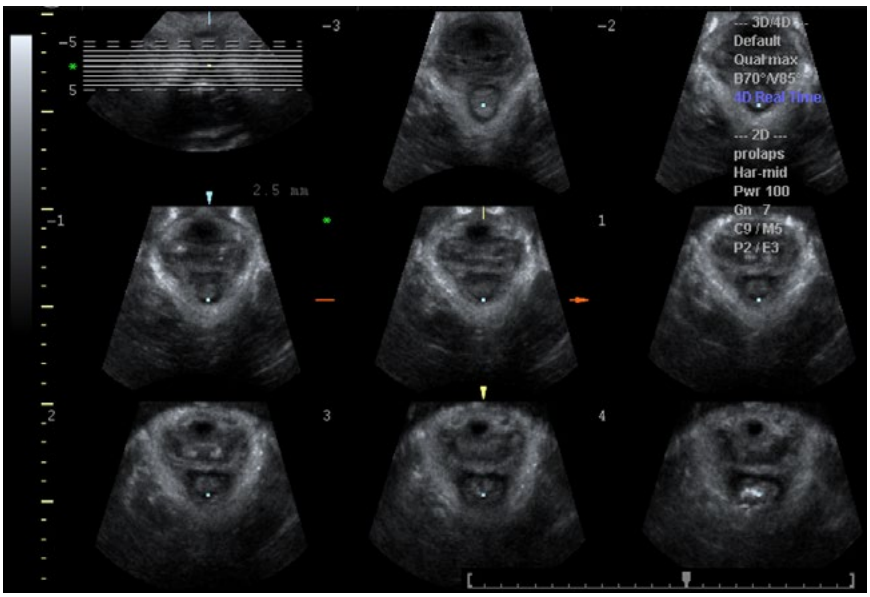

Figure 57a Tomographic ultrasound imaging in oblique axial plane. Normal attachment of the levator ani muscle.

5. CONCLUSIONS

Claims for superiority of one or other modality for the detection of sphincter tears probably depend largely on individual experience, but the relative low cost and speed of EAUS makes this an ideal screening procedure to assess sphincter integrity. A leading issue is the significance of occult sphincter tears (diagnosed on endosonography but not apparent clinically) following vaginal delivery. Although these may be detected by careful examination immediately post-partum (40), retrospective detection will still require EAUS. A meta-analysis of 717 vaginal deliveries revealed a 26.9% incidence of anal sphincter tears in primiparous, with 8.5% new tears in multiparous women. Overall, 29.7% of women with tears were symptomatic, compared to only 3.4% without tears. The probability of faecal incontinence being due to a sphincter tear was 76.8-82.8% (41). Recent studies confirm the strong relationship between obstetric sphincter damage and faecal incontinence (42), and its late onset (43, 44). Subsequent deliveries increase the risk of incontinence particularly if there has been a tear at the first delivery (45). Tears that involve the internal sphincter increase the severity of incontinence (46). A sphincter tear at EAUS is therefore an important finding, but how this is used to decide management a little

more controversial. Secondary anal sphincter repair has fallen out of fashion a little following the finding that results deteriorate over a few years (47), although a more recent study (48) suggests a better response.

Fluoroscopic studies have little role in faecal incontinence, unless there is an underlying rectal abnormality such as obstructive defactory symptoms and prolapse. Dynamic MRI studies have the added value of demonstrating prolapse in the rest of the pelvis, but apart from the lack of ionising radiation, has no real advantage for studying rectal function.

EAUS therefore remains the first line imaging investigation for anal incontinence, giving accurate information as to external and/or internal sphincter tears and the likelihood of atrophy. Dynamic studies of rectal evacuation are required only if there is some other problem suspected, such as prolapse. The advantages of using MRI are the lack of ionising radiation and a global view of the pelvic floor. Although imaging gives hard evidence of sphincter damage, this is really only part of a much more complex functional problem, and colorectal abnormalities may be just as important (49) with tears accounting for perhaps only 45% of incontinence (50).

6. RECOMMENDATIONS

- EAUS is the first line imaging investigation for faecal incontinence providing accurate information as to external and/or internal sphincter tears and the likelihood of atrophy. [Level of Evidence 3, Grade of Recommendation C].
- 3-D EAUS offer better quality images and diagnosis of the depth of anal sphincter injury. However routine use is not recommended because of the cost. [Level of Evidence 3, Grade of Recommendation C].
- Routine use of transperineal, transvaginal and translabial ultrasonography to image the anal sphincter complex are not recommended. [Level of Evidence 3, Grade of Recommendation C].
- Dynamic imaging of rectal function is required when rectal abnormalities such as prolapse are suspected [Level of Evidence 3, Grade of Recommendation C].
- MRI offers no advantage over other imaging modalities except for the lack of ionising radiation and global view of the pelvis [Level of Evidence 3, Grade of Recommendation C]

7. SUGGESTED RESEARCH AREAS

Better image quality with 3D EAUS and MRI have improved the understanding of pelvic floor anatomy, and this in turn has enabled the sonographic anatomy to be re-evaluated. However, conflicting views of anal sphincter anatomy remain with different MRI modalities as well as when comparison of sonographic abnormalities with ano-rectal function.

- Are clinical symptoms related to the size and the site of anal sphincter defect (51) or not (52)?
- Significance of the imaging in detecting anal sphincter injury especially immediately after childbirth in preventing future anal incontinence (40, 53).
- The value of ano-rectal physiological studies combined with imaging in assessing the success of surgical repair of anal sphincter complex (54).
- Identify (and modify) the risk factors leading to anal sphincter injury especially during childbirth and develop preventive strategies (55).

The most valuable aspect of 3-D ultrasonography and MRI imaging is that they give a global view of the pelvis, capable of investigating urological, gynaecological and coloproctological problems at the same time (18). Many patients do not have faecal incontinence as an isolated symptom, but also have urinary, prolapse or defecatory problems. The overview provided by imaging sets the way for a combined approach to the pelvic floor and should be the prime area future investigation (18).

IV. PAD TESTING

The use of a perineal electronic nappy using electrical conductivity to estimate the amount of urine leakage was first proposed by James et al.(1, 2). Accuracy of this technique was, however, questioned by others and the technique was improved (3-8). Walsh & Mills and Sutherst et al. introduced a more simple approach by estimating leakage by perineal pad weight gain (9, 10). These tests were not standardised until Bates et al. described a “structured” one hour pad test which was endorsed by the International Continence Society in 1988 (11). This test, however, was shown to have poor interdepartmental correlation and to be highly dependent on bladder volume (12, 13). In an attempt to make pad tests more reliable 24 hour and 48 hour pad tests were developed. A more precise estimation of urine loss was shown, but they were more cumbersome. The Pyridium pad test was also proposed for diagnosing urinary incontinence (14).

1. DEFINITION

The pad test is a diagnostic method to detect and quantify urine loss based on weight gain of absorbent pads during a test period under standardised conditions.

2. INDICATION AND METHODOLOGY

A pad test allows the detection and quantification of urine loss, but it is not diagnostic of the cause of the incontinence. Several different standards have been developed. Tests can be divided into four groups according to the length of the test: <1h, 1h, 24h and 48 h. (Table 4).

Although pad testing has been proposed mainly for research purposes it may also have a role in our clinical practice.

Quantification of urinary incontinence can be of importance in our daily practice. A large cohort study to evaluate the appropriateness of continence product prescription showed a poor correaltion between patient pad count and 48 hour pad testing (R^2 0.12, 0.19 for men and 0.11 for women) suggesting that pad testing is a more accurate measure of UI severity (15). In large cohort of women undergoing surgery for correction of vesico-vaginal fistula in Africa, a negative 1-hour pad test performed at the time oh hospital discharge had a highly negative predictive value for continue continence at follow-up (16). In women undergoing surgery for pelvic organ prolapse, 1-hour pad test with prolapse reduction with pessary can be used to diagnose occult stress urinary incontinence. A positive test before prolapse surgery was associated with and increased risk of mid-urethral sling postoperatively (17).

Table 4: types of pad test

Author	Time	Bladder load	Exercise
Hahn & Fall (18)	20 min	50% of MCC*	stair climbing, 100 steps, coughing (10x), running (1 min), wash hands (1 min) jumping(1 min)
ICS (11)	1h	Drink 500 ml (15 min) before test	walking & stair climbing (30 min), standing up 10x, coughing (10x), running (1 min), bending (5x), wash hands (1 min)
Jorgensen et al. (19)	24h		Everyday activities
Jakobseny et al. (20)	48h		Everyday activities

Maximum Cystometric Capacity

3. OFFICE-BASED PAD TESTING

Pad tests up to 2 hours were developed to be performed in outpatient clinics or hospital wards under supervised conditions. Bladder volume is predefined to reduce variability and a structured set of exercises is usually implemented to elicit the occurrence of urine loss.

3.1. Short Pad Test

Quantification:
These tests are based on a fixed bladder volume and a standard set of activities to facilitate the occurrence of urine loss, if any, over a short period of time. Jakobseny et al. found that the 40 minute test with a bladder volume of 75% maximum cystometric capacity and similar activities as a 1-hour ward test produced consistently larger amounts of urine loss than a standard 1-hour ward test (20). The difference was attributed to significantly larger bladder volumes during performance of physical activity in a 40 minute pad test.

Kinn & Larsson reported no correlation between a short 10 minute test with fixed bladder volume and the degree of incontinence as judged from the symptoms (21).

Hahn & Fall in a 20 minute test with half cystometric capacity showed no false negative results in 50 women with stress urinary incontinence although there was a discrepancy in 12% of patients between the perception of incontinence severity and pad test results (18).

These data suggest that short pad tests are more provocative than activities of daily living.

Acceptance: a randomized cross-over study suggests that 16% of patients undergoing a 20 minutes pad test were very statisfied with it and 84% were satisfied. A good level of agreement between the two etst was measured (kappa R = 0.84)(22).

Reproducibility:
The correlation factor (Pitman's nonparametric permutation test) between two separate 20 minute tests was 0.94 ($p<0.001$) (18). Kinn and Kinn & Larsson showed that the 10 minute test with a fixed pre-test bladder volume of 75% of maximal capacity was moderatey reproducible (r=0.74) (21).

A 20 minute pad test with an infused volume equal to the volume that elicited a strong desire to void during cystometry was proposed to tailor bladder filling the capacity of the individual patient. A good correlation was found in a test-retest study with a Spearman's rho of 0.788 ($p < 0.0001$) and an intraclass correlation coefcient was 0.793 (95% confdence interval, 0.704–0.882; $p < 0.0001$)(23).

Using a 1 hour pad test, a standardised bladder volume of 300ml and standardised physical activity mean differences of leakage was 8.5 ml and coefficient of repeatability was 33.6 ml (24).

3.2. One-Hour Pad Test

The use of a one-hour pad test has been investigated thoroughly for validity, reproducibility and sensitivity to change.

Quantification
Jakobseny et al. reported that a one hour test detected less leakage at 3 g compared to a 40 minute (7 g) and a 48 hour pad test (37 g) (20). In the elderly, a one-hour ward test did not demonstrate incontinence in 66% of those complaining of incontinence compared to 90% with a 24 in-patient monitoring of urine leakage (25). A one hour pad test was found to reflect everyday incontinence in only 48% of patients in comparison to 81% with a 48 hour test and 77% with a 40 minute test. Jorgensen et al. noted that 90% completed the test and 69% had test results which correlated with daily leakage (19). Lose et al. found a poor to moderate correlation of the modified one-hour test (200-300 ml in the bladder) with a history of stress urinary incontinence (n=31) (26). Mouritsen et al. showed that a 1-hour ward pad test did not detect grade I stress incontinence in 46%, grade II in 27% and grade III in 66% (27). Thind & Gerstenberg compared a 1-hour ward pad test to a 24-hour home pad test and found that a 1-hour pad test had a 36% false-negative rate as compared to a 24-hour home pad test (28).

Comparison of 24 hour and 7 days pad test in men with psotradical prostatectomy urinary incontinence suggests a good level of agreement using the Bland -Alman Plot with no bias found in the linear regression model ($r=0.19$ $p=0.24$) but the 7 days pad test is more apt to capture maximum urine leakage compared to the short test (29).

Reproducibility
Klarskov & Hald demonstrated in 3 consecutive 1-hour pad tests, a correlation coefficient of 0.75 and 0.97 depending on the activity regimen (30). The test, however, was quite demanding and a lot of patients did not complete the full testing. Christensen et al. compared a one-hour pad test in two different urological and one obstetrics & gynaecological departments (20 women) (13). The test results in two urological departments did not differ with an average pad gain of 24g and 21 g ($p>0.1$). However, pad test results between the departments of urology and gynaecology differed significantly, with average pad weight gain 9 g and 24 g respectively ($p<0.05$).

Lose and co-workers showed a significant variation between 1-hour ward test and retest in 18 patients (correlation coefficient 0.68) (12). In 50% of patients the leakage volume was variable due to differing bladder volume. When the results of the 1-hour pad test were cor-

rected for urine volume, the correlation coefficient value increased to 0.96. Simons et al found the reproducibility of the standard 1 hour pad test to be poor (31).

Validity
Walsh & Mills in the elderly and Holm-Bentzen et al. in patients with an AMS artificial sphincter showed that the one hour pad test did not correlate with subjective patient satisfaction but this may due to other lower urinary tract symptoms (9, 32).

Bladder **volume**
Jorgensen et al showed test-retest correlation was improved when the bladder volume was taken into account and the correlation value (r) raised from 0.68 to 0.93 (19). Fantl et al used a one hour test with the bladder filled to capacity and had a test-retest correlation of 0.97 which was improved if the fluid loss was expressed as a percentage of bladder volume (33). Lose et al. using a 1-hour pad test with standardised bladder volume of 50% of maximal cystometric capacity (MCC) showed in 25 women a test retest correlation of 0.97 but the intertest variation was up to 24g (34). Jakobsen et al. compared a 1-hour pad test with a bladder filled to 50% and 75% of maximal cystometric capacity and found that the final bladder volume was equal in both groups showing the importance of diuresis even with equal starting bladder capacities (35). The amount of leakage in both groups was the same. Simons et al. found the volume in the bladder after a standard 1 hour pad test varies by –44 to +66g in a test-retest situation (31). The fluid volume in the bladder appears to be critical in making the pad test reproducible and increasing the sensitivity of the test for detecting leakage.

Aslan et al compared a 1 hour pad test loss with the symptom impact index (SII) and the symptom severity index (SSI) (36). Only the SSI showed a relationship between the severity of the score and the pad test loss. The 1 hour pad test has also been used in assessing the validity of the Incontinence Impact Questionnaire and the Urogenital Distress Inventory unfortunately both had poor correlations with the pad test (37). This is to be expected as the questionnaires assess other urinary symptoms rather than just leakage.

Diagnosis
Fluid loss was significantly greater in patients with detrusor overactivity in comparison to urodynamic stress incontinence (33, 38). The reverse finding was reported by Matharu and co-workers (39). There is high variability in patients with detrusor overactivity making the test impractical as a diagnostic tool.

Sensitivity to change
The 1 hour pad test has been shown to be useful in detecting significant improvements after pelvic floor exercises for men suffering urinary incontinence after radical prostatectomy (40). Ward et al. found the standard 1 hour pad test to show significant reductions in loss after tension free vaginal tape procedures from 18g (IQR 6-37) and Burch colposuspension from 16g (IQR 6-38) both decreasing to 0g (IQR 0) (41). The 1 hour pad test has also been tested for the reduction in loss after conservative and surgical therapy (42). The changes were significant but there was moderate correlation (r = 0.53) with the changes in the St. George Urinary Incontinence Score.

3.3. Two-Hour Pad Test

A test period of 60-120 minutes after a 1 litre fluid load was proposed as the optimal duration for the pad test because of a consistently high bladder volume (43). Han et al showed, however, that a 1-hour pad test is more practical (44). In children a 2-hour ward pad test yielded 70% positive results for incontinence (45). Richmond et al. compared two exercise regimens with a 2-hour pad test and showed no significant differences regarding which order the exercises were performed (46). Walters et al. performed a 2-hour pad test with standard exercise in 40 women with SUI showing 78% positive tests (>1g pad gain) after 1 hour and 98% after the second hour (47). Overall, the two-hour pad test was found to be superior to the one-hour one. There was no correlation between pad test results and the severity of a symptoms score.

4. HOME BASED PAD TESTING

These tests were developed to diagnose and measure urine loss in a situation as close as possible to standard daily life of the patient. The longer observation period usually requires a less structured procedure.

4.1. 12-Hour Pad Test

Quantification:
Hellstrom et al. demonstrated in 30 children with incontinence a positive 12-hour home pad test in 68%. When a standard fluid load (13 ml/kg) was instituted in 20 children, the frequency of the positive test increased to 80% (45).

4.2. 24-Hour Pad Test

Quantification:
Lose et al. found a 90% correlation of a 24-hour pad test with a history of stress incontinence in 31 women (26). This was better than the results of a 1-hour test. Thirteen of 31 patients were found to be continent after a 1-hour ward test in comparison to only 3 with a 24-hour home pad test. Mouritsen et al. showed that the 24-h home test was well tolerated and as good at detecting incontinence as a 48-h test (27). Griffiths et al. found only a 10% false negative rate of a 24-hour pad test in an elderly population (25). Using non-parametric coefficient of correlation, they found a significant difference between the 1-hour test and the 24 hour test. Lose et al. found that a 24h home test performed during daily activities was more sensitive that a 1-hour ward test with standardised bladder volume of 200-300 ml (26). High fluid intake did not change the results of a 24-h home test, but a low fluid intake reduced a positive test by 56% (48). Ryhammer et al. showed that 24-h test is superior to subjective self-reported assessment of urinary incontinence (49).

Reproducibility
Lose et al showed poor correlation in a test-retest study with a variation of more than 100% (26) although Groutz et al. using Lin's concordance correlation coefficient (CCC), found the 24-h test to be very reliable instrument (50). Increasing test duration to 48 and 72 hours slightly improved reliability but decreased patient compliance.

The values for the pad test increase in asymptomatic men and women were reported by Karantanis et al with the median value 0.3g (IQR 0.2 – 0.6; 95th centile 1.3g). It is surprising that the loss is so low and the same for men and women (51).

Diagnosis
Matharu et al found women with urodynamic stress incontinence leaked more than women with detrusor overactivity but the amounts were not diagnostic for the individual abnormalities (39). Pad test loss is unaffected by the degree of hypermobility however there is increased loss associated with urethral sphincter incompetence diagnosed by a vesical leak point pressure less than 60 cmH_2O (52).

Validity
Karantanis et al found the 24-hour pad test was poorly correlated in women with urodynamic stress incontinence with incontinence episodes on a 3 day urinary diary (Kendall's corr coeff b = 0.4) and the ICIQ-SF (r = 0.4) (53). Singh et al. reported that fewer (52%) women after surgery were willing to complete a 24 hour pad test at follow up (54).

4.3. 48-Hour Pad Test

Quantification:
Jakobseny et al. showed that 48-hour pad test reflects everyday incontinence in 81% of patients (20). No statistical analysis data were given. Ekelund et al., found patients own weighing correlate well to control weighing at the clinic in 48-h pad test (r=0.99) (55).

Nygaard and Zmolek in 14 continent women showed a mean pad weight, attributed to sweat for all exercise sessions of 3.19 $\pm$ 3.16 g (the Kendall coefficient of concordance of the test-retest reliability was 0.96) but there was a lot of variation between patients (59). Pyridium staining was not helpful in increasing specificity. Similar results with Pyridium were reported by Wall et al. in a 1-hour ward test (14). In his study (n=18) the Pyridium test was 100% positive in patients with SUI but had false positive results in normal women (52%).

Mean pad weight loss due to evaporation or leakage (was calculated to be 1.003 g, and ranged from -6.5 to +3.85 g (SD 1.85 g) (9). Lose et al. showed no evidence of evaporation over 7 days if the pad was stored in a plastic bag (26). Versi et al. showed pads wetted with saline showed no difference in weight after 1 week and less than 10% weight loss after 8 weeks (57). Twelve pads were weighed by the patient and a healthcare worker with a coefficient of variance =1.55% with a mean deviation of 49%.

Comments
Pad tests can either be used as a qualitative diagnostic tool to diagnose urinary incontinence and as a quantitative test to grade its severity. Pad test is unable to distinguish among different types of incontinence such as stress, urgency or mixed urinary incontinence. The ICS definition of urinary incontinence (the complaint of any involuntary leakage of urine) does not describe how the diag-

Table 5: test-retest correlation

nosis is made but clearly refers to a patient's complaint that excludes urodynamics and rather points at the patient perception of the condition. Following this line of thought, research in this area has moved away from the evaluation of diagnostic accuracy of pad test versus a urodynamic diagnosis of UI and entered the more interesting field of the relationship between the patient perception of UI and pad test. Franco and co-workers in London, UK tested the correlation between different questionnaires for UI and 1-hour pad test showing that only the ICIQ-SF reached statistical significance with a Kendall's τb of 0.177 and a P value of 0.037 while no significant correlation was found for a 0 to 10 Vas score, a patient-based 3-point symptom severity scale, Stamey grade, Urogenital Distress Inventory and the Incontinence Impact Questionnaire (IIQ-7) (62). In another study from Wijma and co-workers, the diagnostic accuracy of pad test for self-reported symptoms of UI was evaluated during pregnancy and after childbirth and the authors conclude that the diagnostic value of pad testing has no clinical relevance in this setting (63). A similar analysis, performed in a male population undergoing sling surgery for post-radical prostatectomy incontinence suggested a good correlation between ICIQ-SF and the Patient Global Perception of Improvement (PGPI) with a 24-hour pad test (64).

Studies from the Urinary Incontinence Treatment Network in US investigated the relation between different measures of incontinence severity and showed how pad weight from a 24-hour test had a good correlation with the incontinence episode frequency derived from a 3-day bladder diary (Spearman correlation coefficient 0.61 but a much lower degree of correlation was found with questionnaires such as the Medical, Epidemiological, and Social Aspect of Aging (r=0.33), the Urogenital Distress Inventory (r=0.17) and the Incontinence Impact Questionnaire (r=0.34) (65). In the same study, the use of pad testing as a prognostic parameter for treatment outcome was investigated but 24-hour pad testing showed no prognostic value for treatment failure in a study of Burch colposuspension versus autologous rectus fascia sling (66). An interesting result was obtained in a predominantely female population of patients receiving neuromodulation for refractory urgency incontinence in which a 24-hour pad test performed after the initial test stimulation was able to predict long term satisfaction in this difficult patient population (67). In this, as in other studies, the number of pads used per day proved to be an unreliable measure of urinary incontinence (68).

A couple of important methodological issues have been raised concerning the use of pad testing. Khan & Chien eloquently pointed out that test-retest comparison should include methods of blinding and use of an appropriate index of degree of agreement which is the intra-class correlation coefficient. In most of the literature this was not implemented (69). Kromann-Andersen et al. argued that with considerable inter- and intra-individual variation of urine loss, the correlation of test/retest results may be overestimated and suggested different trials for small, modest and large leakage in large numbers of patients (70). This trial has not been carried out.

A recent Health Technology Assessment of pad testing concluded that although high sensitivity and specificity for the diagnosis of UI was reported in some studies, it was difficult to draw any conclusions about the diagnostic accuracy for SUI because of the differences existing in pad test methodology. The number of studies comparing the same pad tests with adequate reporting is insufficient and no formal pooling of published data could be performed (71).

Role of the investigation

The test has been standardised by ICS in 1988 for quantification of urine loss and suggested uses for assessment and comparison of treatment results for different types of urinary incontinence in different centres. Also, the AUA report on Surgical Management of Female Stress Urinary Incontinence includes a pad test (pretreatment evaluation) as a standard of efficiency for clinical trials (72). The Urodynamic Society included a pad test in a Standards of Efficacy for Evaluation of Treatment Outcomes in Urinary Incontinence (73). No suggestion was made in the last two reports of which test to use.

5. CONCLUSIONS

- The 1-hour pad test is not very accurate unless a fixed bladder volume is applied
- Set exercises during the test improve test-retest reliability
- The sequence of exercises has little effect on test results
- A pad weight gain ≥1 g suggests a positive 1h test
- A 24 hour test correlates well with symptoms of incontinence
- A 24-hour test has good reproducibility but poorer compliance
- A pad weight gain ≥1.3g = positive 24 h test
- A test lasting longer than 24 h has little advantage
- A pad test cannot distinguish between USI and DO

6. CONSENSUS STATEMENTS

- The pad test is an optional investigative tool in the routine evaluation of UI**(Level of Evidence 3, Grade of Recommendation C)**
- Pad test is a useful outcome measure in clinical trials and research studies. **(Level of Evidence 3, Grade of Recommendation C)**

The following standards are suggested:

- 20 min-1 h ward/office test with fixed bladder volume (pad weight gain ≥ 1g = positive test) **(Level of Evidence 3, Grade of Recommendation C)**
- 24 h home pad test during daily activity (pad weight gain ≥ 1.3g/24h = positive test) **(Level of Evidence 3, Grade of Recommendation C)**

7. FUTURE RESEARCH AREAS

Proper validation analysis using the coefficient of variability

Evaluation of the ability to detect all the spectrum of urinary incontinence (from mild to severe)

Sensitivity to change in time of incontinence status for 24 hour pad tests

Validity of pad tests with other measures of incontinence such as urinary diaries and symptom questionnaires.

V. NEUROPHYSIOLOGY

1. INTRODUCTION

Neurophysiological investigations of muscles and nerves in the perineum and pelvis originated in the 1930-ties and have evolved with the developments in general clinical neurophysiology. The data from these investigations can assist clinicians in diagnosing neurological disease or injury; the tests can be used intraoperatively for identification of nerves and muscles.

This text details the investigations, their applications and limitations, enabling investigators and clinicians to make a well-informed decision about using these tests.

The present text is based on the previous chapter on clinical neurophysiology prepared for the International Consultations on Incontinence (1), which has been updated by a literature search in Medline using key words incontinence, clinical neurophysiology, electromyography, reflex, evoked potentials, autonomic nervous system tests.

1.1. Classification Of Clinical Neurophysiological Tests

Although different types of tests may be included under the term "neurophysiological", it is particularly the electrophysiological tests that shall be discussed in the present text.

Electrophysiological tests are an extension of the clinical examination, and a functional anatomic approach to classification makes most sense. For the purpose of this categorisation, the nervous system is divided into the somatic and the autonomic nervous systems. The somatic nervous system provides motor innervation to the skeletal muscles and joints, and sensory innervation from skin and muscle spindles. The autonomic nervous system provides motor innervation to the viscera and other end-organs not under voluntary control (e.g., sweat glands). Its sensory fibres are referred to as visceral afferents. Both systems have central pathways (neurons participating in spinal cord and supraspinal control) and peripheral nerves (those going to and from end-organs).

Thus, electrophysiological tests can be divided into: a) somatic motor system tests (EMG, terminal motor latency measurements/ motor nerve conduction studies, and motor evoked potentials (MEP)); b) somatosensory system tests (sensory neurography, somatosensory evoked potentials (SEP)); c) reflexes; and d) the autonomic nervous system tests (for sympathetic or parasympathetic fibres).

Electrophysiological tests may also be categorized "technically" into those limited to simple recording some bioelectrical activity (for instance: electromyography), and those which record particular biological responses to anatomically localized stimulation (these may be subsumed under the term "conduction tests").

1.2. Biological Correlates Of Electrophysiological Tests

It is always difficult to have a perfect correlation between electrophysiological test results and clinical and pathological conditions.

Some abnormalities are sub-clinical. Electrophysiological tests are more relevant and accurate in cases of lower motor neuron lesions. They are less effective in the case of upper motor neuron lesions or in the case of autonomic nervous system dysfunction.

But usually, electrophysiological tests allow the etiological and topographical diagnosis of perineal disorders to be made more precise. A neurological cause and the level of lesion can thus be determined in the case of a urinary, anorectal or genital-sexual disorder.

The prognosis of urinary or anorectal dysfunction during neurological lesions can also be determined by electrophysiological tests.

1.2.1. Conduction Tests: Nerve Conduction, Evoked Potential and Reflex Studies

The electrophysiological responses obtained on stimulation are compound action potentials and relate to populations of biological units (neurons, axons, motor units, muscle fibres, etc.). Latency and amplitude are commonly measured parameters of responses during neurophysiological testing. If the onset of the potential is measured, the latency of a compound potential represents the fastest conduction through a particular neural channel. As a general rule, latency measurements are not markedly affected by technical factors, but provide little information about the loss of biological units (e.g., motor neurons or axons). The amplitude of the compound potential correlates with the number of activated biological units. In theory, the amplitudes are the more relevant physiological parameter, as they reflect the functional or structural loss of biological units. Unfortunately, amplitudes are also strongly influenced by many poorly controllable technical factors. Measurements of latencies and amplitudes of evoked potentials and reflex responses, including sympathetic skin responses, relate not only to conduction in peripheral and central neural pathways, but also to trans-synaptic transmission.

1.2.2. Electromyography (EMG)

Knowledge of the structure and function of the motor unit (Figure 58) is fundamental to understanding the application of EMG. Motor neurons, which innervate striated muscle, lie in the anterior horn of the spinal cord and are called "lower motor neurons". (Neurons that innervate the sphincters lie in Onuf's nucleus in the sacral spinal cord; they are somewhat smaller than those innervating skeletal limb and trunk muscles). Within the muscle, the motor axon branches to innervate a certain number of muscle fibres, which are scattered throughout the muscle. All muscle fibres innervated by one lower motor neuron are activated simultaneously; all these constituents together are called "motor unit". The innervation of muscle fibres is such that it is unlikely that muscle fibres that are part of the same motor unit will be adjacent to one another.

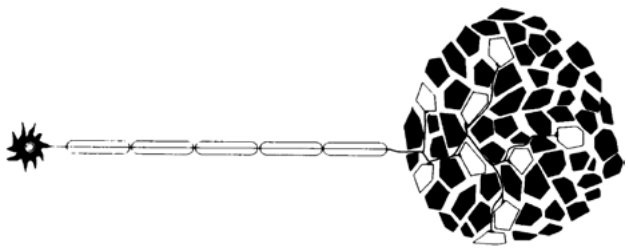

Figure 58: Schematic representation of a motor unit. The alpha motor neuron with its cell body, its myelinated axon and the peripheral nerve endings is shown. The muscle fibres innervated by this alpha motor neuron are shown in white. (Note that the muscle fibres from one motor unit are intermingled with motor fibres from other motor units).

It is difficult to estimate the number of muscle fibres innervated by a single axon (i.e., the "innervation ratio") or the number of motor units supplying a muscle, by clinically available neurophysiological techniques.

1.3. General Methodological Considerations

To date, there are no universally accepted standards for conducting individual uro-genital-anal neurophysiological tests, but the variations of testing in different laboratories are minor.

There are technical standards on equipment safety.

1.3.1. Equipment

Clinical neurophysiological tests are conducted with complex electronic instruments and various devices that come into contact with the patient. Though this equipment is mostly standard, some specially constructed electrodes or stimulating devices have been devised to conform to uro-genito-anal anatomy. As long as the standards of electrical safety are adhered to, the risk to patients is negligible.

Surface electrodes, which are applied to skin or mucosal surfaces, or needle electrodes are used for electrical stimulation and to record bioelectrical activity. The important neurophysiological difference between surface and needle electrodes is their selectivity, and the practical difference is their invasiveness. The choice and application of electrodes is guided by the need for selective recording or stimulation. Less commonly, special devices are used for magnetic and mechanical stimulation.

The electrical stimulation should be specified and characterised both in technical (e.g., rectangular electrical pulse, 0.2 ms, 15 mA) and physiological terms (e.g., 3-times sensory threshold). A stimulus with defined technical parameters may have variable biological effects because of the variable influences of electrode condition, contact, tissue conductivity etc. Supramaximal stimulation is preferred to elicit a compound muscle action potential (CMAP) or sensory nerve action potential. Supramaximal stimuli yield responses with the largest amplitude and shortest latency and are the least variable and most reproducible. The sites at which stimulation electrodes are applied should be described using anatomical terms.

1.3.2. Recording

1.3.2.1. Apparatus settings

For recording, the apparatus settings (gain, sweep speed) have to be adapted to the known range of amplitudes, latencies, and duration of the response and it has to be appropriately displayed for analysis. Particularly important is the frequency setting of filters: for surface electrode recordings it is typically 2 Hz – 1 kHz; for concentric needle EMG recordings, it is 5 Hz – 10 kHz.

Placement of electrodes on the scalp for evoked potential recordings is defined according to the 10-20 International EEG System.

1.3.2.2. Reproducibility and Reliability

Any potential recorded should be reproducible; therefore, as a rule, at least two to three consecutive recording procedures need to be performed. To improve the signal-to-noise ratio some small amplitude responses need to be averaged. Therefore, many repetitions of stimulation/recording need to be done (typically 100-200). Even such an averaged recording needs to be repeated at least twice. Responses whose nervous pathways include synapses may show marked fatiguability with stimulus repetition (e.g., SSR), others are facilitated (the bulbocavernosus reflex).

1.3.2.3. Waveform Analysis

For a particular recorded potential, its shape, latency, and amplitude are analysed. Morphologically, a particular response (or part of it) needs to be recognised as present or absent. The shape of potentials is important to accurately determine the latency and duration (if applicable) and amplitude of the response. The onset of the response obtained on stimulation (for M-waves, MEP and sacral reflex testing) or the individual peaks of the potentials (for SEP) are used to determine the latency. The amplitudes are analysed relative to the baseline or "peak to peak".

2. CLINICAL NEUROPHYSIOLOGICAL TESTS

2.1. Somatic Motor System Tests

2.1.1. Electromyography (EMG)

The term "EMG" is used for several different procedures, the common denominator of which is the recording of bioelectrical activity from muscle. In practice, EMG is used a) to record the activity of a particular striated muscle as a functional unit (as for instance in combined urethral sphincter EMG and a pressure-flow study - see kinesiological EMG); b) to indicate that a particular muscle has been activated, either by stimulation applied to its motor innervation (M-wave, MEP) or to sensory pathways (reflex response); c) to differentiate between normal, denervated, reinnervated, and myopathic striated muscle; and d) to measure neuromuscular transmission (the latter is not relevant for clinical diagnostics in pelvic floor muscles).

EMG recordings from smooth muscles are as yet only experimental.

2.1.1.1. General Technique for Needle EMG in Pelvic Floor Striated Muscles

All tests requiring needle electrodes are invasive and some pain is inevitable, even with use of local anaesthetics. Local anaesthesia is infrequently used for needle EMG examination. Intramuscular electrodes need to be appropriately placed in the target muscle.

The pelvic floor and perineal muscles can be examined, including the levator ani, the bulbocavernosus muscle and the striated anal and urethral sphincter muscle. Facility with needle examination requires some practice. As a rule, several sites from one or more skin penetrations are sampled, which is difficult in small muscles.

The audio output from the loudspeaker of the EMG apparatus helps in assessment of the quality of recording as well as in recognition of the electrophysiologic phenomena.

2.1.1.2. Concentric needle EMG (CNEMG)

The examination is conducted with a single use, disposable electrode, and all different "types of EMG" mentioned above can be performed with this electrode. It consists of a central insulated platinum wire inserted through a steel cannula and the tip ground to give an elliptical area which can record spike or near activity from about 20 muscle fibres (2). The number of motor units recorded therefore depends both upon the local arrangement of motor units within the muscle fascicle and the level of contraction of the muscle.

In principle, CNEMG can provide information on a) muscle insertion activity, b) abnormal spontaneous activity within the muscle (Figure 59), c) MUPs, d) interference pattern (IP), neuromuscular jitter.

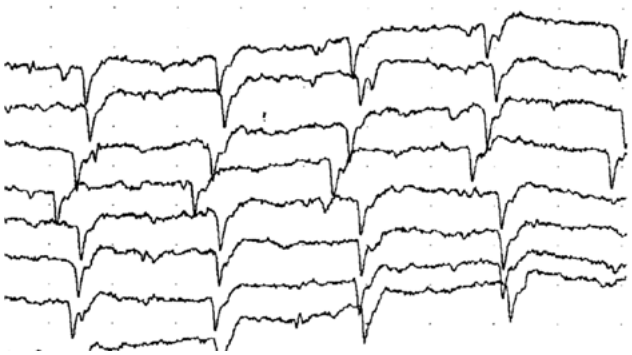

Figure 59: Concentric needle EMG recording from right bulbocavernosus muscle of a 49-years old male with urinary incontinence diagnosed as possible Multiple system atrophy. Pathological spontaneous activity (a burst of positive sharp waves) is shown.

In normal striated muscle, needle movement elicits a short burst of "insertion activity," which is due to mechanical stimulation of excitable muscle cell membranes. This is recorded at a gain setting of 50 µV per division (sweep speed 5 – 10 ms/division), which is also used to record spontaneous activity. Absence of insertion activity with appropriately placed needle electrode usually means a complete denervation atrophy of the examined muscle.

The amount of recruitable motor units during voluntary and reflex activation can also be estimated. Normally, MUPs should intermingle to produce an "interference" pattern on the oscilloscope during muscle contraction, and during a strong cough. In addition, the number of continuously active MUPs during relaxation (3), MUP variability (neuromuscular jitter) as well as MUP recruitment on reflex and voluntary activation (kinesiological parameters) can be observed (4).

MUPs (and occasionally encountered end-plate activity) are recordable in normal resting sphincter muscles in a relaxed subject. This is in contrast to limb muscles where relaxation is associated with "electrical silence" by EMG. In addition to continuously firing motor units, new MUPs are recruited voluntarily and reflexly in the sphincters. It has been shown that the two MUP populations differ in their characteristics: reflexly or voluntarily activated "high-threshold MUPs" being larger than continuously active "low-threshold MUPs". As a consequence, standardised level of activity at which a template based multi-MUP analysis obtains 3-5 MUPs on a single muscle site was suggested (5).

Although EMG abnormalities of striated muscle are detected as a result of a host of different lesions and diseases, there are in principle only two standard manifestations which can occur: a) disease of the muscle fibres themselves ("myogenic" changes), and b) changes in their innervation ("neuropathic" changes). Myogenic changes may result from muscle disease, probably also from direct trauma (e.g., the anal sphincter tear during vaginal delivery). Neurogenic changes may be attributable to injury at any level along the lower motor neuron supplying the particular muscle, extending from the motor neuron body, sacral nerve roots to the small branches within the muscle. (In the pelvic floor muscles, only neurogenic changes are well recognised and routinely evaluated).

In partially denervated sphincter muscle there is – by definition – a loss of motor units (MUs). This can be estimated during relaxation by counting the number of continuously firing low-threshold MUPs. In patients with cauda equina or conus medullaris lesions, fewer MUPs fire continuously during relaxation (6), probably due to partial axonal loss. The main obstacle to qualified assessment of reduced number of activated MUs and activation of MUs at increased firing rates (as occurs in limb muscles) is a lack of concomitant measurement of level of contraction of the examined muscle (this can be readily assessed when studying limb muscles).

There are two approaches to analysing the bioelectrical activity of motor units: either analysis of individual motor unit potentials (MUPs), or analysis of the overall activity of intermingled MUPs. (This is the so called "interference pattern" – IP. Exploring different sites of the activated muscle with a needle electrode provides "samples" of intermingled motor unit potentials (IP epochs), which can be analysed).

Generally, three different techniques of MUP analysis (manual-MUP, single-MUP and multi-MUP) and 1 technique of IP analysis (turn/amplitude – T/A) are available on advanced EMG systems (6).

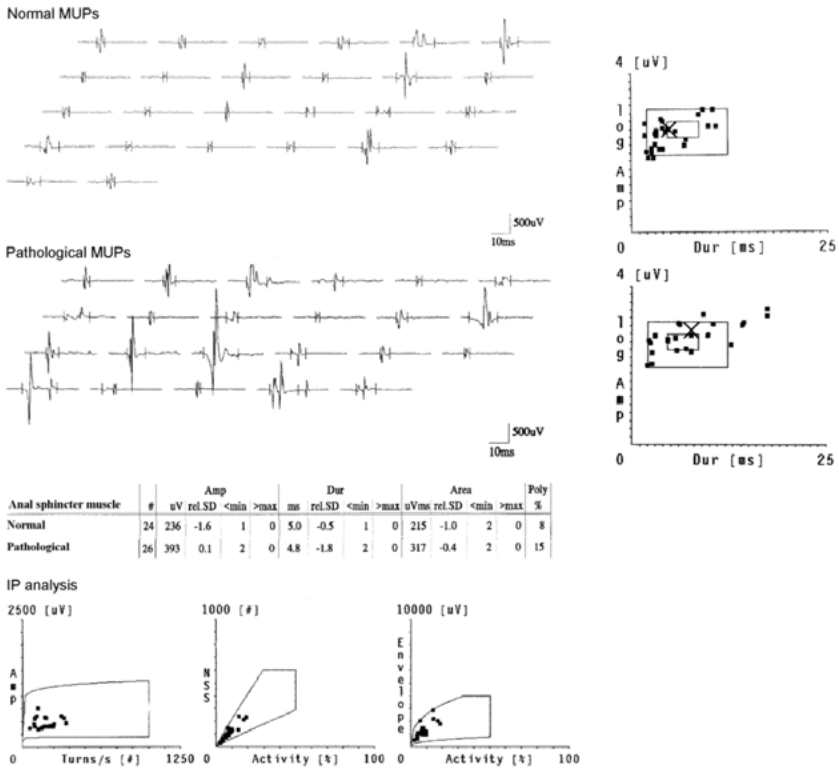
It is easy to grasp the "motor unit potential analysis", as it is simply a measurement (by different methods) of the "parameters" of single individual MUPs (i.e., its amplitude, duration, number of phases…). The changes in MUP parameters furthermore are "direct" results of understandable physiological changes and are thus "meaningful" to the interpreter.

The changes in IP parameters are, however, less readily grasped. These are: numbers of turns per second (any peak or trough of the signal where the activity changes by more than 100 µV); amplitude/turn (change in volts between two turns); number of short segments (parts of signal that has "sharp" activity) percent activity (percent of epoch with sharp activity); envelope (peak to trough amplitude exceeded by 1% of peaks/troughs). These parameters relate both to MUP parameters and to the activation level of the muscle. Recorded data are log transformed and linear regression lines are created. Amplitude/turn, and number of turns/second data from normal subjects can be used to create upper and lower boundaries (95 % confidence intervals) for assembly of future data from individual patients. Individual data create a scatter plot ("cloud") which compares to the normative boundaries. (See Figure 60). It has been asserted that this approach does not require a standardized muscle contraction, but the shape of the "cloud" is dependent on the strength of muscle contraction. Therefore, it has been suggested to standardize the method by measuring pressure exerted by the contracting sphincter (7).

Both the template based multi-MUP analysis of MUP and T/A analysis of IP are fast (5-10 and 2-3 minutes per muscle, respectively), easy to apply, and, technically, represent clinically useful techniques.

2.1.1.2.1. CNEMG Findings Due to Denervation and Reinnervation

After complete denervation, all motor unit activity ceases. In a denervated muscle, complete "electrical silence" is noted in the first days after such an event. The diagnosis of complete denervation is confirmed by the absence of muscle response during electrical stimulation. Because motor axons take days to degenerate after injury, this proof is not available for up to 5-7 days after a denervation injury. However, it is rarely necessary to demonstrate complete denervation in the acute stage because the clinical condition is usually obvious. Denervated muscle fibres become hyperexcitable and start to fire spontaneously giving rise to abnormal spontane-



Anal sphincter muscle	#	Amp uV	Amp rel.SD	Amp <min	Amp >max	Dur ms	Dur rel.SD	Dur <min	Dur >max	Area uVms	Area rel.SD	Area <min	Area >max	Poly %
Normal	24	236	-1.6	1	0	5.0	-0.5	1	0	215	-1.0	2	0	8
Pathological	26	393	0.1	2	0	4.8	-1.8	2	0	317	-0.4	2	0	15

Figure 60: Comparison of normal (above) and pathological (below) motor unit potentials (MUPs) sampled by multi-MUP analysis from the right halves of the subcutaneous parts of the external anal sphincter (EAS) muscles. To the right logarithm (amplitude) vs. duration plots of the MUPs are shown; the inner rectangle presents normative range for mean.

ous activity, but these may take up to three weeks to appear. The "insertion activity" becomes prolonged and short biphasic spikes (fibrillation potentials) and biphasic potentials with prominent positive deflections (positive sharp waves) appear (Figure 59). Thus, concentric needle EMG (CNEMG) correlates of denervation are pathologically prolonged insertion activity and pathological spontaneous activity. Completely denervated muscle may be reinnervated by axonal regrowth from the proximal nerve stump with few muscle fibres constituting "nascent" motor units. These are short, bi- and triphasic, soon becoming polyphasic, serrated and with prolonged duration. In partially denervated muscle, collateral reinnervation takes place. Surviving motor axons will sprout and grow out to reinnervate those muscle fibres that have lost their nerve supply. This results in a change in the arrangement of muscle fibres within the unit. Whereas in healthy muscle, it is unusual for two adjacent muscle fibres to be part of the same motor unit, following reinnervation, several muscle fibres belonging to the same motor unit come to be adjacent to one another. CNEMG correlates are changes in MUPs (duration, amplitude, number of phases, turns, etc). Early in the process of reinnervation, the newly outgrown motor sprouts are thin. Therefore, they conduct slowly such that the time taken for excitatory impulses to spread through the axonal tree is abnormally prolonged. Moreover, the neuromuscular transmission is unstable due to immaturity of the motor endplates. The CNEMG correlate is instability of long-duration complex potentials.

In partially denervated muscle, some MUPs remain and mingle eventually with abnormal spontaneous activity. Changes due to collateral reinnervation are reflected by: prolongation of the wave form of the MUP (Figure 60) which may have small, late components ("satellite potentials"). MUPs show "instability" due to insecure transmission in newly formed axon sprouts and endplates. This "instability of potentials" (meaning both "jitter" and "blocking" of individual components in a complex potential) is not routinely assessed during sphincter EMG (8). In striated muscle, the diameter of reinnervating axonal sprouts and conduction velocity increase with time, thereby improving synchrony of activation in the reinnervated motor unit. Thus, MUP amplitude increases while MUP duration reverts towards normal. However, in degenerative neurological diseases (such as multiple system atrophy), long duration motor units are a prominent feature of anal sphincter reinnervation (9). It is important to note that in patients with more severe neurogenic lesions, reinnervation may be inefficient resulting in MUP with parameters below confidence limits describing size (area, duration) (10).

The changes in MUP parameters (along with changed number of MUPs and changes in activation frequency of MUPs) will be reflected also in IP parameters.

Abnormalities of parameters evaluated by needle EMG are in principle non-specific, i.e., most abnormalities can occur both in neuropathic or myopathic conditions. It is the overall clinical picture that dictates interpretation of results. It has been suggested that the combination of MUP thickness and number of turns might be even more accurate (11) than previously suggested combination of MUP area, duration, and number of turns (12).

2.1.1.2.2. CNEMG of the External Anal Sphincter

The external anal sphincter (EAS) is the most practical indicator muscle for sacral myotomes because it is easy to access, has enough muscle bulk for exact EMG analysis, and its examination is not too uncomfortable.

The needle electrode is inserted into the subcutaneous EAS muscle about 1 cm from the anal orifice to a depth of a 3-6 mm under the non-keratinised epithelium. For the deeper part of the EAS muscle 1-3 cm deep insertions are made at the anal orifice, at an angle of about 30° to the anal canal axis (13). In most patients only examination of the subcutaneous EAS muscle is necessary. Separate examinations of the left and right EAS muscles are recommended. The needle is inserted into the middle of the anterior and posterior halves of each side ("quadrants") of the EAS muscle. After insertion in two positions on each side the electrode is turned backwards and forwards in a systematic manner. At least 4 sites in each of the subcutaneous and/or the deeper EAS muscle are thus analysed (13, 14).

Use of quantitative MUP and IP analyses of the EAS is further facilitated by the availability of normative values (15) that can be introduced into the EMG systems' software. It has been shown that normative data are not significantly affected by age, gender (15), number of uncomplicated vaginal deliveries (16), mild chronic constipation (17), and the part of EAS muscle (i.e. subcutaneous or deeper) examined (16).

Intramuscular electrode insertion into other perineal muscles and pelvic floor muscles is not standardized and is described in textbooks and primary literature.

2.1.1.3. Single fibre EMG (SFEMG)

SFEMG is nowadays used practically only in diagnostics of neuromuscular transmission disorders, and not anymore in the pelvic floor muscles.

The SFEMG electrode has similar external proportions to a concentric needle electrode, but with a smaller recording surface. It will pick up activity from within a hemispherical muscle volume 300 µm in diameter, much smaller than the volume of 2-3 mm diameter from which a concentric needle electrode records (2). Apart from the neuromuscular jitter it can also record data which reflect motor unit morphology (muscle fiber density)(8), but for this purpose it has several disadvantages in comparison to the concentric needle EMG.

2.1.1.4. Kinesiological EMG

Kinesiological EMG is the term for the type of EMG recording aimed only to assess the pattern of an individual muscle's activity/inactivity during defined manoeuvres (Figure 61), typically during urodynamics. Any type of electrode can be used to make kinesiological recordings. The electrical activity of a muscle is described as present or absent (and can also be quantified). Technical issues will be dealt here; the relevance for diagnostics will be discussed in the Chapter on dynamic testing.

Although either standard EMG equipment or EMG facilities contained within urodynamic systems can be used, the better visual and audio control provided by standard EMG equipment facilitate optimal electrode placement and improve recordings (18). When using surface electrodes there are problems related to validity of signal (e.g., artefacts, contamination from other muscles). The quality of the EMG recorded from the external urethral sphincter (EUS) muscle is improved by a catheter-mounted surface electrode device that applies mild suction (19). With intramuscular electrodes, the procedure is more invasive, and there are questions as to whether the whole muscle in large pelvic floor muscles is properly represented by the sampled muscle portions. Intramuscular electrodes should ideally be fine wire electrodes, as they do not dislodge, and no pain is induced with muscle contraction.

The kinesiological sphincter EMG recordings in health show continuous activity of MUPs at rest. It can be recorded in many but not all detection sites of the levator ani muscle. The urethral and anal sphincter as well as the other pelvic floor musculature (e.g. pubococcygei) can be voluntarily activated typically for less than 1 minute (20). Timely activation of the levator ani muscle has been demonstrated to be an important aspect of stable bladder neck support; its activation precedes activity of other muscles in the cough reflex (21). A consistent contraction sequence of the superficial and deep pelvic floor muscles is found in continent but not in incontinent women (22).

Sphincter activity during voiding is characterised by the cessation of all EMG activity prior to detrusor contraction. Needle electrodes are more useful than perineal patch electrodes to demonstrate MU quiescence during voiding (23, 24).

Pathologic incoordination of the detrusor and sphincter is called detrusor sphincter dyssynergia. In selected patients with neurogenic detrusor overactivity, EMG of the EUS muscle can be used to demonstrate the onset of detrusor contractions (20).

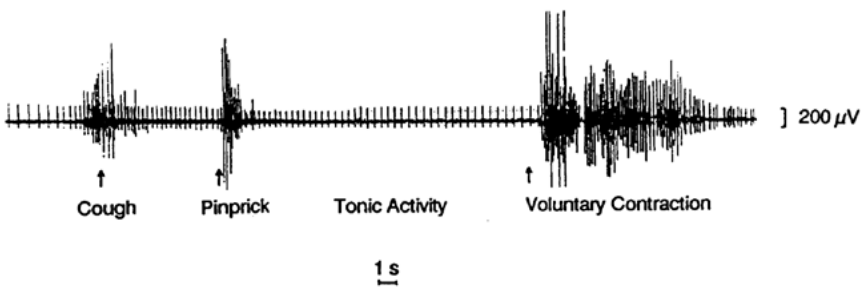


Figure 61: Kinesiological EMG recording from the urethral sphincter muscle of a healthy 53-year-old continent female. Recruitment of motor units on reflex manoeuvres and on a command to contract is shown; regular continuous activity of motor units represents "tonic activity". (Recorded with concentric needle electrode).

Apart from polygraph urodynamic recordings to assess detrusor-sphincter coordination, the diagnostic usefulness of kinesiologic EMG has not been established.

2.1.1.4.1. Surface Electromyography Using Non-invasive Electrode Arrays

Surface EMG recording using non-invasive electrode arrays and multichannel EMG amplifiers can localize muscle innervation zones and asymmetry in muscle innervation (25), and analyze discharge patterns of MUPs, and propagation velocities along the muscle fibers (26). While it is expected that the new sophisticated computer assisted analysis techniques will help diagnosing sphincter function (for instance the "circumferential urinary sphincter surface electromyography")(27) the clinical value of new methods has not yet been widely explored and validated. Surface EMG recording can be also used in order to quantify external anal fatigability which is probably one of the mechanisms of fecal incontinence (28).

2.1.1.5. Clinical application of EMG

There are many clinical applications of electrophysiological testing.

These tests make it possible to detect a neurological lesion in case of a urinary or anorectal disorder, to specify the importance, the lesion level and sometimes the prognosis.

2.1.1.5.1. Neurogenic Conditions

Trauma, surgery (for instance: radical prostatectomy)(29), and neurologic disease have all been implicated in denervation of pelvic floor and perineal muscles and pelvic organs. In a series of 194 consecutive patients referred for electrodiagnostic evaluation, quantitative needle EMG of the EAS muscles supported a diagnosis of a cauda equina or conus medullaris lesion in 36 patients, a lesion of the EAS muscle in 6, a pudendal nerve lesion in 2, and a sacral plexus lesion in 1 patient. Furthermore, neuropathic findings in the EAS were compatible with a diagnosis of multisystem atrophy in 11 and were most probably caused by severe polyneuropathy in 2 patients. In another 11 patients, the etiology of the pathologic findings could not be established at time of electrodiagnostic testing (30).

Lesions of the cauda equina or conus medullaris commonly cause pelvic floor dysfunction. These have mainly been a consequence of neural compression within the spinal canal caused by intervertebral disc herniation, spinal fractures, epidural hematomas, and intraspinal tumors; or a result of spinal surgery, mainly on lumbar discs (31, 32). Electrodiagnostic tests are also useful in the assessment of neurogenic lesions in children with spinal dysraphism (33). After detailed clinical examination of the lumbosacral segments (with particular emphasis on perianal sensation), neurophysiologic testing assesses the severity of the lesion and may clarify the diagnosis. In the authors' series, 10 percent of patients with cauda equina lesions reported normal perianal sensation (34). Electrodiagnostic tests that need to be considered are bilateral needle EMG of the EAS muscle and the bulbocavernosus muscle in subacute situations; and electrophysiologic evaluation of the bulbocavernosus reflex (35, 36). Detection of spontaneous denervation activity by needle EMG (in the bulbocavernosus muscle!) is common from approximately 3 weeks to several months after injury. Later, MUP analysis becomes more important for demonstrating reinnervation. Most of these lesions cause partial denervation; a traumatic lesion to the lumbosacral spine or pelvis is probably the only acquired condition in which complete denervation of the perineal muscles can be observed (6, 10, 37).

Following a cauda equina or a conus medullaris lesion, the MUP of pelvic floor and perineal muscles are prolonged and polyphasic, of increased amplitude, area, number of turns (6). Surgical dissections can also affect the innervation of the sphincter and lead to loss of motor units and reinnervation of those surviving (38). After pelvic trauma, gross changes of denervation and reinnervation may be detected in pelvic floor muscles. Abnormalities in polyneuropathy, as for instance diabetic, are usually minor (39).

Neuropathic changes can be recorded in sphincter muscles of patients with multiple system atrophy (MSA), a progressive neurodegenerative disease, which can be mistaken for Parkinson's disease (PD) (40). Among 30 patients with a pathologic diagnosis of multisystem atrophy, 24 had abnormal, 5 had a borderline, and only 1 had a normal sphincter EMG (41). Sphincter EMG has been proposed to distinguish MSA from Parkinson's disease but is probably not specific in the later stages of parkinsonism and may not be sensitive enough in the early phase of the disease (42-45). Some studies have failed to demonstrate the effectiveness of MUP analysis in sphincter muscles (46, 47), probably because of the exclusion of late components from MUP duration (9). Extensive discussion on the subject can be found elsewhere (48). The changes of chronic reinnervation may also be found in progressive supranuclear palsy (49, 50), and in Machado–Joseph disease (51), in which neuronal loss in Onuf's nucleus has also been demonstrated histologically (52).

In patients with acute idiopathic autonomic neuropathy and lower urinary tract (LUT) dysfunction the EMG of external sphincter muscles was reported as normal (53).

2.1.1.5.2. Changes in Primary Muscle Disease

In skeletal muscle, the "typical" features of a myopathy are small, low amplitude polyphasic units recruited at mild effort. There are few reports of pelvic floor muscle EMG in generalised myopathy. In a nulliparous woman with limb-girdle muscular dystrophy, histology revealed involvement of pelvic floor muscles, but concentric needle EMG of the urethral sphincter was normal (54). Myopathic EMG changes were observed in the puborectalis and the EAS in patients with myotonic dystrophy (55), but not in another group of patients with myopathy (56).

2.1.1.5.3. Stress Incontinence

Pelvic floor muscle denervation has been implicated in the pathophysiology of genuine stress incontinence (GSI) (57). EMG techniques have been used to identify sphincter injury after childbirth and to evaluate women with GSI. Stress incontinence and genitourinary prolapse were associated with partial denervation of the pelvic floor (58). The changes were most marked in women who were incontinent after delivery, who had a prolonged second stage of labour, and had given birth to heavier babies. In a recent study, nearly all EMG parameters showed significant differences between continent and SUI women consistent with better motor unit recruitment in continent women. Continent women had larger-amplitude, longer-duration MUPs with increased turns and better MUP recruitment during bladder filling ($P < 0.05$) (59).

Myogenic histological changes in pelvic floor muscles after vaginal delivery were also reported (60), with some EMG support by another group (61). "Myopathic EMG changes" (i.e. short, small MUPs) may, however, be a consequence of deficient reinnervation (37). There were claims urethral sphincter EMG can assist in selecting the type of surgery for patients with intrinsic sphincter deficiency (60).

Although CNEMG of the urethral sphincter seems the logical choice in patients with urinary incontinence of possibly neurogenic origin, only a small amount of pathological muscle tissue remains in many incontinent parous women, which makes EMG of the muscle impractical (38). CNEMG findings generally will not affect therapeutic considerations (62).

2.1.1.5.4. Idiopathic Faecal Incontinence

"Idiopathic" faecal incontinence refers to patients in whom this symptom is not attributable to an underlying disorder, but it has been often implied that it is a neurogenic condition. Vaginal delivery is proven to cause structural sphincter defects; it may cause outright sphincter denervation in rare cases, but its more widespread implication in causing "idiopathic" incontinence is controversial. CNEMG may be helpful in selected patients with faecal incontinence if a specific neurogenic condition (e.g., trauma or disease affecting the conus, sacral roots, sacral plexus or pudendal nerves) is suspected on clinical grounds. External anal sphincter muscle innervation pattern evaluation by multichannel surface EMG has been claimed to offer information to the obstetrician to prevent damaging epiziotomies (63).

2.1.1.5.5. Idiopathic Urinary Retention in Women

In the external urethral sphincter of young women with urinary retention (or obstructed voiding) complex repetitive discharges (and decelerating bursts) in profuse amounts have been described (64, 65). The abnormality was reported to be a predictor of the long-term success of therapeutic sacral neuromodulation (66). In a group of such women an occult generalized dysautonomia was found (67). It has been known before that repetitive discharges develop in chronically partially denervated sphincters, and that they are present even in a proportion of asymptomatic women. Recently, it has been shown that this activity changes during the menstrual cycle (more commonly found in the luteal phase of the menstrual cycle in asymptomatic women). The importance of this abnormal EMG activity in the aetiology of urinary retention in young women remains uncertain (68). Currently, the diagnosis of Fowler syndrome remains a clinical one, based on a multimodal assessment of the patient.

2.1.1.5.6. EMG in Urodynamic and Functional Anorectal Studies

In health, voiding is characterised by cessation of motor unit firing in the urethral sphincter prior to detrusor contraction, as can be demonstrated by recording of "kinesiological EMG". Bladder-sphincter coordination is impaired with lesions between the lower sacral segments and the upper pons. Consequently, sphincter activity is not inhibited, and often increases before detrusor contraction (i.e., 'detrusor-sphincter dyssynergia'). On the basis of the temporal relationship between urethral sphincter and detrusor contractions, three types of dyssynergia have been described (69).

There are other clinical situations that mimic detrusor sphincter dyssynergia. Sphincter contraction or at least failure of relaxation during involuntary detrusor contractions can be seen in patients with Parkinson's disease. The pelvic floor muscle contractions of the so-called nonneurogenic voiding dyssynergia may be a learned abnormal behaviour (70), and are a feature of dysfunctional voiding (65). There is insufficient data to determine the nature of the non-relaxation of sphincter activity as demonstrated by EMG signals during micturition (often seen in children and females) by EMG as such. The EMG recording has to be interpreted in the light of the overall clinical picture of the examinee.

The pubococcygeus in the healthy female reveals similar activity patterns to the urethral and anal sphincters at most detection sites: continuous activity at rest, often some increase of activity during bladder filling, and reflex increases in activity during any activation manoeuvre performed by the subject such as talking, deep breathing, coughing. The pubococcygeus relaxes during voiding; the muscles on either side act in unison (20). In stress incontinent patients, the patterns of activation and the co-ordination between the two sides can be lost (71). A delay in muscle activation on coughing has also been demonstrated, as compared to continent women (21).

Little is known about the complex activity patterns of different pelvic floor muscles (the urethral sphincter, urethrovaginal sphincter, anal sphincter muscle, different parts of the levator ani) during different manoeuvres. It is generally assumed that they all act in a co-ordinated fashion functionally as one muscle. However there are demonstrable differences between the intra- and peri-urethral sphincter in healthy females (72) and in activation of the levator ani and the urethral sphincter (73). Co-ordinated behaviour is frequently lost in abnormal conditions.

Kinesiological needle EMG analysis of the urethra with the patient at rest and coughing may predict the outcome after certain types of incontinence surgery (74). However, other studies found that preoperative EMG did not predict patients at risk for postoperative voiding dysfunction (24).

Indeed, while kinesiological EMG (particularly when combined with other urodynamic tests) promises theoretically relevant data, technical standards are lacking, and findings have been reported in single center studies. Further basic research is necessary to delineate the correlation of EMG signals and their interpretation in terms of clinical significance (the significance of EMG data for defining overall LUT function) (75).

Current concepts suggest that defecation requires increased rectal pressure co-ordinated with relaxation of the anal sphincters and pelvic floor muscles. Pelvic floor relaxation allows opening of the anorectal angle and perineal descent, facilitating faecal expulsion. During defecation puborectalis activity is as a rule inhibited, but was unchanged in 9 % and increased in 25 % of healthy subjects (76). Thus, while "paradoxical" puborectalis contraction during defecation is used to diagnose pelvic floor dyssynergia in patients with typical symptoms, this finding may be a variation of the normal. Same considerations regarding the lack of controlled studies, technical standards, etc. apply as stated above for kinesiological EMG in studies of LUT function.

2.1.2. Pudendal Nerve Conduction Tests

Measurement of motor conduction velocity is routinely used to evaluate limb nerves, distinguishing between a demyelinating and axonal neuropathy. To make the measurement requires access to the nerve at two well-separated points and measurement of the distance between them, a requirement that cannot be met in the pelvis. Another way to evaluate peripheral motor nerve function is the measurement of the latency of a muscle response, requiring only a single stimulation site. The muscle response is the compound muscle action potential (CMAP) or M-wave. Because in limb nerves the site of stimulation to obtain only the motor latency (without measuring the actual conduction velocity) is as a rule placed distally on the nerve, it is also called the distal (or terminal) latency. For the pudendal nerve the site of stimulation may be more or less "distally", but the term distal or terminal has – in accordance with general clinical neurophysiology – become generally used. Distal motor latency can be measured by recording with a concentric needle electrode from

the bulbocavernosus, the EAS and the EUS muscles in response to bipolar surface stimulation placed in the perianal/perineal region, or with needle electrode stimulation of the pudendal nerve in the perineum. The most widely employed technique to obtain pudendal nerve terminal motor latency (PNTML) relies on stimulation with a special surface electrode assembly fixed on a gloved index finger, known as the St Mark's stimulator (77). It consists of a bipolar stimulating electrode on the tip of the gloved finger with the recording electrode pair placed proximally on the base of the finger. The finger is inserted into the rectum or vagina and stimulation is applied close to the ischial spine. It is assumed that, using this approach, the pudendal nerve is stimulated close to the ischial spine, and that the response recorded is of the EAS muscle. In women, intravaginal stimulation and recording from the bulbocavernosus muscles has also been undertaken, with similar distal latencies (78). However, the latency of such a response is typically only around 2 msec, which seems unusually short compared with the perineal technique and with conduction in the much thicker motor fibers of peripheral nerves in the limbs. It seems unlikely that the PNTML using the St. Mark's electrode really evaluates conduction along the last 8 cm of the pudendal nerve. Stimulation of the terminal pudendal branches or pelvic floor muscles near their motor points seems more likely, and this is supported by the much longer PNTML (3.7 ± 0.9 msec) obtained with a monopolar intrarectal stimulation electrode (79). If a catheter-mounted electrode is used for recording, EMG responses from the striated muscle of the urethral sphincter can be obtained. Experts differ in their estimation of validity of this test. A prospective evaluation of anorectal physiologic tests in 90 patients with faecal incontinence did not find that PNTML results changed treatment decisions (80). Indeed, the American Gastroenterological Association statement indicated that "PNTML cannot be recommended for evaluation of patients with fecal incontinence (81).

2.1.3. Anterior Sacral Root (Cauda Equina) Stimulation

Anterior root stimulation has been used to study conduction of the sacral nerve roots. Electrical stimulation with needle electrodes at vertebral laminae Th12-LI elicits M-waves in the bulbocavernosus and EAS muscle (82). Transcutaneous stimulation of deeply situated nervous tissue became possible with development of special electrical and magnetic stimulators. When applied over the spine, these stimulators activate the roots as they exit the vertebral canal. Needle EMG rather than non-selective surface electrodes should be used to record pelvic floor and particularly sphincter responses to electrical or magnetic stimulation of the cauda equina. These stimuli non-selectively depolarise underlying neural structures, thereby activating several muscles innervated by lumbosacral segments (83). Lumbosacral stimulation often evokes a large stimulus artifact that can be decreased by positioning the ground electrode between the stimulating and recording electrodes (84). Invasive percutaneous stimulation of individual roots in sacral foramina is used to identify patients with lower urinary and anorectal dysfunction who are likely to benefit from long-term stimulation, e.g., with the Interstim (Medtronic, Inc., Minneapolis, USA). Electrical stimulation of nerve roots at the level of the appropriate sacral foramina results in observable muscle contraction in the foot and perineum. These responses can be identified as MEP or reflex responses on the basis of their latency. Selective stimulation of individual sacral roots is possible by appropriate positioning of surface stimulating electrodes (85).

In conclusion, demonstrating the presence of a perineal MEP on stimulation over lumbosacral spine may occasionally be helpful in patients without voluntarily activated muscles. It also identifies the particular nerve root before introducing therapeutic electrical stimulation. However, the clinical value of the test has yet to be established and there are no sensitivity and specificity data on test results in individual patients.

2.1.4. Motor Evoked Potentials

Using magnetic or electric stimulation, it is possible to depolarise the motor cortex and record a response from the pelvic floor. Magnetic cortical stimulation is better tolerated than electrical stimulation, which has been abandoned in awake subjects, but may be useful for intraoperative monitoring.

By performing the stimulation at two different sites (brain and spinal roots), it is possible to record three different conduction times: a total conduction time, a peripheral conduction time, and a central conduction time (Figure 62). The total conduction time corresponds to the transit time from brain to target muscle. The peripheral conduction time is the transit time from sacral roots to the muscle. The central conduction time is obtained by subtracting the peripheral conduction time from the total conduction time. The total conduction time can be measured both at rest and during a facilitation procedure. MEPs from the EAS, the urethral sphincter, the bulbocavernosus muscle, and the levator ani muscle have been reported, but normative values have only been obtained (for transcranial magnetic stimulation) for the urethral sphincter and the puborectalis muscle in adult women (86). A central conduction time of 15 to 16 msec without and 13 to 14 msec with facilitation is obtained for pelvic floor and sphincter muscles (87-89). The necessity to use concentric needle EMG for recording has been reconfirmed (90).

Substantially longer central conduction times have been found in patients with multiple sclerosis and spinal cord lesions as compared to healthy controls (89-91). However, all patients in this study had clinically recognisable cord disease. Nevertheless, MEPs may be useful in patients with unclear localization of spinal lesions (89).

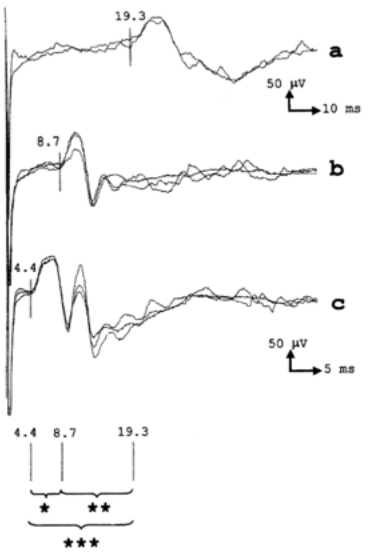

Figure 62: MEPs recorded by concentric needle in the external urethral sphincter of a 51-year-old-woman. Cortical (a), thoracic (b), and sacral (c) stimulation. Central motor conduction time (CMCT) is calculated as cortical - lumbar latency (** = 10.6 ms). Cauda equina motor conduction time is calculated as lumbar - sacral latency (* = 4.3 ms). (From (Brostrom et al., 2003a), with permission).

Conceptually, MEP may help to differentiate between involvement of motor and sensory pathways. However, the clinical utility of these measurements is not established. MEP have opened an avenue of research on excitability of motor cortex. It has been demonstrated that in comparison to the motor area for hand muscles the anal sphincter motor cortex has less intracortical inhibition (92).

2.2. Sensory System Tests

There are several methods of sensory testing for the perineum, the genitourinary and anorectal tract. Clinical testing includes perineal and external genital skin sensation for light touch and pinprick, and sensation of bladder filling during cystometry. Anorectal sensory testing can be clinically assessed through rating of applied stimuli. More objective sensory testing can be performed with quantitative sensory testing (QST), which assesses sensory perception. For evaluation of the integrity of sensory pathways sensory neurography, and somatosensory evoked potentials (SEP) can be used.

2.2.1. Sensory Measurements During Cystometry

During routine cystometry bladder sensation is assessed by recording first sensation of bladder filling, first desire to void and strong desire to void. Although not strictly a neurophysiologic test, measurement of electrical thresholds adds clinically non-obtainable information on sensory function of the lower urinary tract (93). Bladder and urethral sensory thresholds have also been measured using electrical stimulation (93), and mechanical traction on the bladder trigone (93). Electrical currents are applied to the bladder, urethra or genital skin using catheter-mounted or surface electrodes. High-frequency stimulation (> 20 Hz), with a stimulus duration of 0.5 or 1 msec is used because it is more easily perceived in the lower urinary tract. Measurement of sensory thresholds with such stimulation is reproducible, and normative data have been published (93). To date it has been used in only a few conditions (e.g., painful bladder syndrome) (94). There is no established clinical use for any of these tests other than simple reporting of sensation during cystometry.

In addition, palmar SSR and perineal surface EMG recordings can be used for more objectively demonstrating sensations during cystometry. The activity of both appears and increases in parallel with the first sensation of bladder filling, and with the first desire to void, respectively (95). Further studies using these methods are needed to establish their clinical utility.

2.2.2. Assessment of Anorectal Sensation

Rectal sensation is assessed by progressively distending a balloon manually or by a barostat while measuring thresholds for first perception, desire to defecate, and severe discomfort. The intensity of perception during rectal distension can be recorded by a visual analogue scale during phasic distensions of graded intensity (96). The rate and pattern of distension affect rectal perception and internal sphincter relaxation (97).

Anal sensation can be assessed by determining the perception threshold to an electrical stimulus or temperature change in the anal canal. Electrical testing does not activate mucosal receptors. Anal sensitivity to temperature change has been reported reduced in faecal incontinence (98).

2.2.3. Quantitative Sensory Testing

Quantitative sensory testing (QST) of the urogenitoanal system should provide more objective and reproducible data than routine clinical testing. QST sensory modalities applied to the evaluation of urogenital function include vibration (99), temperature (100), and electrical current (101). (See also Sensory Measurements During Cystometry). There is no commonly accepted, detailed, standardised test, and the specificity and sensitivity of the tests are not known. The relationship of cutaneous quantitative sensory tests to bladder and urethral sensation and function is unknown. The physiological, psychophysiological and methodological issues and controversies will not be addressed in this chapter.

2.2.4. Sensory Neurography

Nerve conduction velocities of the dorsal nerve of the penis can be calculated by placing a pair of stimulating electrodes across the glans and a pair of recording electrodes across the base of penis. A nerve action potential can be recorded with an amplitude of about 10 µV. It can also be recorded by stimulating the nerve trans-rectally or transperineally. There is no known association between penile sensory neuropathy and bladder/sphincter dysfunction.

A few studies have recorded activity in sacral roots during electrical stimulation. Intraoperatively, when the sacral roots are exposed, compound sensory action potentials on stimulation of dorsal penile and clitoral nerve may be recorded directly (102). This helps to preserve roots mediating perineal sensation in spastic children undergoing dorsal rhizotomy, and reduce the incidence of postoper-

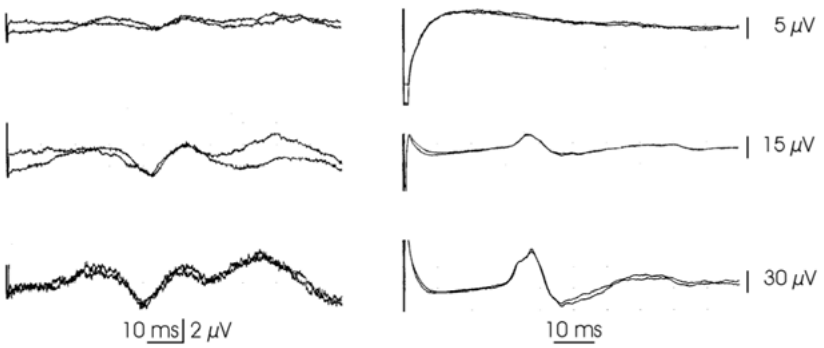

Figure 63: SEPs (traces on the left) and sacral reflexes (traces on the right) in a healthy woman. Cerebral SEPs are recorded from Cz - 2 cm; sacral reflexes from the anal sphincter. The dorsal clitoral nerve is being stimulated with rectangular electrical pulses at 2 Hz. Stimulation and recording are performed with surface electrodes. The cerebral SEP and sacral reflex are recorded simultaneously. In the upper row the stimulation is just above sensory threshold, in the middle row the stimulation is 1.5, and in the lower row at 2-times sensory threshold (pulse duration 0.2 ms; two consecutive averages of 128 responses are superimposed).

ative voiding dysfunction (103). These tests are limited to their very specific intraoperative indications.

2.2.5. Somatosensory Evoked Potentials (SEP)

Somatosensory evoked potentials are electric waveforms of biologic origin elicited by stimulation of a sensory nerve (or a sensory innervated skin area – dermatome). The most commonly performed tests in the urogenitoanal region are pudendal somatosensory evoked potentials (SEP), which assesses conduction in large fibre pathways between the site of nerve stimulation and the parietal sensory cortex. Potentials can also be measured at the spinal level (spinal SEP).

Visceral (thin) fibre pathways are assessed by recording SEPs while stimulating the proximal urethra and bladder, although this is technically not depolarization of nerves, but a mesh of afferents.

2.2.5.1. Pudendal Somatosensory Evoked Potentials

2.2.5.1.1. Cerebral Pudendal SEP

On electrical stimulation of the dorsal penile/clitoral or perineal nerve, a cerebral SEP can be recorded. (Figure 63) This SEP is as a rule of highest amplitude at the central recording site (Cz - 2 cm : Fz of the International 10-20 EEG System) and is highly reproducible. The first positive peak at about 40 ms (called P40) is usually clearly defined in healthy subjects using a stimulus 2-4 times stronger than the sensory threshold (104). The presence and amplitude of subsequent negative and positive waves are quite variable between subjects. Classically described pudendal SEP techniques stimulate both dorsal penile/clitoral nerves, thus reducing the sensitivity of the test. However, techniques of pudendal SEP that isolate each dorsal penile/clitoral nerve may be more sensitive for identifying pathology (105).

Pudendal SEPs have been advocated in patients with neurogenic bladder dysfunction, e.g. in multiple sclerosis (106). However, even in patients with multiple sclerosis and bladder symptoms, the tibial cerebral SEP was more often abnormal than the pudendal SEP. The combination of an abnormal pudendal SEP with a normal tibial SEP suggests isolated conus involvement (107). The pudendal SEP was less useful than neurological examination for identifying neurological disease in patients with uro-genital symptoms (108). Following spinal cord injury, tibial and pudendal SEPs may be of some value for predicting recovery in bladder control (109). Cerebral SEP during penile/clitoral stimulation may be useful for intraoperative monitoring. Pudendal SEP were used to study the mechanism of sacral neuromodulation (110).

2.2.5.1.2. Spinal Pudendal SEP

Stimulating the dorsal penile nerve and recording with surface electrodes at the level of the Th12-L2 vertebrae (and the S1, Th6 or iliac spine as reference) reveals the postsynaptic segmental spinal cord activity (the spinal SEP). Unfortunately, this spinal SEP may be difficult to record even in normal (particularly obese) subjects.

2.2.5.1.3. Nerve conduction velocity of dorsal nerve of penis

The dorsal nerve of the penis is involved in sexual function. The nerve conduction velocity (NCV) of the dorsal nerve of the penis is measured by dividing the distance between the stimulating and the recording electrodes by the latency to the negative peak of the action potential. With the penis stretched with a 1 lb weight, the NCV in normal men is 33 m/sec +/- 3.8 (111-113). Evidence is missing for the interest of this technique in sexual disorders.

2.2.5.1.4. Pudendal nerve terminal sensitive latency

To elicit response endorectal stimulation of the pudendal nerve is delivered just to the left then right of the ischiatic spine using an electrode (114). The sensory potential is recorded in the balanopreputial zone with ring contact electrodes wrapped around the shaft of the penis. From 5 to 40 responses are averaged to obtain the sensory potential. Mean latency value plus or minus standard deviation is 5.35+/-0.97 milliseconds. This method allows comparative study of the right and left terminal sensory branches of the pudendal nerve and may be helpful in the diagnosis of different perineal disorders, such as sexual dysfunction, perineal pain and fecal incontinence, but further experience is necessary.

2.3. Sacral Reflexes

Clinically, two reflexes are commonly elicited in the lower sacral segments: (1) the penilo- or clitoro-cavernosus (i.e. bulbocavernosus) reflex; and (2) the anal reflex (115). To elicit sacral reflexes, electrical (116-123), mechanical (120, 121, 124), or magnetic stimulation (125) can be used. Whereas the latter two modalities have only been applied to the penis (122-124), clitoris, electrical stimuli can be applied to various sites: to the dorsal penile or clitoral nerve; perianally; and, using a catheter-mounted ring electrode, to the bladder neck/proximal urethra (126).

2.3.1. Sacral Reflex on Electrical Stimulation

Electrical stimulation of the dorsal penile or clitoral nerve elicits (somato-somatic) sacral reflexes in perineal muscles with a typical latency approx. 33 ms (29.9 ± 5.7 msec in one study in men (122)), traditionally called the bulbocavernosus reflex (Figure 63). In addition to single-pulse electrical stimulation, two identical electrical pulses separated by a 3-msec interval can be used (i.e., double-pulse electrical stimulation) (122, 123). Double-pulse electrical stimulation is more efficient in eliciting sacral reflexes (122). Stimulation of the perianal skin, bladder neck or proximal urethra elicits sacral reflexes with latencies above 50 ms. This latency is longer compared to responses conveyed by the pudendal nerve, suggesting that the afferent limb for these responses involves visceral afferent fibres accompanying the pelvic nerves, which are thinly myelinated and have a slower conduction velocity than the thicker pudendal afferents. With visceral denervation (e.g., following radical hysterectomy) the viscerosomatic reflexes (from both bladder and urethral stimulation) may be lost while the bulbocavernosus (penilo-/clitoro-cavernosus) reflex is preserved. Loss of bladder-urethral reflex with preservation of bladder-anal reflex has been described with urethral afferent injury after recurrent urethral surgeries (127).

The longer latency anal reflex (the contraction of the EAS on stimulation of the perianal region) is quite variable thus limiting its usefulness as a diagnostic tool.

On perianal stimulation, a short latency response can also be recorded, as a result of depolarisation of motor branches to the EAS, possibly involving antidromic travelling of the depolarisation, with “returning” of the depolarisation orthodromically to the sphincter at a branching point of the motor axon.

EMG recording of the sacral reflex has been shown to be more reliable than the clinically assessed response (e.g. observing and palpating the contraction) in males and particularly in females (128). In men, value of 40, 36 and 36 msec have been suggested as the upper limit of normal for the shortest latency obtained on eliciting a series of reflex responses using single, double and mechanical stimulation, respectively (122). In men with cauda equina lesions penilo-cavernosus reflex could not be elicited in 64%, 47% and 47% of patients on single electrical, double electrical, and me-

chanical stimulation, respectively. Measurement of the reflex latency increased the sensitivity to record abnormalities for 17%, 36%, and 34%, respectively. Furthermore, it has been shown that sacral reflex measurement increase sensitivity of quantitative EMG of the EAS muscles from 73% to 81-83% using the different stimulation techniques mentioned (123).

Sacral reflex testing has been studied extensively and is used in many laboratories in everyday practice to demonstrate objectively the integrity of the S2-S4 reflex arc. The sacral reflex evoked on dorsal penile or clitoral nerve stimulation (the bulbocavernosus or penilo-/clitoro-cavernosus reflex) was shown to be a complex response, often forming two components. The first component with a typical latency of about 33 ms, is the response that has been most often called the bulbocavernosus reflex. It is stable, does not habituate, and has other attributes of an oligosynaptic reflex response (117). The second component has latency similar to the sacral reflexes evoked by stimulation perianally or from the proximal urethra and is not always demonstrable as a discreet response. In those subjects in whom the first reflex component is difficult to elicit, stimulation strength should be increased, but preferably double electrical stimuli should be used. A complete reflex arc lesion should not be inferred by absence of a response if only single pulse is used for stimulation. During voiding sacral reflexes are un-elicitable but in presence of spinal cord lesions such as myelodysplasia this normal suppression is lost.

Sacral reflex responses recorded with needle or wire electrodes can be analysed separately for each side from the EAS or bulbocavernosus muscle. Using unilateral dorsal penile nerve blocks, the existence of two unilateral BCR arcs has been demonstrated. Thus, by detection from the left and right bulbocavernosus (and also the EAS) muscles separate testing of right and left reflex arcs can be performed. Some authors reported that sensitivity of the test can be increased by use of the inter-side latency difference (normative limits: < 3 ms), but finding could not be confirmed by others (normative limits: < 7.2 ms) (122). In cases of unilateral (sacral plexopathy, pudendal neuropathy) or asymmetrical lesions (cauda equina), a healthy reflex arc may obscure a pathological one on clinical elicitation, but not on neurophysiologic measurements of the sacral reflexes.

As described above, penilo-cavernosus reflexes were absent in 47-64%, and delayed in additional 17-19% of patients with conus/cauda lesions. Of these patients 47% were incontinent for urine and 47% for faeces. However, a reflex with a normal latency does not exclude the possibility of an axonal lesion in its reflex arc, as demonstrated by pathologic quantitative EMG of the EAS in 79-86% of patients with conus/cauda lesions (123). Furthermore, much delayed sacral reflex responses are compatible with normal bladder and sexual function as found in patients with hereditary motor and sensory demyelinating neuropathy. In a proportion of women with non-neurogenic sacral dysfunction clitoro-cavernosus reflex latencies were found to be much longer compared to those obtained in women with intact sacral function (129). Sacral reflex recording is suggested as a complementary test to CNEMG examination of pelvic floor muscles in patients with suspected peripheral nervous lesions (4).

In addition to latency, a number of other parameters can also be measured using electrical, but not mechanical stimulation. These are the sensory threshold (i.e., the stimulus strength (mA) at which subjects feels stimulation), and reflex threshold (i.e., the stimulus strength (mA) at which the reproducible penilo/clitoro-cavernosus reflex appears on the screen). They evaluate lower sacral sensory pathways, and excitation level of the sacral reflex pathway, respectively. Although for men normative data for these parameters is available (122), their utility in clinical situation remains unclear. Continuous intraoperative recording of sacral reflex responses on penis/clitoris stimulation is feasible if double pulses or a train of stimuli are used (130).

2.3.2. Sacral Reflex on Mechanical Stimulation

Mechanical stimulation has been used to elicit BCR in both sexes and found to be a robust technique. Either a standard reflex hammer or a customised electromechanical hammer can be used. Using a reflex hammer, the stimulus is applied to a wooden spatula placed on the glans penis or clitoris (122, 123). Such stimulation is painless and can be used in children (124). The latency of the BCR elicited mechanically is comparable to the electrically elicited reflex in the same patients but depends on the electromechanical device used (122, 124).

2.3.3. Sacral Reflex as Assessment of Sacral Spinal Excitability

It is possible to analyze and quantify sacral spinal excitability through bulbocavernosus reflex (BCR) stimulus-response curves (131). Variations in the slope of the stimulus- response curve can be considered as an indicator of the modulation of sacral spinal excitability. This response is amplified during bladder filling as well as in patients with UMN in comparison with a control group. Thus, BCR, through stimulus-response curves, might be an indicator of pelvic-perineal exaggerated reflex response and possibly a tool for evaluating treatment effectiveness.

2.4. Autonomical Function Tests

Most uro-neurophysiological methods discussed so far assess myelinated fibres, but not the autonomic nervous system, especially the parasympathetic component, which is most relevant for pelvic organ functions. Methods for evaluating the autonomic nerves innervating the pelvic viscera are not available. Cystometry indirectly evaluates the parasympathetic innervation to the bladder. However, from a clinical neurophysiological point of view direct electrophysiological testing would be desirable.

2.4.1. Tests in Generalised Autonomic Neuropathy

Cardiovascular autonomic function tests are useful for identifying generalised autonomic dysfunction in patients with bladder or gastrointestinal motility disturbances.

In cases when a general involvement of thin fibres is expected, an indirect way to examine autonomic fibres is to assess thin sensory fibre function. Thin visceral sensory fibres are tested by stimulating the proximal urethra or bladder, and by recording sacral reflex responses or cerebral SEP.

2.4.2. Dartos Reflex

In men, another approach to test lumbosacral sympathetic function is by neurophysiologic measurement of the dartos reflex obtained by electrical cutaneous stimulation of the thigh. The dartos muscle is a sympathetically innervated dermal layer within the scrotum, distinct from the somatically innervated cremasteric muscle. A reliable and reproducible dartos reflex (i.e., scrotal skin contraction) with a latency of about 5 seconds has been demonstrated in healthy men (132).

Technical problems have so far limited smooth muscle electromyography of the detrusor muscle, and of genital smooth muscle. Recently, successful intrinsic (smooth muscle) anal sphincter muscle EMG recordings on electric autonomic nerve stimulations were re-

ported to spare the autonomic nerve supply during surgery in pigs (133).

2.4.3. Sympathetic Skin Response (SSR)

The sympathetic nervous system mediates sweat gland activity in the skin. Changes in sweat gland activity lead to changes in skin resistance. On noxious stimulation (such as a sudden noise, electrical pulse, etc.) a potential shift can be recorded with surface electrodes from the skin of the palms and the soles and has been reported to be a useful parameter in assessment of neuropathy involving non-myelinated nerve fibres. The response, known as the SSR, can also be recorded from perineal skin and the penis. Similarly, the SSR can be recorded from the genital region in women. The SSR is a reflex, which consists of myelinated sensory fibres, a complex central integrative mechanism and a sympathetic efferent limb with postganglionic nonmyelinated C fibres. SSR is the only electrophysiological method directly testing sympathetic fibres; recording from the perineal region assesses sympathetic nerve function of thoracolumbar segments. Limited literature exists regarding the relationship between SSR results and bladder dysfunction. A correlation has been shown between the absence of the SSR response in the foot and bladder neck dyssynergia following spinal cord injury (134). Only complete absence of response can be regarded as abnormal. Its utility in evaluating bladder and urethral dysfunction is not established.

2.4.4. Cremasteric Reflexes

Electromyography of the cremasteric muscle is recorded using disposable needle electrodes (135). Cremasteric muscle reflex is obtained with tactile and/or electrical stimulation of the inner thigh. In theory, sacrolumbar intersegmental reflex circuit and cremasteric muscle activity are useful for evaluating ejaculatory dysfunction but there is a lack of evidence in literature.

3. EVIDENCE BASED USE OF CLINICAL NEUROPHYSIOLOGICAL TESTS

Evidence-based medicine is founded on the assessment of evidence for and against the efficacy of particular types of therapeutic intervention. Clinical neurophysiology testing should thus demonstrate evidence that testing improves outcome (through treatment choice and patient selection). However, testing and therapeutic intervention are different concepts, and neurophysiological testing has another important objective. It is to generate knowledge about the situation to be treated in a given patient, so that the practitioner can formulate rational treatment options based on knowledge rather than do so blindfold; that is, he or she can practice “knowledge-based medicine”.

To judge the importance of this second objective different criteria are needed. Particularly in the referral setting, the physician is confronted with complicated cases in which the underlying pathophysiology is quite uncertain, and what is required is to identify all the factors that may be contributing. Neurophysiology is helpful in assessment of neurogenic dysfunction because it contributes to “knowledge-based medicine”, whether or not there is narrowly defined “evidence” that it improves outcomes.

Of course, it remains true that we should seek evidence of the conventional kind for and against testing. Any test should be subjected to three questions:

1. Does the test have good technical performance?
2. Does the test have good diagnostic performance, ideally against a “gold standard” measure?
3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

Clinical diagnosis requires that measures obtained in individual patients be compared to population norms with the intent of determining whether they are “normal” or “abnormal”. Data can be classified as “abnormal” only with the understanding that they are compared to a sample from the normal population. Predictive statements are made possible by the use of tolerance limits. For most clinical neurophysiological tests, one-tailed tolerance limits are recommended. For any given limit of normality, there is a certain probability of falsely interpreting values (obtaining false-positives or false-negatives). Further confounding these issues is the practice of applying multiple criteria of abnormality. But ultimately, the adequacy of any given normal limit in discriminating between normal and abnormal must be supported by appropriate clinical or clinico-pathological correlations; for uroneurophysiological techniques, such data are scarce.

3.1. Usefulness of Clinical Neurophysiological Tests in Evaluation of Individual Patients

Whenever pathophysiology is uncertain or unpredictable, and especially if irreversible treatment is necessary or contemplated, it seems logical to gather quantitative knowledge of the dysfunction in order to make a rational treatment choice. In most patient groups with neurogenic incontinence, the pathophysiology is unpredictable and comprehensive urodynamic evaluation is essential in order to practice knowledge-based medicine. In selected patients from these groups, clinical neurophysiological testing will clarify issues related to the neural control of lower urinary tract, relevant for understanding pathophysiology (136).

As is generally true for electrophysiological tests, uroneurophysiological examinations are particularly useful for substantiating the clinical diagnosis of a peripheral nerve lesion. The potential usefulness of testing in an individual patient needs to be analysed in the overall clinical setting. The indications for testing are guided primarily by expert opinion, not on definitely established criteria derived from controlled studies.

In the incontinent patient without other signs or symptoms of a neurologic condition, as in most patients with stress/urge, or mixed urinary incontinence electrophysiological testing is as a rule non-contributory (62). Neurophysiological methods may have other uses, as for instance using the EMG signal for correct needle positioning for infiltration of sphincter muscle with botulinum toxin (137), or using tests for intraoperative identification and monitoring of nerves and muscles (132).

3.2. Usefulness of Clinical Neurophysiological Tests in Research

As understanding pathophysiology of neural control of lower urinary tract is essential in the application of more sophisticated therapeutic methods, such as electrical stimulation techniques (138, 139), there is a continuing place for clinical neurophysiology in research on neurogenic urinary and anorectal dysfunction and their therapy. There is ongoing research on already described techniques to validate their usefulness in diagnostics (140), and in intraoperative monitoring (141).

4. CONSENSUS STATEMENT

4.1. Recommendation for Clinical Neurophysiological Testing
The information gained by clinical examination and urodynamic testing may be enhanced by uroneurophysiological tests in selected patient groups with suspected neurogenic urinary incontinence with lesions within the nervous reflex arcs of sacral segments 2 – 5. Concentric needle EMG to diagnose denervation and reinnervation of pelvic floor and perineal muscles, and sacral reflex testing to assess the continuity of the sacral reflex arc, are the recommended tests.

Level of evidence: 2b

Level of recommendation: B

Clinical neurophysiological testing should be performed in accredited laboratories, by trained and certified staff, with formal control of the quality of the results. Ideally, the uroneurophysiologist should be in liaison with general clinical neurophysiologists.

It seems optimal to create interdisciplinary teams between urology, urogynecology, proctology, and neurology departments.

4.2. Recommendation for Technical Standards
Even in the more widely used "general" clinical neurophysiology there is no universal standardisation of tests. This is mainly due to different historical backgrounds of testing developed in different countries. The need to standardise methods is, however, recognised.

Proposals for standardisation for external anal sphincter CNEMG (4) and the bulbocavernosus (penilo/clitoro-cavernosus) reflex (122) have been made, and seem to be widely adopted.

Level of evidence: 2b

Level of recommendation: B

4.3. Future Research Areas
Clinical neurophysiological methods should be further explored and used to better define the neural control in lower urinary tract function, demonstrating both the nervous system's "hardware" (integrity of anatomy) (142) as well as "software" (level of activity, excitation thresholds) for co-ordinated urinary storage and voiding, in physiological and in pathological conditions (143).

There is as yet no standardization of the technical aspects of (kinesiological) EMG within urodynamic (and anorectal) function testing. Furthermore, more research is needed to shed light on the relationship between the EMG signals, pelvic floor muscle function, and overall LUT (anorectal) function (75).

There are also challenges to validate the use of the described techniques for intraoperative identification of structures and monitoring nervous function (144), to define neurophysiological changes induced by therapeutic electrostimulation, and to develop tests to assess directly the sacral parasympathetic system.

VI. OTHER INVESTIGATIONS

1. URINALYSIS

"Urinalysis is a fundamental test that should be performed in all urological patients" (1). In patients with urinary incontinence, urinalysis is not a diagnostic test for the condition, but it is rather used to screen for haematuria, glucosuria, pyuria and bacteriuria and rule out other diagnoses. Even in the absence of controlled studies, there is general expert consensus that the benefits of urinalysis clearly outweigh the costs involved (2). A positive urinalysis will prompt infection treatment and/or the use of additional tests such as endoscopy and urinary tract imaging. In the evaluation of urinary incontinence in the female, urinalysis is recommended since 60% of women develop urgency symptoms at the time of urinary tract infection (UTI). Pyuria was found to be common among incontinent but otherwise asymptomatic, female patients. Pyuria was not necessarily associated with UTI, the significance of sterile pyuria in the elderly population is still unclear (3).

A Norwegian survey of general practitioners' management of female urinary incontinence suggested that urinalysis is the most frequently performed test (73%) and is far more frequent than gynaecological examination (54%) (4). Another survey suggested that urinalysis is one of the three-part assessment of UI together with patient history and physical examination (5).The same apply, according to Stricker, for patient selection for collagen implant (6). A minority of the reviewed papers suggested that urine culture should be carried out together with urinalysis (3, 7). Urinalysis is also considered of importance in the evaluation of nursing home residents who are incontinent (8), in peri- and postmenopausal women (9), in older women reporting urinary incontinence (10). Belmin et al, suggested than significant urine samples can even be obtained from disposable pads in elderly incontinent women (11, 12). It is recommended that geriatric incontinent patients undergo history, physical examination, tests of lower urinary tract function and urinalysis. The latter test is proposed to rule out the presence of UTI (12). The clinical relevance of asymptomatic bacteriuria in the elderly is controversial. Although DuBeau and Resnick suggest the use of urinalysis in the diagnostic algorithm to identify asymptomatic bacteriuria in incontinent residents of nursing homes (13), others consider that the condition does not require any treatment (11). Urinalysis is less sensitive and specific for urinary tract infection in women who have had radiotherapy but the combination of leucocyte esterase and nitrates still has a positive predictive value of 95% (14). Urinalysis in patients with stents and patients on haemodialysis has not been found to be an effective screening test and routine culture is recommended(15, 16).

1.1. Consensus Statement
- It is considered standard practice to perform a urinalysis either by using a dipstick test or examining the spun sediment. (Level of Evidence 3, Grade of Recommendation C)
- If a dipstick test is used, it is recommended chosing of a "multiproperty" strip that includes testing for haematuria, proteinuria, glucose and ketones, leukocytes esterase (indicating the presence of leukocytes in the urine) and nitrite tests (suggesting bacteriuria). (Level of Evidence 3, Grade of Recommendation C)

1.2. Future Research Areas
- Needed to screen analysis of urinalysis in the diagnosis and treatment of UI, MUI and SUI

- Testing bedside point of testing against urinalysis and culture for the diagnosis of urinary tract infection

2. BLOOD TESTS

The prevalence of renal damage or of biochemical abnormalities in the general population of patients with urinary incontinence is very low, but there are subgroups of patients where the prevalence can be higher (e.g., neurogenic incontinence, overflow incontinence). The routine use of a battery of common chemical and/or haematological tests in patients with UI appears to be a prudent rule of good clinical practice in the following situations:

- chronic retention with incontinence
- neurogenic LUT dysfunction
- when surgery is contemplated
- when there is a clinical suspicion
- sodium plasma concentration may be reduced in patients on desmopressin.
- Confirmation of urinary tract infection

Special tests such as measurement of anti-diuretic hormone (ADH) and atrial natriuretic polypeptide have proven useful in research of enuresis in childhood and nocturia in the elderly (17, 18). Changes in the circadian rhythm of these, and probably also other hormones regulating the renal excretion of water, will in the future contribute to a better understanding of pathophysiology. Synthetic ADH analogues have already come into clinical use for the treatment of nocturnal enuresis. However, the clinical value of these specific tests remains to be established.

Serum procalcitonin is a peptide that undergoes proteolysis into calcitonin. It is an acute phase reactant, which rises quickly and reliably in patients with severe bacterial infections. As such, it may serve as a potentially sensitive and specific marker for identification of bacterial illness, particularly in elderly patients (19) and serves in decision support for antibiotic initiation or cessation (20-22).

3. TISSUE ANALYSIS

Pelvic floor-supporting tissues are composed mainly of connective tissue in which fibrous elements such as collagen and elastic fibres and visco-elastic matrix based on proteoglycans are the predominant components of the socalled extracellular matrix. Extracellular matrix is a complex network of numerous macromolecules that fulfill a large number of mechanical, chemical and biological functions (23). While collagens and elastin fibres confer strength and elasticity to tissues, respectively, structural proteoglycans allow tissue cohesiveness. Specifically, collagen is the most prevalent component, with type I fibres usually well organised and associated with ligamentous tissue, while type III collagen is more common in the loose areolar tissue, which makes up the vaginal wall adventitia and surrounds the pelvic organs (24). According to the molecular weight, indeed, proteoglycans are distinguished into large molecules (aggrecan, versican and perlecan) and small molecules, such as decorin, fibromodulin, biglycan, lumican and chondroadherin (25).

The organised structure of the matrix is due to a clear balance between the production of the different constituents and their breakdown. There are many proteolytic enzymes capable of degrading the elements of the extracellular matrix, falling into into three groups: the serine proteases, the cysteine proteases, and matrix metalloproteinases (MMPs) (26).

Several authors evaluated the expression of the different proteins as well as of their precursors and fragments of degradation. With regards to the metabolism of collagen, some studies seem to indicate that women with SUI have a reduced total collagen content in the skin and urogenital tissue (27-29), while other studies reported higher total collagen concentration and higher levels of mRNAs for type I and type III collagen in paraurethral connective tissue (30). Chen et al., evaluating cultures of fibroblasts taken from endopelvic fascia and skin biopsies in 14 patients with stress urinary incontinence and 12 controls, showed that the overall collagen synthesis and the ratio of type III and type I fibres were not significantly different between fibroblasts obtained from women with or without SUI (31) indicating that alteration in the collagen synthesis might not be involved in SUI.

On the other hand, a few studies reported change in the relative percentages of the different fibres, with a decrease in type I and increase in type III ones (32, 33). In women with SUI, Skorupski et al. evaluated the transcription factor Sp1-binding site in the gene encoding a-1 chain of type I collagen, andsuggested that the observed G-T polymorphism is a risk factor for incontinence (34). Again, at the molecular level, some studies evaluated the cycle regulatory proteins in patients with pelvic organ prolapse, showing controversial results. Some papers reported reduced expression of proteins such as p53 and p21 which normally cause cycle G1 arrest suggesting an increase in proliferation capacities for fibroblasts derived from human cardinal ligaments of patients with prolapse (24).

Other authors evaluated markers of collagen degradation. Specifically, Edwall et al. evaluated markers of collagen synthesis and breakdown such as the carboxy-terminal propeptide of type I procollagen (PICP), the carboxy-terminal telopeptide of type I collagen (ICTP), and the amino-terminal propeptide of procollagen III (PIIINP) in urogenital tissue homogenates and peripheral serum from 71 patients with SUI and 31 healthy control women (35). After adjusting for age, BMI, parity, and hormonal status, the patients with SUI had significantly lower serum concentrations of PICP and significantly lower tissue concentrations of PIIINP and ICTP than the controls, suggesting reducing breakdown in the presence of unchanged synthesis of type I collagen and, regarding type III collagen, a potential reduction in either synthesis or breakdown, the second being considered more probable (35). These data may lead to the hypothesis that SUI might be associated with impaired degradation of collagen, leading to reduced turnover and accumulation of aging collagen, negatively affecting the strength and elasticity of urogenital tissue. Further studies on transforming growth factor-β (TGF-β) identified the molecular basis of such mechanism, suggesting that overexpression of TGF-β might trigger the accumulation of aging collagen, inhibiting the expression of collagenases and increasing the production of the tissue inhibitor metalloproteinase (36-38). Moreover, some genes, such as those of the Homebox A (HOXA) family, encoding transcription factors that regulate mammalian embryonic growth and development of the urogenital tract, have been shown to be underexpressed in patients with pelvic organ prolapse, suggesting a further molecular basis for the alterations in collagens (39).

Some other studies investigated the role of proteinases that may degrade elements of the extracellular matrix. Chen et al., evaluating full-thickness peri-urethral vaginal wall tissues from patients with SUI or prolapsed and matched control women, found significant decrease in mRNA and protein expressions of alpha-1 antit-

rypsin (ATT), a neutrophil elastase inhibitor in tissues from affected women, while no difference was found in neutrophil elastase and cathepsin K expressions (40). Similarly, Gabriel et al. studied the expression of different MMPs in 17 women with prolapse and 18 control, identifying higher expression of MMP2 in patients with prolapse (41). These studies allowed to hypothesize that altered catabolism of some components of the extracellular matrix might contribute to the connective tissue alterations observed in pelvic floor dysfunction.

Other studies were focused on the expression of small proteoglycans. Wen et al. studied mRNA and protein levels of biglycan, decorin, and fibromodulin in vaginal wall tissue from women with SUI and menstrual-cycle matched continent women (23). Specifically, the authors demonstrated that the mRNA expression of fibromodulin was significantly lower in patients in the proliferative phase compared to controls, while decorin mRNA expression was higher both in the proliferative and secretory phases in the patients with SUI, supporting the hypothesis that the expression of such small proteoglycans was hormonally modulated and may contribute to the altered pelvic floor connective tissues of women with SUI (23).

Oestrogens interact with specific receptors which, when activated by the ligand, have conformational change, dimerisation and recruitment of co-factors, once translocated into the nucleus, these promote the expression of region of oestrogen-responsive genes, called the oestrogen response elements, leading to the synthesis of proteins (42). Selective modulators of oestrogen receptors modulate the activity of the receptors, working as agonists, partial agonists, or antagonists in a tissue-dependent manner (43). Studies on these molecules supported a new role of oestrogens in SUI and pelvic organ prolapse. Specifically, in a randomised controlled trial testing one of these molecules (levormeloxifene) as osteoporosis treatment, a 3.4-fold increase in the reporting of POP and an almost 5-fold increase in the reporting of UI have been observed (44). To explain such effect, the expression of more than 500 proteins have been studied in the rat model, showing that oestradiol induced the expression of metalloproteinase 7 and 14, reduced the expression of their inhibitors such as TIMP-3, while selective modulators of oestrogens receptors such as raloxifene had minimal effects on metalloproteinase 7, and maintained or restored expression of the mRNA for tissue inhibitor of metalloproteinases-3 (TIMP-3) and other components of the extracellular matrix, such as glypican, and biglycan (42). Although the role of selective oestrogen-receptor modulators (SERMs) in the expression of the component of extracellular matrix has to be further clarified, these findings support the hypothesis that the increased occurrence of urinary incontinence and pelvic organ prolapse observed with oestrogen therapy and SERMs such as levormeloxifene may be related to changes in expression of genes regulating collagen turnover that ultimately weaken the normal structural integrity and support for the genitourinary system (42).

Recent research has focused on the role of urinary biomarkers and the microbiome in the investigation and treatment of urinary incontinence. The idea behind this is that the identification of specific biomarkers may be useful to phenotype patients and select more effective target therapies (45). Urinary nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and adenosine triphosphate (ATP) are increased in many overactive bladder (OAB) patients (45). Urinary NGF has also been suggested as a surrogate marker of detrusor detrusor overactivity (DO) (46). There are numerous genes that are associated with urinary incontinence and pelvic organ prolapse (47). These genes are involved in collagen metabolism, protein–lipid complex remodeling, and extracellular matrix organization. A recent review of the literature (48) highlighted the following: 4 genes were found to be associated with overactive bladder and urge urinary incontinence: adrenergic receptor β3, Rho guanine nucleotide exchange factor 10, Rho-associated coiled-coil containing protein kinase 2, and potassium two pore domain channel subfamily K member-1. Genetic variations in the human β3-adrenoceptor (*β3-AR*) gene may be associated with impaired detrusor relaxation, leading to OAB/DO (20). 13 genes were found to be associated with stress Urinary incontinence (SUI): skin-derived antileukoproteinase, collagen type XVII alpha 1 chain, plakophilin 1, keratin 16, decorin, biglycan, protein bicaudal D homolog 2, growth factor receptor-bound protein 2, signal transducer and activator of transcription 3, apolipoprotein E, Golgi SNAP receptor complex member 1, fibromodulin, and glucocerebrosidase. Seven genes were identified in association with pelvic organ prolapse: homeobox A13, matrix metallopeptidase 9, estrogen receptor 2, collagen type XIV alpha 1 chain, collagen type V alpha 1 chain, collagen type IV alpha 2 chain, and catenin beta 1. Whole genome studies are needed in order to elucidate this further.

Contrary to previous belief, the urinary tract is not sterile. An imbalance in the urinary microbiome may contribute to the development of urinary tract symptoms (48). Growing knowledge and insight into the urinary microbiome may provide understanding of different conditions and optimize their management. Urinary microbiota seems to be related to OAB symptoms, in particular urgency urinary incontinence (45). In women with urge urinary incontinence the microbiome was composed of increased Gardnerella and decreased Lactobacillus, which may have implications for prevention measures (49). This is a growing research area.

3.1. Consensus Statement

To date, tissue analyses are not part of the everyday clinical practice.

3.2. Future Research Areas

- The relationship between tissue composition, genetic composition, the urinary microbiome and risk of UI and POP.
- The relationship between tissue composition, genetic composition, the urinary microbiome and treatment outcome in patients with UI and POP.

VII. CONCLUSIONS

Clinical research involving diagnostic accuracy and clinical benefit of imaging studies and other diagnostic tests is particularly difficult. Recommendation of a diagnostic test is based upon the evidence that the outcome of it provides valuable information for patient management and this often involves evaluating the outcome of surgery. Implementation of good clinical research in this area remains difficult and sometimes lacks adequate founding. We acknowledge that only a few of the imaging techniques and other investigations we reviewed in the current chapter have been properly evaluated with respect to reproducibility, specificity, sensitivity and predictive value in connection with the diagnosis and management of urinary incontinence. Nevertheless, we acknowledge the great amount of work performed in the last four years and the continuous advancement in this field. The use of imaging and other investigations, described in this chapter, remains mostly based on expert opinion, common sense, availability and local expertise, rather than on evidence based clinical research. The diagnostic tests we considered can be subdivided into safety tests, tests with specific and selected indications, investigational tests.

Safety tests - Intended to protect patients' health, they are indicated in all patients complaining of urinary incontinence. They include urinalysis and measurement of post-void residual urine. While a consensus is easily achieved for urinalysis, the clinical benefit and cost-effectiveness of PVR measurement in the primary evaluation of urinary incontinence needs to be confirmed in prospective studies.

Tests with specific and selected indications. Upper urinary tract imaging (as well as renal function assessment) may be indicated in cases of neurogenic urinary incontinence with risk of renal damage, chronic retention with incontinence, incontinence associated with severe genitourinary prolapse and suspicion of extraurethral incontinence. No other imaging technique is recommended in the primary evaluation of uncomplicated urinary incontinence and/or pelvic organ prolapse. Cystourethrography remains a reasonable option only in the preoperative evaluation of complicated and/or recurrent cases. Video urodynamics, is the gold standard in the evaluation of neurogenic incontinence, particularly in the paediatric population, although the clinical benefit of it remains unclear. In female urinary incontinence videourodynamics is not recommended except under specific complex circumstances. MRI remains the gold standard for the diagnosis of urethral diverticula although ultrasonography is a good alternative option. Lumbosacral spine X-rays have specific indications in children with suspect neurogenic incontinence without gluteo-sacral stigmata. Imaging of the CNS should be considered when a neurological disorder is suspected on the basis of clinical, imaging and neurophysiological findings. Urethrocystoscopy is indicated in cases of incontinence with microscopic haematuria, in the evaluation of recurrent or iatrogenic cases, in the evaluation of vesico-vaginal fistula and extra-urethral urinary incontinence.

Endoanal ultrasound and endocoil MRI are the gold standard for the evaluation of anal sphincter disorders, dynamic X-ray imaging remains the standard for evaluating rectal prolapse.

Investigational tests Pelvic floor ultrasound is widely used as an adjunct to physical examination in patients with urinary incontinence and/or pelvic organ prolapse. Although the technique is rapidly evolving and much progress has been made in clinical research in this field, ultrasonography remains optional as evidence of its clinical benefit is not there yet.

MRI of the pelvic floor is rapidly gaining popularity in the evaluation of enteroceles and in the morphological analysis of pelvic floor muscles although evidence of its clinical benefit is still lacking. Both ultrasonography and MRI are the most rapidly evolving techniques and hold promises for potential future clinical applications.

Research in this area is also performed to improve our understanding of the pathophysiology of continence disorders and POP. Functional neuroimaging continues to provide new insight regarding functional anatomy of CNS related to vesicourethral function and dysfunction. The content of the draft reflects the composition of the Committee is made up of clinicians with a particular interest in a specific area of imaging and neurophysiology. The chapter certainly reveals the enthusiasm the authors poured in clinical research into this area, but we believe that the methodology implemented by the Consultation is the best guarantee of a balanced opinion and evidence-based recommendations. We hope that this chapter will stimulate clinical research in this field and will inspire those involved in the management of continence disorders and POP.

Neurophysiological testing should be part of the armamentarium available in the management of neurogenic incontinence and the establishment of good collaboration with neurophysiologists is recommended.

I. INTRODUCTION

In this chapter the diagnostic and treatment modalities of urinary incontinence in childhood will be discussed. The whole range of urinary incontinence will be covered, from non-neurogenic to neurogenic and from the normal developed child to those children with special needs. In order to understand the pathophysiology of the most frequently encountered problems in children, we shall also consider the normal development of bladder and sphincter.

Underlying pathophysiology will be outlined and the specific investigations for children will be covered but for general information on epidemiology and urodynamic investigations their respective chapters should be consulted.

1. NORMAL DEVELOPMENT OF BLADDER AND SPHINCTER CONTROL

Normal bladder storage and voiding involve low-pressure and adequate bladder volume filling followed by a continuous detrusor contraction that results in bladder emptying, associated with adequate relaxation of the sphincter complex. This process requires normal sensation and normal bladder outlet resistance. The neurophysiological mechanisms involved in normal bladder storage and evacuation include a complex integration of sympathetic, parasympathetic and somatic innervation which is ultimately controlled by a complex interaction between spinal cord, brain stem, midbrain and higher cortical structures

In newborns, the bladder has been traditionally described as “uninhibited”, and it has been assumed that micturition occurs automatically by a simple spinal cord reflex, with little or no mediation by the higher neural centres. However, studies have indicated that even in full-term fetuses and newborns, micturition is modulated by higher centres and the previous notion that voiding is spontaneous and mediated by a simple spinal reflex is an oversimplification (1). Fetal micturition seems to be a behavioural state-dependent event: intra-uterine micturition is not randomly distributed between sleep and arousal, but occurs almost exclusively while the fetus is awake (1).

During the last trimester the intra-uterine urine production is much higher than in the postnatal period (30ml/hr) and the voiding frequency is approximately 30 times every 24 hours (2). In preterm infants diuresis is higher than in term born children. (3)

Immediately after birth voiding is very infrequent during the first few days of life. The first void may only take place after 12 to 24 hours. In preterm infants the voiding frequency is higher and the voided volume smaller than in term infants. After the first week following birth, frequency increases rapidly and peaks at the age of 2 to 4 weeks to an average of once per hour. It then decreases and remains stable after 6 months to about 10 to 15 times per day. After the first year it decreases to 8 to 10 times per day, while voided volumes increase by three-to-fourfold. (4)

During the postnatal period, micturition control mechanisms undergo further changes and extensive modulation. Using ambulatory bladder monitoring techniques in conjunction with polysomnographic recordings it has been shown that even in newborns the bladder is normally quiescent during sleep and micturition does not occur during these periods (5).

This inhibition (or lack of facilitation) of detrusor contractions during sleep is also observed in infants with neurogenic bladder dysfunction who have marked detrusor overactivity while they are awake. In response to bladder distension during sleep, an infant nearly always exhibits clear electro-encephalographic evidence of cortical arousal, facial grimaces or limb movements, or actual awakening. A significant change in sleep pattern, with a shift from quiet sleep to REM or indeterminate sleep, occurs. Sixty percent of term infants are seen to wake up before the bladder contracts after which voiding occurs (3). This arousal period may be transient and the infant may cry and move for a brief period before micturition and then shortly afterward go back to sleep. Because this wakening response is already well established in newborns, it follows that the control of micturition probably involves more complicated neural pathways and higher centres than has been appreciated. It suggests a close relationship between the locus coeruleus and the control center (the pons and the dorsal tegmentum) of micturition. There is also strong evidence that a pronounced reorganisation of pre-existing synaptic connections and neural pathways involved in bladder control occurs during the early postnatal period.

In newborns micturition occurs at frequent intervals and may have an intermittent pattern although bladder emptying efficiency is usually satisfactory. In over 80 percent of voids the bladder empties completely, but infants do not empty their bladder at every void. Post void residual subsides with age (3).

During infancy voiding pressures are much higher than in adults. It has also been noted that these pressures are higher in boys than in girls (mean pdet max of 118 vs. 75 cm H2O, respectively) (6,7).

These higher detrusor pressures decrease progressively with increasing age. In up to 70 percent of infants (up to the age of 3 years) with normal lower urinary tracts, intermittent patterns of voiding were observed. They tend to disappear with increasing age, and are thought to represent variations between individual infants in the maturation of detrusor and sphincteric coordination during the first 1 to 2 years of life. Videourodynamic studies have confirmed these findings (3,6-9).

Between the age of 1 and 2, conscious sensation of bladder filling develops. The ability to void or inhibit voiding voluntarily at any degree of bladder filling commonly develops in the second and third years of life. Central inhibition is crucial to obtain continence.

During the second and third year of life, there is progressive development towards a socially conscious continence and a more voluntary type of micturition control develops. The child becomes more aware of the sensation of bladder distension and the need to urinate, as well as social norms and embarrassment associated with urinary incontinence. Through an active learning process, the child acquires the ability to voluntarily inhibit and delay voiding until a socially convenient time, then actively initiate urination even when the bladder is not completely full, and and then subsequently allowing urination to proceed to completion. During the first years of life, gradual development to an adult type of voluntary micturition control that conforms to the social norms depends on an intact nervous system, in addition to at least three other events occurring concomitantly:

a) a progressive increase in functional storage capacity,

b) maturation of function and control over the external urinary sphincter,

c) and most importantly, achievement of volitional control over the bladder-sphincteric unit so that the child can voluntarily initiate or inhibit the micturition reflex (10).

The final steps are usually achieved at the age of 3 to 4 years when most children have developed the adult pattern of urinary control and are dry both day and night. The child has learned to inhibit a micturition reflex and postpone voiding and voluntarily initiate micturition at socially acceptable and convenient times and places. This development is also dependent on behavioural learning and can be influenced by toilet training, which in turn depends on cognitive perception of the maturing urinary tract.

It is understandable that this series of complex events is highly susceptible to malfunction. Various functional derangements of the bladder-sphincter-perineal complex may occur during this sophisticated course of early development of normal micturition control mechanisms. These acquired "functional" disorders overlap with other types of bladder functional disturbances that may have a more organic underlying pathophysiological basis.

2. NORMAL VALUES

2.1. Normal bladder capacity

Bladder capacity increases during the first 8 years of life roughly with 30 ml per year, so with an average capacity of 30 ml in the neonatal period, a child's bladder volume can be calculated as Y = 30 + 30 X, where Y = capacity in ml and X = age in years (Fig 1) (11).

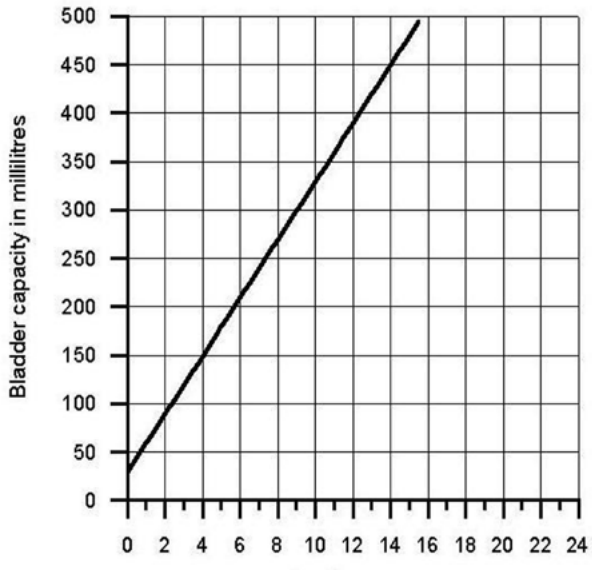

Fig 1. Bladder capacity using the formula Y = 30 + 30 X (Y= capacity in ml, X = age in years)

Hjälmås described a linear correlation that could be used up to 12 years of age: in boys, Y = 24.8 X + 31.6, in girls Y = 22.6 X + 37.4, where Y is capacity in ml, and X is age in years (12).

It should be noted that these data were obtained during cystometric investigations. Cystometric capacity is generally less than normal bladder volumes. Obviously, the relation between age and bladder capacity is not linear for all ages, nor is the relation between body weight and bladder capacity (15).

Another formula to calculate bladder capacity in infants is: bladder capacity (ml) = 38 + (2.5 x age (mo)) (13).

Kaefer and co-workers demonstrated that a non-linear model was the most accurate for the relation between age and bladder capacity, and they determined two practical linear equations:

Y = 2 X + 2 for children less than 2 years old, and Y = X/2+6 for those 2 years old or older; Y = capacity in ounces, X = age in years (Fig. 2) (14).

Normal urinary flow rates

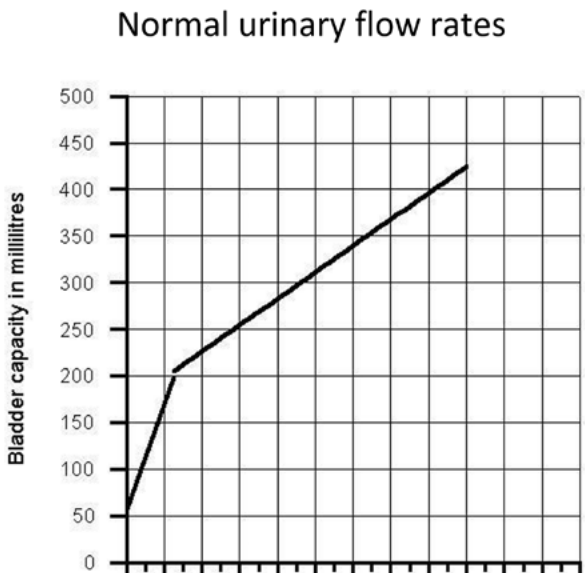

Fig 2. Bladder capacity using the formula
Y = (2 X + 2) x 28.35 ml < 2 years
Y = (X/2+6) x 28.35 ml > 2 years
(Y = capacity in ml, X is age in years)

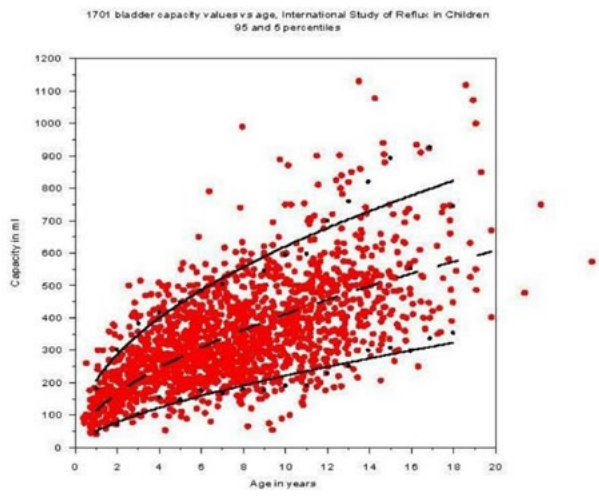

Fig 3. Bladder capacities determined by VCUG in the International Reflux Study

None of these formulas have been derived from a population based study and do not reflect normal bladder capacity. Normal bladder capacity should be regarded as the maximum voided volume of urine and shows huge variation. Recent work of Rittig et al looked at Maximum Voided Volumes (MVV). The Koff Formula showed a reasonably good correlation with 2836 daytime voids, if first morning voids were neglected (15). Girls were found to have a larger capacity than boys, but the rate of increase with age was not significantly different between them. Data on 'normal' bladder capacity have been obtained in continent children undergoing cystography, with retrograde filling of the bladder. Data obtained from the International Reflux Study indicate that there is not a linear relation between age and capacity and that there is a huge variability. (Fig. 3) (16).

2.2. Normal Voiding

The micturition frequency of the fetus during the last trimester is approximately 30 per 24 hours. It decreases to 12 during the first year of life, and after that it is gradually reduced to an average of 5±1 voidings per day (9, 13). The normal range for micturition frequency at age seven is 3 to 7. By age 12, the daily pattern of voiding includes 4-6 voids per day (17,18). Mattson and Lindström emphasize the enormous variability of voiding frequencies in children: also in individual children, the weight-corrected diuresis could vary up to 10-fold (19).

2.3. Normal voiding pressures

Bladder dynamics in children have demonstrated developmental changes with age. Detrusor pressures at voiding in children after the age of 2 years are similar to adults, with a mean maximum pressure of 66 cm H2O in boys, and 57 cm H2O in girls (20).

These pressures are lower than those reported in infancy by Yeung et al, who found boys having pressures of 118 cm H2O and girls 75 cm H2O (7).

2.4. Normal urinary flow rates

Urinary flow rates in normal children have been only minimally described. Szabo et al published nomograms for flow rates vs. age in normal children (21). Flow rates do increase with age.

As in adults, flow rates are clearly dependent upon voided volume, and normal values can only be applied to flow rates that have been registered when voiding at a bladder volume approximating the normal capacity for age (3,22).

II. EVALUATION IN CHILDREN WHO WET

The first steps in the evaluation of the child that wets are a thorough history and physical examination. It is not uncommon that the complaint leading to the referral is only part of the issues that need to be addressed. Thus, a systematic and structured approach is mandatory. The overall objective of history taking and physical examination is to identify symptoms of bladder and bowel dysfunction, investigate for underlying pathology, establish habits regarding fluid intake and toilet visits, and appreciate the effect of previous treatment attempts if any. The combination of structured interviews, validated questionnaires and home recordings (frequency volume charts, bowel-movement charts, recordings of night-time urine production) often suffices to successfully treat the majority of patients with daytime incontinence and enuresis. When anatomical or neurological issues are suspected, urodynamic studies, non-invasive or invasive as well as imaging studies are typically warranted. That said, imaging studies may be helpful in children suffering daytime symptoms but are seldomly required in children with monosymptomatic enuresis.

The International Children's Continence Society (ICCS) has produced standardization documents covering the diagnostic evaluation of children with daytime incontinence as well as the diagnostics and treatment in children with enuresis. According to these documents evaluation and treatment is advised from the age of 6 years in the enuretic child and from the age of 5 years in children suffering daytime urinary incontinence at least once a month for a period of at least 3 months.

In case of refractory patients, diagnostic re-evaluation may be necessary and may reveal additional or overlooked issues that need to be addressed before a breakthrough in treatment efficacy is seen. Since home recordings with charts require time and effort, families need to be well informed about the reasons as well as the clinical value of these recordings in order to improve adherence and the quality of the data received.

1. HISTORY TAKING

History taking is the first and most important step when diagnosing children with incontinence. The young patients should be addressed directly when possible but even for the trained physician it can be equally difficult to connect with a 5-year-old as well as with the teenager with bladder and bowel complains. Establishing a trusting relationship is mandatory in order to be able to discuss issues that are considered a taboo. Sociocultural aspects and psychomotor development have to be taken into account. History taking needs to be detailed and structured [1]. The ICCS has provided standardization documents on the diagnostic evaluation of children with daytime incontinence, dysfunctional voiding, as well as on the evaluation of and treatment for enuresis [2, 3]. A number of validated questionnaires are at our disposal [4].

Conclusion: Validated questionnaires are an aid in history taking in children with enuresis and urinary incontinence (LoE 3)

Recommendation: the use of validated questionnaires is recommended in history taking in children with enuresis and urinary incontinence (GR:C)

The medical history should include questions regarding LUTS as well as bowel function and dysfunction, comorbidities and psychological assessment/behavioural problems. During history taking, the degree of motivation for both the parents and the child may become evident. An important task for the physician is to identify all the issues that need attention as often the initial complaints are not covering the entire spectrum of identified issues.

The following should be covered:
- Family history
- Birth history and development
- Past medical history, surgery, UTIs, medication
- Specify LUTS (daytime symptoms, enuresis)
- Bowel habits and dysfunction according to Rome IV criteria
- Toilet behaviour, toilet training and age of acquisition of bladder / bowel control
- Fluid intake habits
- Comorbidities, behavioural issues/psychosocial issues
- Sleep problems (signs of sleep disordered breathing)
- Previous treatment attempts
- Expectations of the parents/child

Specifically, for LUTS one can differentiate between storage symptoms (pollakisuria, voiding postponement, incontinence, urgency, nocturia, enuresis) and voiding symptoms (hesitancy, straining, dysuria, urine stream issues, intermittency, retention, post micturition dribble). In cases such as vaginal reflux, giggle incontinence etc. the diagnosis can be based solely on the history.

Warning signs suggesting an underlying pathology may include neurological issues, history of recurrent urinary tract infections and continuous incontinence.

Importantly, sexual abuse can be signalled first by symptoms of the lower urinary or gastrointestinal tract [5],[6]. However other symptoms may predominate.

2. SCREENING TOOLS

Self-reporting of symptoms is very often unreliable especially for the paediatric patient, therefore scoring systems and home recordings are of great value when evaluating bladder and bowel dysfunction in children. Not only can such tools help fully appreciate the symptoms, they can also be used in the follow-up, to assess the effect parameters.

A voiding diary is mandatory to determine the child's voiding frequency and voided volumes. A 48h frequency volume chart is advisable [2, 7] . For younger children 4-h void observations can be used [8]. Such charts can be filled in at home either on paper or through apps.

For the assessment of bowel function when desired 1-2 week diaries can be used registering frequency, stool consistency according to Bristol Scale [9], straining, pain and bleeding.

There is a well-documented high rate of behavioural disorders in children with bowel and bladder dysfunction (BBD) [10]. The ICCS recommends behavioural screening of all children with incontinence with validated questionnaire forms such as the Child Behaviour Checklist (CBCL Achenbach) or Strengths and Difficulties Questionnaire (SDQ) of the Behaviour Assessment of children (BASC) [11].

A short screening instrument for psychological problems in enuresis (SSIPPE) derived from CBCL [12] and a disease specific quality of life questionnaire for children with LUTD (PinQ) [13] are also available. If a clinically relevant behavioural or emotional disorder is suspected, a full child psychological or psychiatric assessment is recommended [14].

When sleep disordered breathing is suspected validated questionnaires can be used to identify patients in need for sleep studies [15]. This is particularly important in children who habitually snore, are overweight or have other risk factors for obstructive sleep apnoeas [16].

Conclusion: The use of validated questionnaires on behavioural screening and on sleep disorders in children with bowel and bladder dysfunction is effective to determine which patients needs further specified investigations (LoE:4)

Recommendation: Validated questionnaires on behavioural screening and on sleep disorders are recommended to determine which patients need further specified investigations (GR:C)

3. PHYSICAL EXAMINATION

Physical examination should be systematic with special focus on the genital region, pelvic region and lower back. Bedside ultrasound can be used for evaluation of bladder wall thickness and rectal diameter when needed.

The physical examination should include the assessment of perineal sensation and reflexes supplied by the sacral segments S1-S4 (standing on toes, bulbocavernosus reflex) and anal sphincter tone and control. The genital region should be thoroughly inspected as well as the positioning and characteristics of the urethral meatus. Asymmetry of buttocks, legs or feet, as well as other signs of spinal dysraphism in the lumbosacral area (subcutaneous lipoma, skin discoloration, hair growth and abnormal gait) should not be missed [17].

Palpation of the abdomen may reveal the presence of a full bladder, or a palpable mass on the left side representing a full sigmoid or descending colon. Although uncommon, it is also important to exclude other palpable masses.

When possible, direct observation of the child's voiding is advisable. Toilet posture should be evaluated and corrected if needed [18] (Figure 1). This can be done during uroflowmetry.

Once history is established and physical examination performed, further evaluation may include imaging studies, uroflowmetry and post void residual measurements, urine dipstick, transabdominal rectal US, pelvic floor US, and home recordings (frequency volume charts, stool calendar, recordings of night-time urine output).

Figure 1. Improper position for voiding: the feet are not supported (unbalanced position) and the boy is bent forward. Support of the feet will correct this and will allow the pelvic floor muscles to relax properly.

In selected cases invasive urodynamic studies, cystoscopy or further imaging may be warranted depending on the suspected diagnosis [1].

4. NON-INVASIVE DIAGNOSTIC TECHNIQUES

4.1. Urinalysis

Physical examination should include urinalysis to identify patients with urinary tract infection, proteinuria or haematuria. Further biochemical measurements in urine can be performed when needed to exclude hypercalciuria, tubular dysfunction, diabetes insipidus

Conclusion: urinalysis is essential to evaluate for UTI in patients with urinary incontinence (LoE:3)

Recommendation: urinalysis is recommended to evaluate for UTI in patients with urinary incontinence (GR:B)

4.2. Bladder diaries

The frequency/volume chart is a detailed diary recording each void by time and urine output over preferably four and a minimum of two 24-hour periods [7]. The chart gives objective information on the number of voids, the distribution of day and night voids, along with the voided volumes and episodes of urgency, leakage, or dribbling. In order to obtain a complete picture, defecation frequency and type according to Bristol scale and/or soiling episodes can also be recorded [19].

The frequency volume (FV) chart provides the maximum storage capacity as the maximal voided volume (MVV) [14]. First morning void reflects the nocturnal bladder capacity and should be excluded from the evaluation of MVV. MVV can be compared to the expected bladder capacity for age as calculated by the formula 30 x age +30 [3]. ICCS definition of normality is an MVV between 65% and 130% of the expected MVV. Normal voiding frequency is 4-7 voids per day on a normal fluid intake.

Whenever possible, filling out the chart should be the responsibility of the child with the parents providing assistance and support. The frequency volume charts can also be used to follow the progress. One has to bear in mind that for children on standard urotherapy on timed voids, FV charts can be misleading in evaluating MVV. Moreover, there may be differences between weekdays and weekends in toilet visits and fluid intake habits.

Registrations of fluid intake are of major importance both for evaluation of the total fluid intake per day but also the distribution throughout the day and of course any consumption of bladder irritants such as caffeine, carbonated drinks etc.

For nocturnal enuresis, patient's registrations of urine production during bedtime can identify the exact pathophysiology and can be used for tailoring treatment in the individual patient. Commonly seven nights of registrations as a minimum can provide a clear picture. Nocturnal urine production can be measured by weighing the diaper adding the first morning void. According to the ICCS a nocturnal urine production exceeding 130% of the expected MVV classifies for nocturnal polyuria. Such registrations of nocturnal urine output are of great importance especially in the patient refractory to first line treatments [3, 7].

Conclusion: a bladder diary is an effective tool to objectively assess the fluid intake and voiding habits of the incontinent child (LoE3)

Recommendation: The use of a bladder diary is recommended in the evaluation of every child suffering urinary incontinence or enuresis (GR:B)

4.3. Bowel diaries and evaluation of constipation

The high prevalence of constipation in children with bladder dysfunction dictates that all children attending incontinence clinics should be evaluated for constipation [20]. The physician will often find that an exact delineation of a child's bowel habits is not possible without a bowel diary. A 2-week bowel diary is advisable. The diagnosis of functional constipation should be based on the Rome IV criteria (https://theromefoundation.org/rome-iv/rome-iv-questionnaire/).

At least 2 of the following present at least once per week for at least 1 month:

- 2 or fewer defecations in the toilet per week
- At least 1 episode of faecal incontinence per week
- History of retentive posturing or excessive volitional stool retention
- History of painful or hard bowel movements
- Presence of a large faecal mass in the rectum
- History of large-diameter stools that may obstruct the toilet

The symptoms should not be fully explained by another medical condition.

Transabdominal rectal ultrasound may be useful not only in the diagnostics but also the follow-up of children with constipation [21, 22]. Using a full bladder as a window one can visualize and measure the diameter of the rectum. A rectal diameter of more than 3 cm predicts faecal impaction and has been validated against palpable mass in rectal examination, one of the criteria of functional constipation. This result was not age dependent.

To investigate for and adequately treat constipation is important in all children with urinary incontinence as this may improve the outcome [23].

Conclusion: constipation does influence the outcome of the treatment of incontinence (LoE:3)

Recommendation: Quantification of constipation is necessary in the diagnostic evaluation of the enuretic or urinary incontinent child (GR B)

4.4. Quantification of urine loss

Subjective grading of incontinence may not reliably indicate the degree of dysfunction. For objective grading a 12-h pad test and frequency/volume charts are validated instruments [24-26]. The dry pie is an alternative to the pad test when exact evaluation of the severity of the incontinence episode is the objective [27].This dry pie is a colorful and interesting home recording sheet designed to quantify the worst incontinence episodes during the day. The chart is very useful in following the progress of the symptoms. One should be aware that home recordings and diaries filled during weekends at home may deviate from what usually happens during school days.

The amount of urine lost during sleep (enuresis volume) can be determined by weighing diapers or absorbent pads, before and after sleep [7]. Although registrations of nocturnal urine output are of importance in the treatment of enuresis, especially the refractory type [3], the value of enuresis volumes remains in the research setting.

4.5. Scoring systems

At present three scoring systems, based on validated questionnaires have been described. Specific scores correlated with lower urinary tract dysfunction with a specificity and sensitivity of about 90% [28-30].

The value of these scoring systems to determine the cause of incontinence seems to be limited for the individual patient, but can be very useful in research studies to determine and compare treatment outcomes.

Conclusion: scoring systems are effective to define lower urinary tract dysfunction (LoE 3)

Recommendation. Scoring systems can be useful especially in research studies (GR: B)

5. URINARY FLOW

Voiding should be analysed in detail in all incontinent children, with the exception of monosymptomatic bedwetting, where voiding is usually normal. Graphic registration of the urinary flow rate (i.e., uroflowmetry) during voiding is a standard office procedure. Flow patterns and rates should be repeated to allow for evaluation, and several recordings are needed to obtain consistency. Afterwards, parents are asked if their child's flowmetry pattern was representative of their ordinary voiding.

In infants, there are features of micturition that can be observed in healthy normal infants. This includes arousal, which is detected in 90% of micturitions in healthy term infants, whereas they are only detected in 60% of pre-term infant micturitions. Parameters such as voided volume, bladder capacity, and flow rates increase with

age, whereas voiding frequency, post-void residual urine (PVR), and interrupted voiding tend to decrease with age [31]. It was previously thought that constant bladder volume would promote bladder voiding in neonates without significant brain involvement. However, investigation using video-electroencephalography showed that bladder voiding during quiet sleep is associated with cortical arousal, suggestive of bladder sensory maturation over time.

Measurement of urinary flow is performed as a solitary procedure, with bladder filling by diuresis (spontaneous or forced), or as part of a pressure/flow study, with bladder filling by catheter. Patterns and rates should be consistent to allow for evaluation, and several recordings are needed to obtain consistency [14, 32-34].

The same parameters used to characterise continuous flow may be applicable, if care is exercised, in children with intermittent, or staccato flow patterns. In measuring flow time, the time intervals between flow episodes are disregarded. Voiding time is the total duration of micturition, including interruptions. Flow time is the total duration of flow, excluding the interval between voiding flow.

When possible, uroflowmetry should be performed with optimal bladder volume. ICCS has recommended 50ml as the lower limit of interpreting uroflowmetry [14]. Flow recordings with a voided volume of less than 50% of the functional capacity are not consistent: they represent voiding on command, and many children will try to comply by using abdominal pressure. On the other hand, overdistension of the bladder can result in abnormal uroflow recordings also [35]. A recent study evaluating children 4-9 years of age, suggested that the best reproducibility and reliability was found when bladder volumes are optimized to between the lowest accepted value of bladder capacity, defined as (age in years x 5 + 50mL), and upper boundary of 115% of expected bladder capacity, defined as (age in years x 30 + 30mL)[36].

A helpful tool to ensure optimal bladder volume is the use of transabdominal ultrasound (e.g. bladder scan) before micturition in order to assess the bladder volume [33, 37]. If the bladder is still nearly empty, the child should be asked to drink some water until the bladder is full enough for a reliable flow.

Urinary flow may be described in terms of rate and pattern and may be continuous, intermittent (in fractions), or staccato (fluctuating) (Fig. 2). An intermittent flow pattern shows an interrupted flow, whereas in staccato voiding the flow does not stop completely but fluctuates due to incomplete relaxation of the sphincter. The continuous smooth flow can be bell, tower or plateau. Only the bell shaped uroflowmetry curves are regarded as normal.

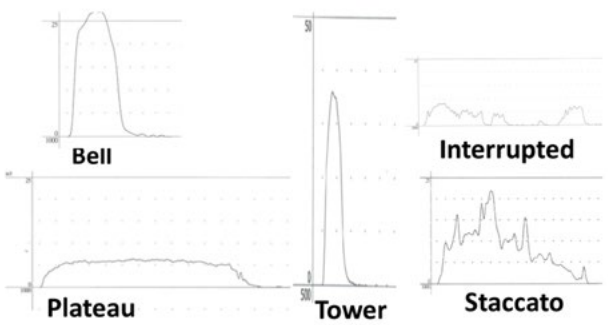

Figure 2. Typical uroflowmetry patterns

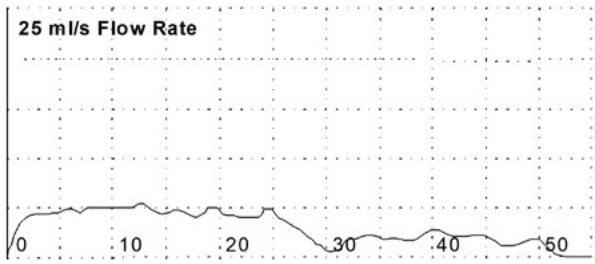
Under optimal bladder volume, approximately 1% of school children have voiding that can be labelled abnormal with flattened or intermittent flow curves. The remaining 99% have a bell-shaped flow curve [33, 38]. It should be noted that a normal flow does not exclude a voiding disturbance, nor does an abnormal flow pattern automatically means a bladder or voiding dysfunction, as in asymptomatic normal school children abnormal patterns were also found [39-41].

As current interpretations of uroflowmetry are descriptive (e.g. "bell-shaped"), there are low interrater agreements. Hence, objective criteria were suggested and may be beneficial to improve agreements between different professionals. Flow index (FI) is derived using the actual Qmax and the estimated Qmax. FI > 1.25 is suggestive of tower, FI 0.71-1.25 is suggestive of bell, and FI <0.71 is suggestive of plateau. FI may be a useful method to distinguish flow patterns with continuous curves [42, 43]. Figure 3 depicts typical plateau pattern with a low flow index. Other criteria that was suggested included Angle of Qmax (Angle_Qmax), which objectively relates the intuitive interpretation of flow patterns (Figure 4). Angle_Qmax ≥ 80° is suggestive of tower, Angle_Qmax 60-79° is suggestive of bell, and Angle_Qmax <60° are related to plateau curves[44, 45].

To better define interrupted flow, if the voided volume of a major curve is ≥80% of total volume of a uroflow curve, it is not an interrupted curve (figure 4a & 5a). In this way, one may avoid terminal dribbling as interrupted flow. A typical interrupted flow is shown in figure 6. There is no major curve, i.e., no single curve has a volume >60% of total volume in the voiding curves. Staccato flow pattern has less agreement. Some experts defined one deep drop as staccato. Since one deep drop can be common in healthy children (Fig. 5b), we recommend at least three deep drops of a curve to justify staccato pattern (Fig. 7)[44, 45].



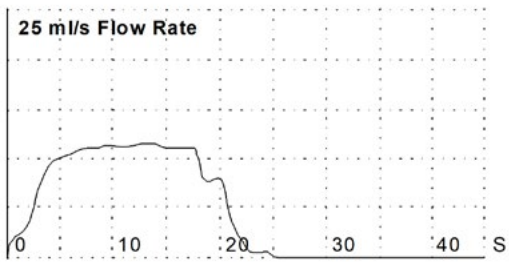


Figure 3: flow curves of 2 children with a static, anatomic obstruction; the curve is continuous but the flow is lower than normal and extended in time.

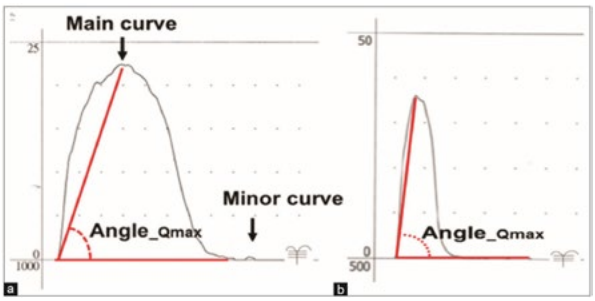

Figure 4. Typical bell (a) and tower (b) uroflowmetry curves show angle at Qmax (Angle_Qmax), and main and minor curves (a) (Shei-Dei Yang, S. and S.-J. Chang, Differentiating tower from bell curves in smooth continuous uroflowmetry curves of healthy adolescents. Urological Science, 2019. 30(2): p. 74.)

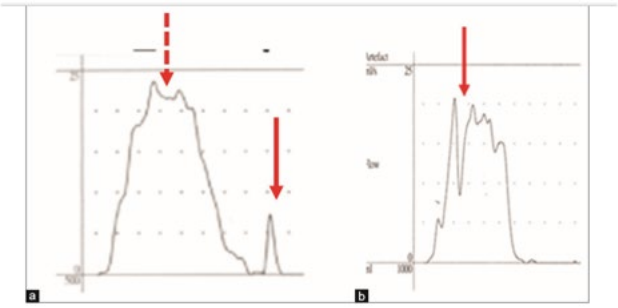

Figure 5. A "bell" curve with drop > 2 ml/s (broken arrow) and terminal minor curve (solid arrow) (a), and a "bell" curve with one deep drop >√ peak floe rate (arrow) and several significant drops > 2 ml/s (b). Both curves were record of healthy adolescents. (Shei-Dei Yang, S. and S.-J. Chang, Differentiating tower from bell curves in smooth continuous uroflowmetry curves of healthy adolescents. Urological Science, 2019. 30(2): p. 74.)

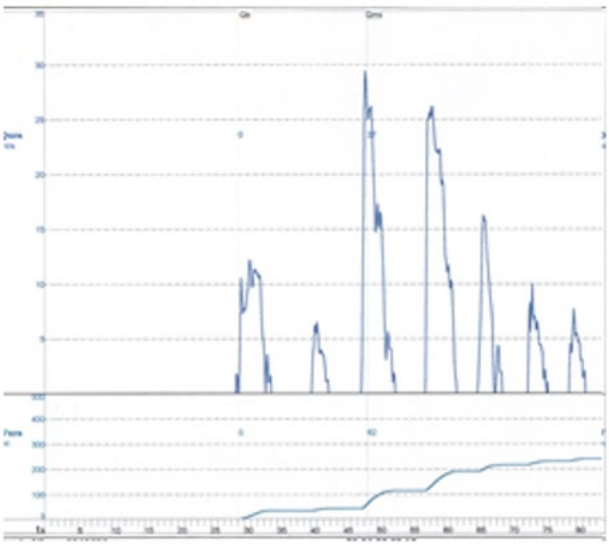

Figure 6: intermittent flow curve in a child voiding with abdominal straining

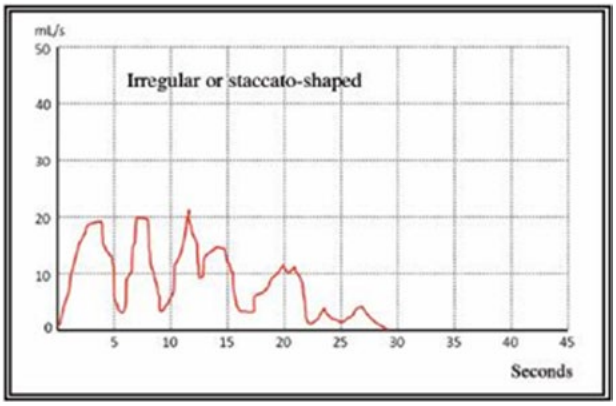

Figure 7: Staccato voiding in a child

Diagnoses based on uroflow pattern appearance without simultaneous electromyography (EMG) to support them can be misleading, and reliance on uroflow pattern alone can lead to overdiagnoses of dysfunctional voiding and detrusor underactivity. Hence, accompaniment of uroflowmetry with simultaneous pelvic floor electromyography is suggested to improve diagnostic accuracy and to provide the most appropriate management[46]. Nonetheless, uroflow-EMG has a low interrater agreement[47] and simultaneous use of uroflowmetry and EMG may require further studies to develop definitions that can be consistently used.

For children with MNE, both 48-hour frequency/volume charts and triplicate urine flow measurement with PVR evaluation are reliable methods of maximum bladder capacity evaluation. For children with OAB or DV, both methods may be necessary for accurate evaluation of decreased bladder capacity, as F/V chart and uroflow results may not be comparable. [48]

Conclusion: uroflowmetry is an adequate tool to analyse the voiding pattern of the incontinent child, although there exists high interrater variability in the descriptive interpretation of such studies. (LoE:3)

Recommendation: Uroflow is indicated in the evaluation of all incontinent children except those suffering mono-symptomatic enuresis. Adequate bladder filling is necessary for a reliable result. (GR: B)

6. ULTRASOUND IMAGING OF UPPER AND LOWER URINARY TRACT

In most clinical settings, ultrasound-imaging techniques are routinely used in children with incontinence. Upper tract abnormalities such as duplex kidney, dilatation of the collecting system, and gross reflux nephropathy can be readily detected, but detection of the more subtle expressions of these abnormalities requires urological expertise on the part of the ultrasound operator [49]. Most children with non-neurogenic lower urinary tract dysfunction (LUTD) have normal upper tracts. Therefore, routine ultrasound of upper tracts is not recommended for work up of primary nocturnal enuresis [14, 50]. Obtaining ultrasounds for PVR are helpful adjuncts in evaluating infants and children with LUTD and is recommended. These

can also provide additional information about bladder volume and thickness that can suggest neurogenic LUTD.

6.1. Post-void residual volume (PVR)

Except in small infants, the normal bladder will empty completely at every micturition [51].The identification or exclusion of elevated PVR is therefore an integral part of the study of micturition. However, an uneasy child voiding in unfamiliar surroundings may yield unrepresentative results, as may voiding on command with a partially filled or overfilled bladder. When estimating PVR, voided volume and the time interval between voiding and estimation of PVR should be recorded. This is of particular importance if the patient is in a diuretic phase. In patients with gross vesicoureteral reflux, urine from the ureters may enter the bladder immediately after micturition and may falsely be interpreted as residual urine. The absence of residual urine is an observation of clinical value, but does not exclude bladder outlet obstruction or sphincter / pelvic floor overactivity with absolute certainty. An isolated finding of residual urine requires confirmation before being considered significant, especially in infants and young children. Therefore, a single elevated age-specific PVR should prompt a confirmatory second PVR.

Sonographic estimation of PVR, instead of urethral catheterization, is recommended. Increased PVR is associated with prognosis and should be performed after uroflowmetry[52]. In children aged 4-6 years, a repetitive PVR of >20 ml or >10% bladder capacity is considered elevated. In children aged ≥7 years, repetitive PVR>10ml or 6% bladder capacity is regarded as elevated[53]. Ideally 3 uroflows are representative, but 2 will suffice as this maintains accuracy and consistency. First morning uroflows should be avoided as they may exceed normal voided volumes.

Dysfunctional voiding symptoms scores (DVSS), a numerical grading of voiding behaviors of children, is a non-invasive method of evaluating adherence to behavioural modification in pediatric patients with dysfunctional voiding. [30] However, an elevated PVR may mean lower likelihood of responding to treatment, regardless of their DVSS score. Hence, there may be benefit in serial uroflowmetry and PVR measurements in children with primary nocturnal enuresis[54].

6.2. Bladder wall thickness

Lower urinary tract abnormalities are even more difficult to assess for the inexperienced, aside from bladder wall thickness: a bladder wall cross-section of more than 3-4 millimetres, measured at 50% of expected bladder capacity, is suspicious of detrusor overactivity [55, 56]. Because only a few studies have been conducted to compare bladder wall thickness in normal children without complaints and in children with LUTD, more studies need to be performed to validate these non-invasive techniques[57, 58].

Another possibility is to assess bladder volume and bladder wall thickness to calculate the Bladder Volume/ Bladder Wall Thickness index. In children with nocturnal enuresis this index correlated well with response to treatment [59].

Bladder wall thickness and uroflow curve shape are related to the recovery period of pediatric overactive bladder (OAB). The bladder wall thickness, when measured within 5 minutes of voiding (or immediately after voiding if voiding time was greater than 5 minutes), was predictive of patients with shorter time to significant improvement (daytime incontinence less than once a month and no relapse for >6 months after cessation of treatment) following management of OAB. This may be due to strong detrusor overactivity associated with the bladder wall thickness, which will respond better to treatment with medications such as antimuscarinics. This may be the reason why patients who have a tower-shaped uroflowmetry curve may also have a shorter time to improvement compared to those with bell-shaped curve, since a tower-shaped curve may suggest bladder overactivity that may be more responsive to treatments.[60]

6.3. Ultrasound-flow-ultrasound

This combination of imaging and non-invasive urodynamics is a standardised procedure used to obtain representative data on flow rate and flow pattern, as well as PVR. With ultrasound, bladder filling is assessed and when the bladder capacity is equal to the functional or expected bladder capacity for age, the child is asked to void into the flowmeter. After recording the flow, PVR is assessed again. This procedure avoids the registration of flow rates at unrealistic bladder volumes.

Alternatively, children can be asked to use a flowmeter at home: a special flowmeter has been designed to use at home[61]. For those children who have difficulty voiding in a strange environment, this option can be useful.

Overall, non-invasive tests such as uroflowmetry, EMG, kidney and bladder ultrasounds, post-void residuals, and pelvic ultrasounds can all provide additional diagnostic information for children with LUTD. While invasive tests such as pressure flow urodynamics testing and voiding cystourethrograms can provide accurate diagnostic measures for selected patients, non-invasive tests can be considered as surrogate investigations that can provide similar information. Non-invasive diagnostic tests may guide us to select the most appropriate invasive investigations that may lead to the actual diagnosis that clinicians can target treatment for. This in turn, may improve patient and family satisfaction, as well as patient outcomes[62].

Conclusion: the combination of bladder ultrasound and uroflow is an important tool in the evaluation of voiding pattern in the incontinent child (LoE: 3)

Recommendation: Ultrasound and uroflow should be performed in the diagnostic evaluation of the incontinent child except for those with monosymptomatic enuresis, (GR/ B)

7. INVASIVE DIAGNOSTIC TECHNIQUES

The important question (for the incontinent child) “whether invasive diagnostic procedures are necessary” is decided by the results of the non-invasive procedures. At present, there are no studies indicating that a voiding cystourethrogram (VCUG) is useful in children with incontinence, without urinary tract infections.

Urodynamic studies may provide information that may change clinical decision making. However, they do not necessarily lead to improved incontinence outcomes. Hence, it is unclear whether routine use of urodynamics will benefit children who present with incontinence. In general, urodynamic studies will only be done if the outcome will alter the management, and this will also depend on whether the possible treatments being considered are invasive. The diagnostic information needed is that which is necessary to find the correct treatment. Indicators include straining or manual expression during voiding, a weak urinary stream, previous febrile UTI, continuous dribbling incontinence or pronounced apparent

stress incontinence, or previously identified dilating vesicoureteral reflux.

The finding of genitourinary abnormalities or signs of occult spinal dysraphism at physical examination also indicate the need for further diagnostics. Urinary flow registration will detect the plateau-shaped flow curve typical for structural bladder outlet obstruction, and an intermittent flow suggesting detrusor –sphincter- pelvic floor dyscoordination[14].

A clinically significant PVR on repeated occasions clearly points to incomplete bladder emptying. The pad test will detect the cases with obvious stress and urgency incontinence, or continuous dribbling. Ultrasound imaging will raise suspicion of an ectopic ureter, which can sometimes be confirmed on a well conducted physical examination as well. In short, invasive diagnostics are indicated when the non-invasive testing raises suspicion of neurogenic detrusor-sphincter dysfunction (occult spinal dysraphism), obstruction (especially posterior urethral valves), genitourinary abnormalities (e.g. epispadias), advanced non-neurogenic detrusor-sphincter-pelvic floor dysfunction (as in children with vesicoureteral reflux and upper tract dilatation and/or febrile urinary tract infections), or significant PVR.

To diagnose the complex of non-neurogenic detrusor-sphincter dysfunction, recurrent UTI and vesicoureteral reflux, urodynamic studies are needed in only a minority of all children.

7.1. Voiding Cystourethrogram

Technique of VCUG

To improve patient safety and to standardize the data obtained when a VCUG is performed, the American Academy of Paediatrics (AAP) Section on Radiology and the AAP Section on Urology have created a consensus on VCUG protocols to standardize the test [63]. The described technique is summarized below.

Cleanse and rinse the external genitalia with lukewarm water: do not use detergents. Use a feeding tube with side holes and a rounded tip (Ch 06-08), balloon catheter is not recommended; check the urine for infection. Empty the bladder completely before filling. Use a radio-opaque dye of maximum 30% concentration, at body temperature, and fill the bladder by slow-drip infusion, with a hydrostatic pressure of not more than 40 cm H2O. Note the volume of the contrast medium instilled. Use fluoroscopy during filling at regular intervals.

Take spot-films (70mm or 90mm camera) with the child in supine position, with partial filling and at the end of filling, in AP projection. Upper and lower tract should be visible.

When voiding is imminent, change the position of the child, so that spot films of bladder and urethra in 3/4 projection can be taken during voiding. Also take a spot film of the upper urinary tract during voiding, as the degree of vesicoureteral reflux (VUR) may change with the pressure generated by the detrusor muscle during voiding. Post-void residual volumes vary considerably with VCUG. The voiding phase is critically important to VCUG, both for reflux detection and for assessment of voiding dynamics. Without a voiding phase the VCUG is incomplete.

Prophylactic antibiotics are indicated in all children, to minimise the risk for post-VCUG UTI especially in children with history of febrile UTI or an anatomic abnormality.

Indications for VCUG

A VCUG is an invasive procedure and should only be done if the outcome will influence the management. It is indicated in children with recurrent UTIs to detect reflux, in children with a dilated system on ultrasound and in children with an abnormal flow pattern to detect bladder outlet abnormalities (like valves, strictures or a syringocele).

In children with incontinence the lateral projection during voiding is the most important part of the study. Especially in children with stress incontinence or a neurogenic bladder the position and configuration of the bladder neck during filling and voiding should be noted.

In children with non-neurogenic detrusor-sphincter- pelvic floor dysfunction (dysfunctional voiding) as well as in children with neurogenic detrusor-sphincter dyssynergia, the proximal urethra may show the so-called ‘spinning top’ configuration, during filling and during voiding. With detrusor and pelvic floor muscles contracting at the same time, the force of the detrusor contraction will dilate the proximal urethra down to the level of the forcefully closed striated external sphincter. The resulting ‘spinning top’ configuration was previously viewed as a sure sign of distal urethral stenosis, a concept held responsible for recurrent UTIs in girls, with urethral dilatation or blind urethrotomy as the obvious therapy. However, urodynamics has made it clear that the ‘spinning top’ will only appear when the detrusor and pelvic floor contract synchronously, which makes it a functional anomaly, not an anatomical one[64, 66].

Women often recall their experience with VCUG as young girls in terms bordering on abuse. The use of VCUG in children should be limited to those situations where it is absolutely necessary.

7.2. (Video)-Urodynamics

Urodynamic studies have become a major tool in evaluating lower urinary tract dysfunction (LUTD) in children [65]. It is indicated in children suspected of neurogenic or non-neurogenic LUTD refractory to empirical treatments based on non-invasive studies.

International Consultation on Incontinence-Research Society nocturia think tank (NTT) has recommended that standardized ALARA (“As Low As Reasonably Achievable”) principles should be adopted for videourodynamics in children. The risks of radiation related to x-ray images should be balanced with the benefits of the diagnostic test, and only the standardized and minimum necessary images should be obtained to correlate the pressure changes. Moreover, the pelvic muscle surface electromyography technique and its diagnostic relevance should be standardized and further investigated in the future [63].

In children, urodynamic investigations should only be performed if the outcome will have consequences for treatment [67-69]. Furthermore, like VCUG it may be considered when invasive or surgical interventions are planned. The main question is whether the urodynamic study will provide new information that cannot be obtained otherwise and will influence the further management. From the few studies that have addressed this issue it can be concluded that urodynamic studies in the majority of cases do not provide significant additional information to justify this type of investigation as a routine procedure in non-neurogenic children [70-72].

Both children and parents need careful preparation and adequate information before the study is done. It is an invasive procedure and artifacts may occur. Because of the invasiveness of the investigations all children are anxious and this may be reflected in the out-

come of the study. Especially during the first filling cycle, when the child does not know what to expect, detrusor overactivity may be seen and the voiding phase can be incomplete due to contraction or incomplete relaxation of the pelvic floor muscles during voiding. Once the child knows that filling and voiding are not painful a subsequent filling and voiding cycle may show a completely different pattern. The study should be repeated at least 2 or 3 times. Only if during the first filling cycle, no detrusor contractions are seen and also the voiding phase is in accordance with history and uroflow, it is probably sufficient to do only one complete filling and voiding cycle [73]. Still the results may not always be reproducible, and it should be stressed that the primary objective is to treat the child and not a "urodynamic abnormality" per se.

Special attention should be given to a pleasant surrounding for the child: one or both parents should be present and young children may be given a bottle. Older children may be distracted by watching a video movie. The child should be awake, non-anaesthetised and neither sedated nor taking any drugs that affect bladder function. Intranasal midazolam may be administered in certain situations where high anxiety levels cannot be mollified, as this drug appears to be innocuous regarding outcome of the study [74].

During the study the investigator has the opportunity to observe the child and discuss various findings and correlate them to what the child feels and/or normally would do in such circumstances. Because UDS is an invasive procedure artifacts may influence accurate interpretation of results [75].

In children, the transition from filling phase to voiding phase is not as marked as in adults. To avoid missing this important transition, cystometry and pressure-flow/EMG measurements are performed as one continuous study in paediatric urodynamics.

Electromyography of the pelvic floor muscles is assumed to evaluate the activity of the striated urethral sphincter, in the filling phase and in the voiding phase. Surface skin electrodes are usually used to record the EMG. In children the pelvic floor EMG is probably of much more importance than in adults as it helps to differentiate the different voiding disorders.

Filling the bladder can be achieved by diuresis (natural fill cystometry) or retrograde by catheter. For retrograde filling by catheter, saline 0.9% or contrast medium at body temperature is recommended in children. Especially in young children some urodynamic parameters, such as capacity and detrusor activity are influenced by the temperature of the filling fluid. Although the clinical relevance is as yet unknown, it is recommended to fill the bladder with fluid of body temperature [76]. When filling by catheter, slow fill cystometry (5 – 10 percent of expected bladder capacity per minute (based on the voiding diary), or < 10ml/min) is recommended in children.

Involuntary detrusor contractions may be provoked by rapid filling, alterations of posture, coughing, walking, jumping, and other triggering procedures. The presence of these contractions does not necessarily imply a neurological disorder. In infants, detrusor contractions often occur throughout the filling phase (Figure 8).

Bladder sensation is difficult to evaluate in children. Only in toilet-trained cooperative children it is a relevant parameter. Normal desire to void is not relevant in the infant, but can be used as a guideline in children of 4 years and older. Normal desire to void should be considered the volume at which some unrest is noted, e.g., wriggling the toes; this usually indicates voiding is imminent. In the older child, the volume may be small with the first cystometry,

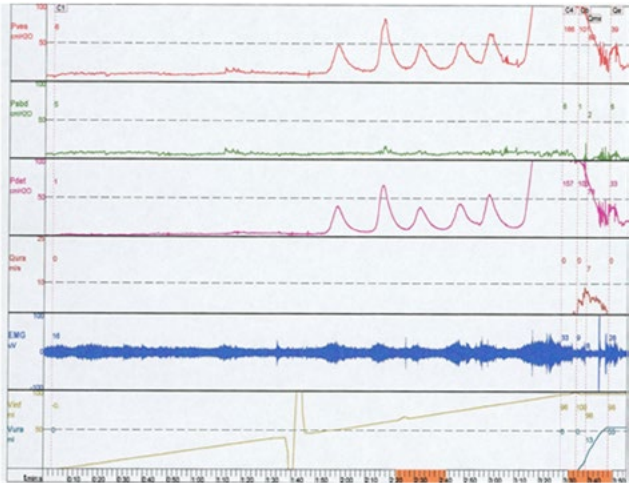

Fig. 8. Urodynamic study illustrating involuntary detrusor contractions, counter action of pelvic floor muscles (guarding reflex) and incomplete pelvic floor relaxation during voiding resulting in post void residual urine (detrusor overactivity + dysfunctional voiding) [77].

for fear of discomfort. Also, involuntary detrusor contractions occur more often during the first filling cycle [76]. This is the reason that in paediatric urodynamics at least two cycles of filling are recommended.

Maximum cystometric capacity (MCC) is the volume in the bladder at which the infant or child starts voiding. The value for maximum cystometric capacity is derived from volume voided plus residual volume. Values for MCC should be interpreted in relation to normal values for age.

Compliance indicates the change in volume for a change in pressure. For children with neurogenic detrusor-sphincter dysfunction, data are available relating poor compliance to the risk of upper urinary tract damage[78].

The usual notation for compliance is a single value, but a full characterisation of compliance may be helpful, as some children have varying compliance factors throughout filling [80]. This variability depends on several factors: rate of filling, which part of the curve is used for compliance calculation, shape (configuration) of the bladder, thickness, and mechanical properties of the bladder wall, contractility, relaxability of the detrusor, and degree of bladder outlet resistance [73]. To calculate the compliance ΔP represents the change in detrusor pressure from the onset of filling until just before the initiation of voiding or the pressure at the end of filling.

The urethral closure mechanism during storage may be normal or incompetent. The normal urethral closure mechanism maintains a positive urethral closure pressure during filling, even in the presence of increased abdominal pressure or during detrusor overactivity (guarding reflex) [77]. An incompetent closure mechanism is defined as one that allows leakage of urine in the absence of a detrusor contraction.

In urodynamic stress incontinence, leakage occurs when Pves exceeds Purethra (intraurethral resistance) as a result of an increase in intraabdominal pressure, often in conjunction with low Purethra [77]. Although common in multiparous females, it is exceedingly rare in paediatrics but may be noted in athletically active teenage

girls [83]. Immediately prior to micturition the normal closure pressure decreases to allow flow.

Bladder outlet obstruction, recorded with a pressure / flow study, may be anatomical or functional in nature. An anatomical obstruction may be present at the bladder neck or in the urethra as a stenosis or a stricture when there is a small and fixed urethral diameter that does not dilate during voiding. As a result, the flow pattern is plateau shaped, with a low and constant maximum flow rate, despite high detrusor pressure and complete relaxation of the urethral sphincter. In a functional obstruction, it is the active contraction of the urethral sphincter or pelvic floor during passage of urine, that creates the narrow urethral segment as a constant or intermittent obstruction. To differentiate anatomical from functional obstruction, information is needed about the activity of the urethral sphincter during voiding. This information can be obtained, and recorded together with pressure and flow, by monitoring the urethral pressure at the level of the urethral sphincter, or by recording a continuous electromyogram of the pelvic floor, as in clinical practice the urethral sphincter is not readily accessible, and the electromyogram of the external anal sphincter is often used to monitor activity of the striated urethral sphincter. This corresponds to activity of the pelvic floor muscles. Also, the use of video urodynamics can be very helpful in this respect, as contractions of the pelvic floor muscles can actually be seen during the voiding phase (Fig 6 and 7).

In infants and small children, pelvic floor muscle overactivity during voiding (with post-void residuals) is not uncommon: in all probability, it may be a normal developmental feature [79, 81].

Recently, the role of ambulatory urodynamics monitoring (AUM) in children with refractory monosymptomatic nocturnal enuresis has been investigated. AUM may overcome some of the limitations of traditional urodynamics as it allows physiological antegrade filling compared to rapid retrograde filling. AUM was shown to be more accurate compared to conventional urodynamics in evaluating bladder capacity, maximum detrusor pressure, detrusor overactivity, and PVR. For children with refractory monosymptomatic enuresis, AUM may help clarify its aetiology, although further studies validating these findings are required [82].

Conclusion: Video-urodynamic studies in children with non-neurogenic urinary incontinence are only indicated in rare cases (LoE:3)

Recommendation: Video-urodynamic studies should not be routinely performed in the evaluation of the child with non-neurogenic urinary incontinence unless significant additional information is expected from the study. (GR:B)

7.3. Cystoscopy

In the majority of children cystoscopy is not indicated. In boys with therapy resistant LUTS, an abnormal flow pattern, especially in combination with a history of (recurrent) UTI, is suspicious of infra-vesical obstruction such as bladder neck obstruction, urethral valves, syringocele etc. A VCUG may not always show these abnormalities and pressure flow curves may be equivocal [86].

For boys with mild posterior urethral valve type I at the anterior urethral wall, there was an association with refractory urinary incontinence and/or nocturnal enuresis [84]. Hence, for boys presenting with symptoms without success in management, a diagnosis of posterior urethral valve should be considered as cystoscopic ablation of these valves may improve incontinence with low uroflow rates[85].

In girls the flow may be directed upward, indicating an abnormal meatal position or stenosis. A dorsal meatotomy generally solves this problem. It has been postulated that in girls the abnormal direction of the stream triggers the bulbocavernosus reflex resulting in dysfunctional voiding [87].

Conclusion: Cystoscopy is not indicated in the majority of children suffering from urinary incontinence (LE:3)

Recommendation: Cystoscopy should only be performed if there is suspicion of infra-vesical obstruction in boys and in girls with clear anterior deviation of the flow. (Gr: B)

III. CHILDREN WITH NOCTURNAL ENURESIS

Nocturnal enuresis (bedwetting) is a complex, heterogeneous disorder, with multiple pathogenetic factors treated by multiple disciplines. Progressive unravelling of the complexity has led to different terminology papers (ICI & ICCS, versus DMS IV)[1-7] in the past decades, adding confusion to the topic. This panoply of terminology publications is a major barrier to integrate the existing literature, since different authors are referring to different standardisation papers, even within the same decade. This ICI update largely tries to keep as much as possible the same definitions and structure of the chapter of the previous ICI consultations to avoid further confusion, [8], integrating recent ICCS standardisation papers [5]. The DMS III-IV derived standardisation papers on enuresis should be disregarded because they add more confusion to literature, as they overemphasize certain psychiatric characteristics, and do not adequately consider a multidisciplinary approach[9].

1. DEFINITION

Nocturnal enuresis (NE) is involuntary loss of urine during sleep in children over 5 years of age in the absence of congenital or acquired defects of the central nervous system [5, 10].Parental concern and child distress affect the clinical significance of the problem, as well as the urgency for initiation of therapy [7, 11]. This is certainly time, country and culture dependent ([12, 13]. Most children who wet at night after age five are nowadays considered as patients with enuresis[5]. The decision to initiate a diagnostic and therapeutic approach for an individual with NE has to take into account that several factors including the child's development level may play a role. The age criterion of five is not only epidemiology driven, but reflects the natural course of achieving bladder control[9, 13, 14], as well the maturation of the circadian rhythm of diuresis [15-22]. Epidemiology demonstrates that girls acquire earlier continence than boys, a gender difference that disappears after the age of 10 years [14, 23, 24]. Research on pathophysiologic characteristics has demonstrated that both nocturnal diuresis volume and bladder dysfunction might play a role in this gender difference [15, 16].

Conventionally enuresis patients are classified into

- **Monosymptomatic NE:** bedwetting without daytime symptoms.
- **Non-monosymptomatic or polysymptomatic NE:** describes children not only with both day and nighttime wetting [25], but also, according to the latest ICCS and ICI standardisation, patients with nighttime wetting and daytime symptoms other than daytime incontinence (LUTS) [4, 5, 7].

This subtyping is widely accepted to be essential for appropriate diagnostic and therapeutic approach in first line[26], but suffers from

some limitations. There is a large overlap in pathogenesis between the two archetypes. All patients with NMNE have apparent underlying bladder dysfunction, but this does not exclude other factors involved in pathogenesis of the individual patient. Identifying LUTS is largely dependent on the quality of the intake questionnaire, and the added value of a voiding diary, as well if screening was done during normalized fluid intake or not. This has led to a shift in literature, where 2 decades ago, it was widely accepted that NMNE was only present in a minority of patients; it has become evident in the more recent studies that NMNE has the higher prevalence.

2. SEVERITY

Nocturnal enuretic patients vary in wetting frequency. Variations are even seen per week and per season. Although fifteen percent wet each night, most children wet less frequently [5, 27] . Devlin described the frequency in an Irish population : 33 % < once per week in, 11% once per week and 25 % 2 to 4 times per month [28]. Some children and parents are concerned about an occasional wet bed, while others accept regular wetting. We advise to follow consequently . the ICCS definition to qualify the severity of enuresis as frequent (>4 per week) or infrequent (<4 per week), to homogenize literature and future studies[5]. Severe bedwetters at the age of 5 years have a poor prognosis, with a spontaneous regression-rate of only 50-60% [24]

3. PREVALENCE

Bedwetting is common. Prevalence data on MNE, or MNE versus NMNE are not known since most epidemiologic studies are in fact only delivering data on enuresis, and all fail to be in line with the recent ICCS- ICI definitions on MNE/NMNE. Historical data estimated that in the United Kingdom approximately 750,000 children and young people over 7 years regularly wet their bed and in the United States 5 to 7 million children regularly experience primary NE [29-31]. If prevalence has decreased remains questionable, since only few quality epidemiologic studies are recent [32].The prevalence of bedwetting might vary regionally[33, 34]. We should be aware that self-reporting in online surveys will always underestimate the real problem, because it is considered taboo in the majority of cultures[32, 33].

In China, where parents take children out of diapers earlier, bedwetting seems to resolve more quickly. The proportion of children attaining nocturnal urinary control before age 2 was 7.7%, by age 3 this had increased to 53%, and by age 5 to 93%.The overall prevalence of NE was 4.3%, with a significantly higher prevalence in boys than girls. [35] This suggests that structured awakening and toileting is effective prevention for monosymptomatic NE, even in small children. [23, 24, 36].

Bedwetting becomes less common with advancing age. In the West, 15 per cent of children each year develop nocturnal bladder control[10]. By adulthood, bedwetting is rare. Hirasing et al sampled over 13,000 adults [18-64 years] and found only two decades ago an overall prevalence rate of NE at 0.5%[37]. Of these, 12 percent of men and 29 percent of women had daytime incontinence. Despite persistence of wetting into adulthood, 50 % of men and 35% of the women never seek help for their problem. The enuresis prevalence of 0.5% in otherwise healthy adults in Hirasing's study refers to a largely untreated population. Fifty percent of the men had primary enuresis and had never been consistently dry at night. Assuming a prevalence of enuresis of 8 percent in 7-year-old boys, the risk for an enuretic boy to remain so for the rest of his life is 3 percent.[28, 38, 39] CK Yeung documented that the severe cases had only a spontaneous regression-rate of 50-60 % [36]

Adults with enuresis represent a "hard core" group with worse symptoms[24, 37, 40, 41]. These individuals are likely to have associated LUTS during daytime. Goessaert documented that in patients with long-term follow-up, up to one third of the patients persisted to have symptoms into adulthood, especially in a subgroup with nocturia ($p<0.01$) [42]

4. INHERITANCE

Bedwetting runs in the family of many children who suffer from bedwetting. In one study, a positive family history was found in 94 families (23%) of 411 probands with PNE, including 49% of fathers, 9% of mothers, 6% of both parents, 6% of the siblings and 30% of grandfathers or grandmothers. Among the probands the ratio of male to female was 1.3:1 excluding sex-linked inheritance. Family studies indicated autosomal dominant inheritance in 15%, and autosomal recessive inheritance consistent in 1.5% of families (19). Thus, the mode of inheritance is usually autosomal dominant. If both parents were nocturnal enuretics as child, the risk for their children to be enuretic is between 65 to 85 % .[10, 43] If only one parent has NE the risk is about 45 percent [44], Molecular studies have clearly shown that NE is a complex disease with locus heterogeneity and no clear genotype-phenotype association.

Linkage studies to determine the location of the genetic changes have suggested foci on several genes. Linkage studies to markers on chromosomes 4p, 8q, 12q , 13q and 22s demonstrate both clinical, as well as genetic heterogeneity in nocturnal enuresis [45-49]. So far, there has been no reported association of the genotype with a particular phenotype of enuresis [49]. The weak indications from genetic studies might indicate only autosomal monogenetic inheritance in a minority of cases, where in many families the predisposition might be multifactorial.

In the last decade several associations were found with renal transporters and or circadian rhythm genes[50-53]. The clinical relevance in the idiopathic enuresis patient has still to be demonstrated. Recently a Danish genome-wide association study documented common genetic variants contributing considerably to enuresis, and identified potential risk genes to play a role in sleep, urine production and bladder dysfunction[54]. The majority of genetic studies, were not appropriately subtyping into MNE/NME according to the new ICCS-ICI standardisation papers, so it remains questionable if the genetic findings really concentrate on the MNE group.

5. GENDER AND MONOSYMPTOMATIC NE

Boys suffer nocturnal enuresis more frequently [55]. Surveys of monosymptomatic NE undertaken in Great Britain, Holland, New Zealand and Ireland suggest that the prevalence for boys is 13-19% at 5 years, 15-22% at 7 years, 9-13% at 9 years and 1-2% at 16 years. For girls the prevalence rates are reported to be about half that rate: 9-16% at 5 years, 7-15% at 7 years, 5-10% at 9 years and 1- 2% in the late teenage years [9, 14, 28,56,57].. Although monosymptomatic NE is more common in young boys, by adolescence the incidence in males is the same as in females [24, 58]. This might be explained by gender difference in maturation of the

bladder, but also in renal sensitivity to vasopressin, not only in the elderly but also in children[15] [59].[60, 61]. In adults with nocturia and nocturnal polyuria gender differences are documented,however, in children with nocturnal polyuria this is not the case

6. CLASSIFICATION

6.1. Primary versus secondary nocturnal enuresis

Children who have never been free of bedwetting for 6 months have **primary NE**. **Secondary NE** is the re-emergence of wetting after a period of being dry for at least six months. A birth cohort of 1265 New Zealand children studied over 10 years by Fergusson et al found an increased risk of secondary nocturnal enuresis with age [62] . The proportion of children who developed secondary enuresis was 3.3 percent at 5 years up to 8 percent at 10 years. But all studies failed to document how many patients with secondary enuresis had absence of any daytime LUTS and/or nocturia.

In the past major attention was given to the psychological factors involved in pathogenesis [7, 63]. Secondary NE is associated with a higher incidence of stressful events particularly parental separation, disharmony between parents, birth of a sibling, early separation of the child from parents and psychiatric disturbance in a parent. Patents with secondary NE suffer more behavioural problems [44, 62, 64] [8, 65, 66]. Nowadays authors do consider the psychopathology rather as comorbidities but not as underlying primary pathogenetic factors. Both Jarvelin and Fergusson et al argue that primary and secondary enuresis are similar[62, 67]. They believe the two share a common organic etiological basis.

Other sources of secondary enuresis must be excluded prior to proceeding with treatment for enuresis. These include sleep apnoea from obstructive airway disease, obesity, constipation and infrequent or dysfunctional voiding. Treatment of sleep apnoea from obstructive airway has been shown to improve or eliminate NE in some children following surgery or medical management [68, 69]. Obesity has been associated with nocturnal enuresis both independently [70-74] 4]and in the context of sleep apnoea.[75-78]

6.2. Momo-symptomatic versus non-mono-symptomatic NE

Mono-symptomatic NE refers to those children who report no other bladder storage or voiding problems associated with wetting. Non-mono-symptomatic NE refers to bedwetting, that is associated with overt detrusor overactivity or voiding problems such as urgency, frequency and bladder holding during the day [79, 80]. This definition does not include bladder volume for age, nor OAB only overnight, neither differences in fluid intake.

This classification is widely considered to guide the clinician to the most appropriate treatment intervention in primary care. Many parents are unaware of daytime symptoms when seeking help for bedwetting and when identified these symptoms should be treated prior to intervention for the NE. 10-28% of children with NE have associated daytime wetting, and were considered according to the old ICCS standardisation[1] as NMNE . If so, these children should be considered day and night incontinent. In these cases, night time incontinence is not any longer an isolated phenomenon but part of the symptomatology of day and night time incontinence. These children are more resistant to treatment and more vulnerable to relapse [81]. These boys and girls are more appropriately managed in the context of the primary bladder problem.

7. PATHOPHYSIOLOGY OF MONOSYMPTOMATIC NE

NE stems from a mismatch of functional bladder volume overnight, nocturnal urine output and the ability of the child to arouse during sleep. Night wetting is considered normal/ acceptable until age 5. In the past 2 decades delayed maturation in one or more of the following systems resulting in a lack of stability in bladder function (OAB), or a decreased arginine vasopressin (AVP) release, were considered to play a major role in NE. It remains questionable if this can be considered as a real maturation defect. In desmopressin refractory nocturnal polyuria, more complex pathogenetic mechanisms are involved, such as abnormal circadian rhythm of different renal functions resulting in a relative increased solute excretion during the night [82-86] The third parameter is an inability to wake from sleep due to full bladder sensations [87, 88]. Combinations of all three problems may be present.

A unifying and simplistic concept with important clinical implications, is that NE is caused by a mismatch between nocturnal bladder capacity and the amount of urine produced during the night, combined with delayed or incomplete arousal response to the afferent neurological stimulus of the full bladder (Fig. 1).

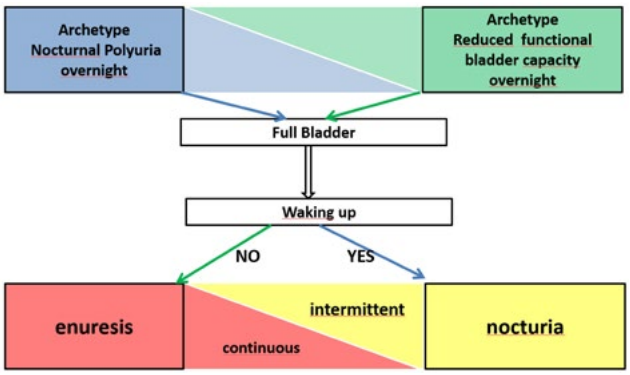

Fig. 1. Basic pathophysiology of NE or nocturia. When the bladder is full because of (relative) polyuria and/or a reduced bladder capacity, the child either wakes up to void (nocturia) or voids while sleeping (NE) . The two archetypes nocturnal polyuria and overactive bladder are well defined, but combination of both factors might be present. Additionally, it is important to stress that the enuresis and/or nocturia might be continuous ore intermittent

7.1. Increased nocturnal urine output

In normal children, the circadian rhythm of urine production results in a nocturnal reduction in diuresis to approximately 50% of daytime levels[55, 89] . In children this is the result of nocturnal release of hormones that regulate free water excretion (arginine vasopressin, (AVP)[90, 91] or solute excretion (angiotensin II and aldosterone, ANP) [92, 93] as well as hemodynamic homeostasis [94] and may result from circadian changes in glomerular filtration [95-97]. In the normal child, this results in increased urine concentration and reduced urine volume during sleep, in presence of decreased osmotic excretion. This is why children who are not enuretic sleep through the night without being wet and do not need to rise to void.

Two thirds of patients with mono-symptomatic NE [5] have been found to have a lack of circadian rhythm of vasopressin, resulting

in high nocturnal urine production, which exceeds bladder capacity [90, 98, 99]. Rittig et .l and Norgaard et al demonstrated abnormalities in the circadian rhythm of AVP secretion resulting in increased nocturnal urine output that exceeded bladder capacity in children with nocturnal enuresis [90,91, 98] .These children make more urine at night, and often overcome their bladder capacity and wet early in the night. Abnormalities can also be intrinsic, related to reduced nocturnal circadian changes in glomerular filtration rate (GFR)[95, 97]) or in sodium and calcium excretion [85, 100-103].

Detection of low plasma vasopressin levels, GFR assessments or specific sodium and calcium excretion are too difficult to measure in first line. Instead, we look for clinical signs of low vasopressin during the assessment interview. Weighing the diapers and adding the first morning void provides the total nocturnal urine output. If this total exceeds the child's functional bladder capacity this may indicate nocturnal polyuria. Nocturnal polyuria is defined as nocturnal diuresis >130% of expected bladder capacity for age, which is based on expert opinion. [104] However, the diuresis volume that might predict desmopressin response has been suggested to be >100% EBV (Expected Bladder Volume for age)[105]. Nocturnal urine output varies appreciably from night to night [61, 106], but seems larger in children with NE who respond best to desmopressin (dDAVP)[107].

By the time the child becomes an adolescent, the circadian rhythm is less prominent. In adolescents and adults with nocturnal enuresis, there is no diurnal rhythm of plasma vasopressin concentration. The changes in urine production at night occur from a decrease in the urinary sodium excretion that is not due to differences in concentration of AVP but due to a lack of sensitivity to AVP[89, 109] with resultant increased urine output[82, 110]

There may be a small sub-group of children with impaired renal sensitivity to vasopressin or desmopressin [83, 106, 111]. Recent work by Devitt et al suggests that 18 percent of children have 'normal' levels of plasma vasopressin release but remain enuretic [99, 112]. These children all failed to respond to a therapeutic dosage of desmopressin. This finding could indicate renal insensitivity to vasopressin but could also be indicative of detrusor overactivity or a small functional bladder capacity. Total urine output during the night could be helpful in differentiating between the two conditions. The archetype of patients with NE and increased nocturnal urine output generally has a favourable response to dDAVP if functional bladder capacity is normal. [4, 105, 107,113]. The archetypical patient with OAB will reduce fluid intake as a compensatory mechanism and has low diuresis volumes overnight. The combination of both also exists.

7.2. Detrusor overactivity during the night

The detrusor needs to be relaxed and accommodate to increasing volumes during filling to function appropriately. Detrusor overactivity usually causes small voided volumes resulting in a decreased functional bladder capacity [114-118].

Functional bladder capacity – defined as the largest daytime void on a frequency- volume (F/V) chart, after excluding the first morning void, may give a reasonably accurate assessment of daytime functional bladder capacity (FBC). [21] Reduced functional bladder capacity, when below 70% of the predicted FBC for age, is likely to result in a poor response to dDAVP treatment [105, 119]. Daytime bladder capacity is smaller than night time capacity in children without NE[120] .

The pattern may be different at night. Yeung et al reported that 44 percent of treatment failures [with desmopressin or the enuresis alarm] have normal daytime bladder function but marked detrusor overactivity during sleep resulting in enuresis [121]. Almost none of these children had nocturnal polyuria. Ultrasound studies of the bladder furthermore revealed an increased bladder wall thickness in these children[122,123]

Increased bladder wall thickness and bladder volume are predictive factors for the response to therapy in children with primary nocturnal enuresis. In one study, Yeung, et al[123], correlated ultrasound measured parameters and urodynamic findings. All the children with a normal bladder volume and bladder wall thickness index (BWWI%) either had a complete or good response to conventional treatment for nocturnal enuresis, whereas 62% of those with an index less than 70 % did not respond to treatment. The bladder dysfunction persisted in the 63% of children who had partial or no response to treatment. What this means is that ultrasound measured bladder parameters may segregate children, prior to management of primary nocturnal enuresis, into groups that have a favourable outcome and those that don't, following conventional treatment. These studies will become more and more important in helping to predict response of various treatment regiments in the future.

This approach may be even more important in adults with refractory monosymptomatic nocturnal enuresis. Bower, et al. [124] found that in 56 consecutive adolescents and adults compared with 293 normal adults, there were significantly higher childhood scores of urgency, frequency, urgency incontinence, infrequent voiding and small volume voids than their normal non-enuretic counterparts. This suggests that adolescents and adults with persistent nocturnal enuresis may have a more significant bladder component, particularly since the majority of patients with adult type nocturnal enuresis do not seem to exhibit the nocturnal polyuria problem seen more commonly in the smaller children.

7.3. Lack of arousal

The fundamental mechanism resulting in nocturia or NE is that the bladder fills to its capacity during sleep and needs to empty (figure 1). Bladder fullness is due to nocturnal polyuria and/or a reduction of the bladder capacity due to detrusor overactivity during sleep. Arousability differentiates patients with diuresis/ bladder volume mismatch into enuresis versus nocturia, but does not reflect underlying/ associated sleep disturbances or CNS disfunctions.

From an adult patient point of view these factors do not fully explain why the enuretic child does not wake up during the night to the sensation of a full or contracting bladder. Regardless of whether the child has detrusor overactivity or nocturnal polyuria, the enuresis event results from the child's inability to awaken from sleep to empty prior to the wetting episode. However it is important to stress that the majority of children eventually become dry, without nocturia, and this might indicate that nocturia is a defence against diuresis/mismatch, but is only present in children with high arousability. For decades enuresis was considered as synonymous with deep sleep, and lack of arousal. There was a widely held belief amongst parents and some clinicians that enuretics are deep sleepers. Many of the children exposed to alarm therapy sleep through the alarm while family members awaken. Neveus reviewed by questionnaire study in 1413 schoolchildren between the ages of six and ten and noted that enuresis was associated with subjectively high threshold arousal and significant confusion upon awakening from sleep [125]. Wolfish in a study of 15 enuretic and 18 control boys and girls found that enuretics wet most frequently during the first two-thirds of the night and that arousal attempts were less successful in

enuretics than in normals [126, 127]. This might explain why the most heavily endorsed view of both children and parents, regarding the aetiology of NE is a belief in deep sleep[128] . Recent findings suggest that the issue of decreased arousability is not the same as deep sleep[129-131], and that many patients have disrupted sleep, rather than a deep sleep [129, 130, 132-136].

7.4. Comorbidities

There is an increasing interest in comorbidities, not only coinciding with enuresis, but with common pathways in pathogenesis and/or interfering with therapy response.

7.4.1. Sleep

Sleep is more than arousal, and there is increasing evidence that sleep disturbances alone , or in combination with disrupted homeostasis play a role in the pathogenesis of nocturnal enuresis.

Enuretic episodes occur during all stages of sleep in proportion to the amount of time spent in that stage and appear to occur independent of sleep stage but occur when the bladder is at a volume equivalent to the maximal daytime functional capacity[137-140] . Bedwetting children have normal sleep but are unable to suppress nocturnal detrusor contractions or awaken in response to them or to bladder fullness.

Waking up becomes easier as the night progresses. Several authors have found that children with NE are also more likely to wet in the first third of the night, often in the first two hours following sleep [126, 127, 139, 141-145], Thus the point of bladder fullness for most enuretic children coincides with a time of night where they find it most difficult to wake from sleep, and not always when there is already an apparent diuresis / bladder mismatch . Maybe the high filling rate (diuresis rate) is more important than the absolute diuresis volume overnight as a reason to induce OAB overnight.[20]

Recently it was documented that enuretic children did not exhibit deep sleep, but rather a disturbed sleep with increased PLMS, cortical arousals, and awakenings [130, 133-136] both in patients with refractory enuresis as in children with monosymptomatic + nocturnal polyuria.. Polysomnography studies documented a significant difference in PLMS index, arousal index, and awakening index compared with healthy control subjects. The presence of sleep fragmentation does not exclude a high sleep pressure or high arousal threshold. The role of sleep fragmentation in children with NE was earlier emphasised using sleep actigraphy [146]. There is evidence that superficial sleep, was coinciding with neurocognitive dysfunctions[147-149], thereby undermining earlier opinions that sleep patterns of children with NE are not different from controls. [133, 136] . These neurocognitive dysfunctions were already documented in the past. In patients with enuresis treatment of enuresis resulted in amelioration of sleep quality and neurocognitive functioning[136].

Obstructive airway syndrome (OSAS) causes nocturnal polyuria in both children and adults, eventually resulting in enuresis[75, 150]. The prevalence of this NE subtype in patients primarily presenting for enuresis is not known, but the anti-enuretic response to OSAS therapy suggests that in refractory cases this might be considered[68, 75-78, 151, 152]. However there seems to be no indication for this therapy in children without clinical apparent OSAS.

In conclusion, albeit there is little doubt that sleep and/or arousal plays a role in the pathophysiology of NE the clinical relevance and possible implications are still unclear and so far sleep investigation is not part of the routine evaluation of enuretic children.

Conclusion: The clinical implication of sleep investigation in the screening of children with NE is not yet proven in prospective clinical trials. In children with refractory NE investigation of sleep is advocated (LoE: 3)

Recommendation: Investigation of sleep disorders is recommended in children with refractory NE (GR:C)

7.4.2. Neurocognitive comorbidities

Several neurocognitive comorbidities, coincide with nocturnal enuresis and might play a role, not only in pathogenesis but certainly in therapy resistance, such as psychological/behavioural problems, attention deficit disorders, and neurocognitive dysfunctions.

Psychological comorbidity among children with functional urinary incontinence is high: 20-30% of children with nocturnal enuresis (NE), 20-40% of children with daytime urinary incontinence (DUI), and 30-50% of children with fecal incontinence (FI) have clinically relevant comorbid disorders[8, 153-165] Both internalizing and externalizing characteristics are represented [162, 166-168]. The best documented comorbidity conditions are attention deficit/hyperactivity disorder (ADHD) and oppositional defiant disorder (ODD) [169]. Attention deficit disorders coincide with higher prevalence of enuresis (both MNE and NMNE), where the prevalence of ADHD in the enuresis population is up to 4 times higher than the background population[170]. The association of abnormal prepulse inhibition (Startle reflex) in both ADHD and enuresis patients, might suggest a common central nervous pathogenic pathway but is far from fully understood.[171-174] The observation that interpeak latencies of the brainstem evoked potentials were increased in children with nocturnal enuresis, suggests a maturational deficit of the brainstem present in children with nocturnal enuresis. Differences in visually evoked potential latencies might point to a reason behind functional cortical differences in children with a family history of nocturnal enuresis [175]. Freitag's study would suggest that a maturational effect is present;[176] however, overnight studies in enuretic children with simultaneous sleep electroencephalographic and cystometry have revealed marked detrusor overactivity, only occurring after sleep at night and not during wakeful periods during the day [176] Because this pattern has not been observed in normal non-enuretic subjects, even during the newborn period, one may hypothesize that this could be due to a small neurologic lesion affecting a tiny area in the vicinity of the pontine micturition centre, the posterior hypothalamus (responsible for secretion of antidiuretic hormone) or the locus coeruleus which may be the cortical arousal centre [177,178]

Baeyens et al.[171] documented significant differences between children with enuresis and control groups, including the startled eye blink reflex which improved with maturation but did not seem to correlate with resolution of enuresis.

But these research lines were stopped and replaced by FMRI-imaging studies[179-181], without conclusive observations at this moment.

7.4.3. Constipation

The coexistence of LUT symptoms and functional constipation and/or faecal incontinence in children is not uncommon and was previously identified as 'Dysfunctional Elimination Syndrome' (DES) [164-166,182-184] and 'Bladder and Bowel Dysfunction' (BBD) in the ICCS paper[182]. Although the association with dysfunctional voiding, decreased voiding frequency and underactivity is obvious, there is also a clear comorbidity between bladder overactivity (urge), increased voiding frequency, bladder underactivity and con-

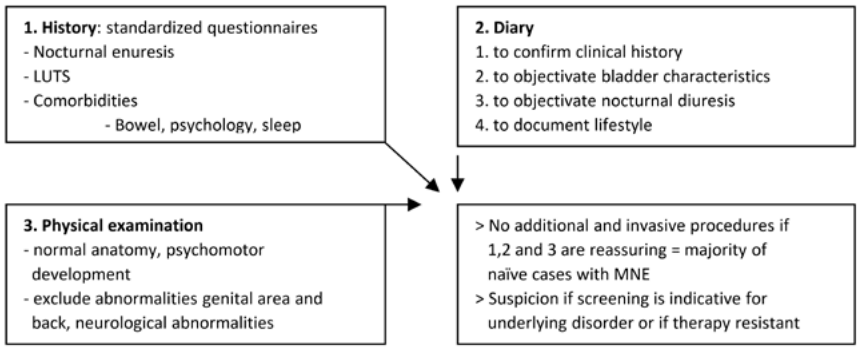

Fig. 2 : Schematic work-up in patients presenting with night-time wetting

stipation. It is well-established in clinical practice that treatment of defecation problems in children with BBD enhances successful management of lower urinary tract disturbances such as daytime urinary incontinence (DUI), enuresis, and urinary tract infections (UTIs) [66, 183, 185, 186]. Treatment of the bowel dysfunction often results in amelioration of the voiding disorder and should be first line treatment[187]. It is less obvious from the literature if there is a difference in enuresis response between MNE, and patients with OAB with and without dysfunctional voiding, since in the majority of studies the new standardisations were not used.

Conclusion: treatment of constipation is effective in the therapy of NE (LoE:3)

Recommendation: constipation should be treated primarily in children with NE.(GR:C)

7.4.4. Mentally and motor disabled

Enuresis has a higher prevalence in mentally and motor disabled patients. Von Gontard studied a variety of syndromes and subpopulations[155, 158, 161, 188-193]. Such comorbidities might have common pathways in the pathogenesis of enuresis including abnormalities of circadian rhythms, sleep disorders, and bladder dysfunction, and might predispose to therapy resistance. Still initial diagnostic and therapeutic approach does not differ from normal developed children suffering enuresis. Many of these children have underlying or associated bladder dysfunctions , but some may suffer classical nocturnal enuresis . As maturation level and cooperation is retarded, initiation of appropriate therapy might be postponed [19].

8. MANAGEMENT OF NOCTURNAL ENURESIS

The age at which the child and his or her parent begins to be concerned about bedwetting varies. Hjalmas, et al. noted that, “for successful treatment of nocturnal enuresis, the child must be brought to the physician by the parents who are concerned and the physician must have the necessary knowledge about the condition and be motivated to start treatment” [55] . In order to fulfil the requirements, parents, teachers, and nurses in primary care need to understand nocturnal enuresis and be ready to treat the child, regardless of age according EBM based guidelines, and not based on the often misleading information found on the internet. Demystification remains a big hurdle not only for patients/parents but also for caregivers in primary care. In such settings, it is important to ask the right questions and be compliant with LUTS questionnaires and diaries.

Nocturnal enuresis is thought of as a social problem and less as a medical problem. Since the majority of children stop wetting as they mature and as there are no persisting health problems associated with enuresis, there is a tendency for many practitioners to take a “wait and see” approach. Too many parents and medical caregivers underestimate the problem for the child. [194] .

The actual timing of treatment for nocturnal enuresis may vary depending on the needs of the child and the parent. It is essential that both the child and his or her parents understand bedwetting pathophysiology and treatment philosophy. The clinician should give the child general advice on proper dietary and fluid behaviours, as well as instructions to void regularly during the day, abstain from drinking too much during the late afternoon and evening and have relaxed routines at bedtime. The clinician should stress that NE is common and usually represents a delay in maturation without any psychopathological undertones. Up to 19 percent of children will become dry within 8 weeks following the initial consultation without any further treatment besides good counselling [55, 195, 196].

8.1. Evaluation and intake

This paragraph has some overlap with the previous chapter, that was drafted for all LUTS symptoms, but we concentrate here on patients primarily consulting for bedwetting and not for daytime incontinence. In the past decades several attempts have been made to standardize the qualitative intake of patients, although there has been limited uptake into primary care. Hjalmas recommended a careful history which we will summarize in these next few paragraphs. (Fig 2, Table 1). This approach, which has been recommended by the International Children’s Continence Society, provides an excellent guide toward the taking of a history for a child with nocturnal enuresis, with few adaptations over time[4, 55, 197-199].

8.1.1. Frequency volume chart (FVC)

Parents are asked to record a two-day three-night record. This includes recording the child’s fluid intake and urine output, frequency of micturition and the frequency and pattern of voiding. The largest single micturition is considered the functional bladder capacity. This chart can be performed beginning on a Friday evening and concluding on Sunday on any weekend[4].

8.1.2. History: Symptoms of nocturnal enuresis[4, 80, 199].

A careful history should include questions about the age of onset of nocturnal enuresis, length and circumstances of dry spells, number and time of episodes of nocturnal enuresis or nocturia, presence of

Table 1. Clinical management tool for diagnostic workup of nocturnal enuresis

	history	diary
Enuresis nocturna		
night time episodes only	Y/N n = /w	Y/N n = /w
nocturia	Y/N n = /w	Y/N n = /w
Exclusion daytime symptoms

daytime voiding symptoms or urinary tract infection, posture while voiding, daytime and evening fluid intake, sleep habits, frequency and consistency of bowel movements and psychosocial situation. One must establish whether or not symptoms represent primary or secondary nocturnal enuresis. It is critical to search for new psychological problems that might cause secondary nocturnal enuresis, particularly when the child presents with nocturnal enuresis after a prolonged period of dryness. The personality of the child, family situation, school environment, and presence of alternate care givers might have an appreciable impact on voiding habits and will influence management options[55] . Children may drink large volumes of fluid in the hours before sleep and this may result in nocturnal enuresis or nocturia.

It is helpful to determine the number of hours of sleep and to compare this to standard charts of average duration of sleep by age. Morning fatigue may be the result of obstructive sleep apnoea or restless legs syndrome. Other symptoms of sleep apnoea include mouth breathing, snoring, and restless sleep [4, 55]. More attention should be given to sleep hygiene: Is the child drinking, eating prior to sleep?. Is the child voiding just before bedtime? Is the light turned off immediately after going to bed? Is the child afraid to go to the toilet alone at night?

It is important to rule out symptoms of anatomical or physiologic urologic conditions that may lead to nocturnal enuresis. Many of these conditions are covered in other parts of this section, and include a failure to store urine or failure to empty urine. Storage symptoms include increased frequency, urgency, and urgency incontinence including squatting behaviour, daytime incontinence and the sensation or need to void again. The clinician must carefully assess daytime wetting, particularly in older children. In many cases, the child may hide these symptoms from the clinician and the family.

Children void four to seven times a day or about every two to three hours[4, 105, 200] . If the child is voiding significantly more frequently than eight or more times a day, this may suggest incomplete emptying or overactive bladder symptoms. Urgency is present in many children and posturing, including squeezing or crossing the legs, squirming while standing or sitting, or physically compressing

the genital area with a hand are all suggestive of overactive bladder due to detrusor overactivity which may or may not be associated with dysfunctional voiding. Other causes include urinary tract infection, polyuria from diabetes mellitus or diabetes insipidus, which can also cause more frequent voiding [55]. Treatment for these symptoms is covered in other sections within this chapter.

Additional symptoms during the daytime include continuous dribbling between voids that can come from an ectopic ureter bypassing sphincter mechanisms, or from failing to empty the bladder or from sphincter incompetence. Also continuous leakage can result from neurologic causes or anatomical causes such as epispadias, or a closed bladder exstrophy or urogenital sinus.

Children may have incomplete emptying from true dysfunctional voiding which results from the sphincter or pelvic floor contracting at the same time as the detrusor contracts during micturition. In addition, detrusor underactivity may result from neuropathy from diabetes mellitus and in some cases conditions such as prune belly syndrome will result in detrusor underactivity. Lastly, urethral strictures may result in incontinence due to detrusor overactivity with poor bladder emptying. Boys with posterior urethral valves or Cobb's collar may also have incomplete emptying. The clinician should be alert for symptoms of constipation and faecal incontinence[201]. It is a common misconception that if a child is stooling once per day then he or she is not constipated. In fact, the most specific symptom of constipation is the infrequent or painful passage of small, hard pellet-like stools. Faecal incontinence may also be present, the principal sign of this being faecal material in the underwear. Excessive stool retention may result in bladder dysfunction. In these cases[202] , this may result in increased urethral sphincter and pelvic floor activity and explain the association of voiding dysfunction with incomplete voiding. Treatment of constipation may result in improvement in enuresis [187].

Several guidelines have tried to standardize clinical management tools (CMT). All CMTs have their benefits and their limitations. It is always a balance between feasibility (short) and optimization (long CMT's). The one described in the previous ICI-consultancy is still up to date to differentiate NMNE from MNE. (table 1.)

8.1.3. Physical examination

Anatomic and behavioural causes for enuresis may be identified through a careful physical examination. Evidence of improper gait, spinal deformities, and foot abnormalities including asymmetry, high-arched feet, or hammer toes are signs of sacral neuropathy. Physical signs of occult spinal abnormalities such as dimples, tufts of hair, skin discoloration, lipoma, asymmetrical buttocks and gluteal clefts are also important. A careful abdominal examination with particular emphasis on the left lower quadrant may identify the colon full of firm stool. In most cases, a rectal examination is not performed but in some cases this may also be indicated. Occult fecal impaction, poor perineal sensation and reduced anal sphincter tone can be indicative of neuropathy.

In boys, marked narrowing of the urethral meatus (when the meatal lips are separated and no mucosa is seen), must be identified and carefully noted. If these signs are present, the boy should be asked to void so the clinician can witness and record the flow rate and residual urine. Narrowed or displaced urinary stream is suggestive of meatal stenosis.

In girls, the introitus should be identified for the position of the urethra and the existence of labial adhesions and meatal web, which can be a cause of vaginal voiding. Evidence of wetting or irritation of the labia or vagina should be identified, as this could be suggestive of post-void dribbling or incomplete emptying with incontinence due to either detrusor overactivity or sphincter weakness [5, 182].

8.1.4. Laboratory examination

There is very little laboratory examination that is required in patients with nocturnal enuresis other than a urinalysis to rule out UTI and evidence of glucosuria and a urine culture if the urinalysis is suggestive of infection[55].

8.1.5. Urodynamics and imaging

Urodynamics and imaging have no place in the initial intake and therapeutic approach of a child with monosymptomatic nocturnal enuresis. If there is any suggestion, however, that daytime wetting is occurring, a full evaluation of the daytime problem should precede the evaluation for nocturnal enuresis.(see later discussion)

Conclusion: Urodynamics and imaging are not indicated in the diagnostic evaluation of monosymptomatic nocturnal enuresis (LoE:3)

Recommendation: Urodynamics and imaging are not recommended in the diagnostic evaluation of monosymptomatic nocturnal enuresis (GR:B)

9. THERAPY

The management of NE depends on:

- the child's motivation to participate in treatment
- exclusion of confounding psychosocial factors
- providing information and instruction about daily habits, underlining the importance of having regular fluid intake, regular voiding's, and relaxed routines at bedtime
- regular review of the new intervention

The therapist should convey a sense of understanding and compassion to both the child and the family. Education about the problem and a realistic discussion about the prognosis will help instil confidence in the treatment offered which may improve both compliance and outcome [78,107, 203-205]

9.1. Evidence based recommendations for treatment

First line treatment and preliminary steps: primary and secondary forms of nocturnal enuresis are treated the same. If faecal incontinence, constipation or daytime wetting are present, they should be treated first [182, 187, 202].

Urotherapy: All guidelines advocate urotherapy (for definition see chapter 4) as first line therapy, although the evidence in children with NMNE is low, and has been recently questioned[199, 206]. (Level of evidence: 4). However it remains rational to initially attempt to normalise the child's life-style including healthy food intake, normalized intake of healthy fluid well spread during the day , and normal toilet habits as well as initially provide urotherapy-advice.

Treatment modalities such as lifting (waking up the child during the night to void), fluid restriction, dry-bed training, retention control training, psychotherapy, acupuncture, and hypnosis are not currently recommended because of insufficient data in the literature [93-100] However, non-invasive behavioural modifications such as resisting over-hydration in the evening is an appropriate recommendation at the initiation of therapy. Normal fluid intake, well spread over the day should be advocated, to reduce osmotic ex-

cretion overnight [85]. The child must void before going to bed. Excessive protein or sodium intake should be avoided in the evening, since it will result in osmotic diuresis [85, 100, 101, 103] .

During the day the child should be instructed to void regularly, not to hold urine until the last minute, to relax during voiding and to take time to completely empty the bladder. If deemed important by the parents, a letter should be sent to the school to explain this.

Timing of treatment for the child who wets is dependent on the family's desire and the child's desire. As a good rule of thumb, children should be six to eight years of age at the initiation of therapy. Some children and families, however, may want to delay the initiation of therapy until later. Others may be ready closer to age six. It is important for the parents to know that relapses can occur. The successful treatment of children with nocturnal enuresis has a foundation consisting of realistic expectations and a motivated family [55] .

Before starting treatment, a "baseline" meeting with counselling, provision of information, positive reinforcement including reassurance that 15% of children with mild enuresis ("mild" defined as NE <4/7d per week) resolve each year, and assessing and optimizing motivation should occur first. Children are asked to fill out a calendar or chart depicting the wet and dry nights. Children became significantly drier in two non-randomized trials associated with fewer wet nights simply by focusing them more on record keeping and true reward charts [146].

Realistic expectations also include the next steps of EBM (Evidence Based Medicine), the alarm and desmopressin, where relapse free success-rates after 1 year often do not exceed 60%.

Conclusion: Urotherapy is effective in the treatment of NE (LoE:3)

Recommendation: Urotherapy is recommended in the treatment of NE (GR:C)

9.2. Alarm

The underlying mechanism of action of the alarm as a treatment for MNE remains uncertain[207],. It is presumed to cure NE by conditioning arousal and/or by reducing nocturnal bladder volume.[209, 210] [211]Furthermore, historical interpretation of the data in the literature is difficult as the new ICCS definitions, do not often allow differentiation of MNE from NMNE, according to the new standards [1, 5, 55, 104, 208].

The enuresis alarm is the most effective means of facilitating arousal from sleep and remains the most effective way to treat NE In unselected or poorly subtyped patients with enuresis [3, 212-214]. There is an average success rate of nearly 68% with efficacy increasing with the duration of therapy. Relapse rates in the 6 month period following treatment are on the order of 15 - 30 %, which is significantly lower than that for desmopressin in populations not subtyped for +/- LUTS and/or nocturnal polyuria. Alarm therapy has been shown in several reports and meta-analysis to have a 43 % lasting cure rate[34, 215-217] . .

Better results occur with optimal motivation of the child and family and higher frequency of wet nights. Reduced efficacy is associated with the lack of concern shown by the child, lack of supervision, inconsistent use, family stress, abnormal scores on behaviour system checklists, a psychiatric disorder of the child, failure to awaken in response to the alarm, unsatisfactory housing conditions and more than one wetting episode per night. Enuresis alarms require several months of continuous use and are, therefore, unsuitable for some families [4, 218, 219], because of the large burden associated with their use . Alarm therapy requires high motivation, high cooperation of the child and his family.

For optimal results, alarm therapy should be individualized; it requires a motivated family and child with significant commitment to time and effort. The impact on other family members should be considered. In some families, alarm therapy may wake other members of the family and may increase parental annoyance and place a child at increased risk for physical or emotional abuse. The caregiver and family should be aware of the burden if the alarm is activated early in the night or several times/night, especially because these are predictive to be parameters of resistance. Close follow-up is important to sustain motivation, troubleshoot technical problems and otherwise monitor the therapy [55], and identify the burden..

The exact mechanisms underlying the efficacy of alarm treatment are not known. The effects are not due to classical conditioning as stimulus awakening occurs after and not before wetting. Instead it is clearly an operant type of behavioural approach, i.e. a learning program with positive reinforcement that includes aversive elements. Dryness is reached either by waking up leading to "nocturia" in 35% of children or by sleeping through the night with a full bladder in 65%. Body worn (vibrating) alarms are at least as effective as bedside alarms [146]. The family should continue alarm therapy for at least 14 consecutive dry nights – or a maximum of 16 weeks before discarding it as ineffective[4] Compliance remains a problem and dropout rates are rarely disclosed in reported studies. Proper guidance and instructions are mandatory.

The key to success is not the stimulus intensity of the alarm triggering, but the child's preparedness to awake and respond to the signal. Comparison of the different types of alarms did not show significantly different outcomes. In general it can be stated that alarm treatment is more effective than other forms of treatment and the lasting cure rate is about twice as high .

In some cases, alarm therapy can be enhanced using the alarm in addition to other behavioural components. Overlearning (giving extra fluids at bedtime after successfully becoming dry using an alarm) and avoiding penalties may further reduce the relapse rate. [212,220, 221]

Conclusion: alarm therapy is an effective first line treatment in NE (LoE:1)

Recommendation: alarm therapy is highly recommended in children with NE (GR:A)

9.3. Dry bed training

Dry bed training is a package of behavioural procedures used in conjunction with the enuresis alarm first described by Azrin et al[222, 223] . It incorporates:

- the enuresis alarm
- cleanliness training (encouraging the child to take responsibility for removing of wet night clothes and sheets, re-making the bed and resetting the alarm),
- waking schedules – to ease arousability from sleep as described above and involving:

1. For the first night, waking the child each hour, praising a dry bed, encouraging the child to decide at the toilet door whether

he or she needs to void, and on returning to bed the child is encouraged to have a further drink
2. On the second night the child is awakened and taken to the toilet 3 hours after going to sleep. For each dry night, the waking time is advanced by 30 minutes. If the child is wet on any night, the waking time stays at the time of the previous evening. The waking schedule is restarted if the child begins wetting twice or more in any week, stating again 3 hours after sleep.

High success rates and low drop out rates have been reported although relapse rates are not different from enuresis alarm treatment alone [224, 225]. Modifications are advocated to remove some of the more punitive elements of the programme. Success-rates with group administered dry bed training is 80%. Girls respond better than boys[226] . Factors not related to success were the child's age, bedwetting frequency, secondary enuresis or family history. In another study a positive effect on behavioural problems was noted[227] .

Conclusion: Dry bed training is effective in the treatment of NE (LoE:2)

Recommendation: Dry bed training is recommended in the treatment of NE (Gr:C)

9.4. Arousal training

Arousal training entails reinforcing appropriate behaviour [waking and toileting] in response to alarm triggering. The aim is to reinforce the child's rapid response to the alarm triggering, not on 'learning to keep the bed dry'[228].

The instructions involve:
- setting up the alarm before sleep
- when the alarm is triggered the child must respond by turning it off within 3 minutes
- the child completes voiding in the toilet, returns to bed and resets the alarm
- when the child reacts in this fashion he is rewarded with 2 stickers
- when the child fails to respond in this way the child pays back one sticker

The initial study by Van London demonstrated significantly higher success-rates than in single alarm therapy., The authors conclude that arousal training is 'definitely the treatment of choice for enuretic children between 6 and 12 years'. Compared with other studies, and considering the experience of daily practice, one may question the very high success rate in this particular group of unselected patients. The study was not confirmed in study populations where categorisation into MNE and NMNE, according to the new standardisation, was performed.

Conclusion: Arousal training is effective in the treatment of NE (LoE:3)

Recommendation: Arousal training is recommended in the treatment of NE (GR:C)

9.5. Pharmacological therapy

Based on the three main causes of enuresis, namely nocturnal polyuria, detrusor overactivity, and a disorder of arousal, pharmacological treatment can be directed towards each of these three areas.

9.5.1. Desmopressin therapy [107, 229-239]

Arginine vasopressin (AVP) or antidiuretic hormone (ADH) is normally produced in the hypothalamus and released in the pituitary in response to hyperosmolality or hypovolemic conditions. Vasopressin acts on the collecting ducts and distal tubules to enhance water absorption. AVP, by virtue of an independent vasoconstrictor effect is also a potent vasopressor. Desmopressin (or dDAVP) is an analogue of vasopressin created by deaminating the cystine residue at position 1 and substituting D-arginine for L -arginine at position 8. These changes result in significantly increased antidiuretic activity but loss of vasopressor activity. The PK half-life of Desmopressin is 1.5 to 3.5 hours, but the duration of action is longer, and there is a certain hysteresis time to activity [236, 240-242]. In the majority of children with monosymptomatic nocturnal enuresis, the normal circadian variation in urine production is disturbed if vasopressin is absent resuting in a rise in nocturnal urine production[91]. In these cases, dDAVP would seem to be particularly appropriate.

Several formulations are on the market,: rhino nasal solution, desmopressin nasal spray, desmopressin oral tablet and the desmopressin oral lyophilizate (sublingual), all characterized by rather low bioavailability, with large intra-individual variability (0.08-0.16% in adults). Only the last 2 formulations (oral tablets and lyophilized) are labelled for the indication of enuresis in children [235, 236].The intranasal form is no longer recommended for nocturnal enuresis, because of concern for water-intoxication, due to unpredictable nasal reabsorption in children.

The low bioavailability is largely related to the peptide structure, making oral /intestinal reabsorption very difficult, although the pharmacodynamic effects remain very predictable, and when used as directed, is rarely associated with serious adverse effects. It is available for the indication of enuresis as a tablet (dosage, 0.1–0.6 mg) or a fast-melting oral lyophilizate (Melt- dosage, 120–240 µg) [243]. The latter is a recommended formulation for all children and is preferred by children from 6 to 12 years [236, 244-246]. It is not affected by nasal congestion or gastrointestinal transit and does not require fluid intake. Since tablets require up to 200 ml of fluid intake, which is ~25% of a 7-year-old's bladder capacity, the Melt formulation is more suited to the antidiuretic indication of desmopressin. Good pharmacokinetic and -dynamic data are available for the Melt and its dosing in children with enuresis [236, 247][58].

Recently PK/PD studies in young children documented different PK/PD characteristics in children and that size-dependent dosing might be necessary in younger age groups.[240]

Some patients have a delayed response and a small group of children who do not respond to desmopressin in ordinary dosages will become dry when the dose is increased. It is recommended that such off label dosing be limited to expert centres [248, 249]. Desmopressin may be particularly beneficial in the child with limited numbers of wet episodes per week. Some clinicians suggest the administration of desmopressin in particular situations such as added security on special nights during a sleepover, etc. However, there is no sound medical evidence for this practice as intermittent regimens have never been proven to be beneficial. [105]

Children with nocturnal polyuria respond the best to desmopressin [82, 105, 250]. ICCS defines nocturnal polyuria >130% of expected bladder capacity for age, but the DRIP study showed that diuresis lower than 60% of EBV is likely desmopressin resistant, where diuresis >100% of EBV has a 60% response-rate[5, 105, 136].[245]

The efficacy of desmopressin in the treatment of enuresis is well documented[83, 231, 232, 251]. In a Cochrane Library analysis 17 controlled trials all showed superiority of desmopressin compared to placebo regardless of the route of administration [233, 252] Up to 70% of the MNE enuresis population might have full or partial response to the drug [136]. The response to desmopressin is highly dependent on factors such as nocturnal urine production and bladder capacity. The few studies that have tried to compare different doses of the drug reveal comparable efficacies[230, 253-255] Several key issues should be taken in consideration when the drug is prescribed. 200 to 400 mg tablets are considered bioequivalent to 120-240 µg melt and are the therapeutic range for children between with MNE from 7 to 18 years. The recently documented size relationship to dosing could mean that higher doses may be needed in larger children [240, 245]

Optimal response is expected if desmopressin is taken 1 h before the last void before bedtime to allow for the timely enhanced concentration of urine to occur. Fluid intake should be reduced from 1 h before desmopressin administration and for 8 h subsequently to encourage optimal concentrating capacity and treatment response, as well as to reduce the risk of hyponatremia/ water intoxication[107, 233, 236, 244]

Desmopressin is only effective on the night of administration; therefore, it must be taken on a daily basis. Full adherence is required to avoid wet nights. Desmopressin acts immediately, but in our expert opinion, the initial duration of treatment should be for 2–6 weeks, to ascertain its anti-enuretic effect [4]. If a sufficient degree of improvement is experienced, treatment can be continued for an additional 3 months—where appropriate. Country-specific regulations regarding treatment breaks should be followed. If patients are dry on treatment after this initial period, breaks are recommended to ascertain whether the problem has resolved and therapy is no longer necessary. If the child does not achieve complete dryness, or if wetting resumes once treatment is withdrawn, it should be continued or resumed. There is some evidence that structured withdrawal of medication may reduce relapse rates following its discontinuation[256, 257] . Desmopressin is well tolerated, but clinicians should be aware that it is a potent antidiuretic and families must be educated regarding the rare possibility of patients developing hyponatremia/water intoxication with symptoms including headache, nausea, and vomiting [235]. Self-titration of medication should be avoided (opinion).

Adherence to the management plan, especially for a drug whose action covers only the night after intake, is important. It is estimated that ~30% of non-responders are not taking medication correctly [204, 205, 258]. Non-adherence to recommendations regarding timing of medication, voiding before bed time, and limitation of evening fluids can decrease treatment success[259] . Moreover, compliance is often overestimated, both by patients and clinicians; therefore, it should be documented in a diary. Regular contacts between caregiver and patient are necessary to keep up compliance. Patients who appear treatment-resistant should be advised of the importance of full adherence and asked if they have had any difficulty with complying with recommendations. It is important that in divorced families, information has to be given to both parents, so that the treatment is appropriately given on daily basis

Desmopressin has higher success rates in children with large bladder capacity and nocturnal polyuria [60, 105, 260]. Initial studies reported response rates of >70%, but subsequent more recent studies suggest that the response rates are lower, in the 20-30% range. The earlier studies may have included occult OAB patients with small bladder volume and low nocturnal diuresis volumes. [261]

Still, there remains several unanswered questions regarding desmopressin therapy. It is unclear whether desmopressin treatment leads to better long-term outcome than the spontaneous resolution rate. Nevertheless, some studies have shown that the long-term cure rate of 15- 30% annually with desmopressin is higher than the spontaneous resolution rate [232, 251, 262]. Long-term follow up has shown persistent LUTs symptoms in the patients with NMNE but not in the MNE patients[42]. Finally, the notion that tapering of the dose and a structured withdrawal program should be beneficial is still unproven[256, 263] .

Desmopressin: Tolerability and Safety :
Considering the world wide prescription-rate, desmopressin is an extremely safe product, if correctly dosed and fluid intake is withheld after administration.[235, 264]. It is clear that dDAVP is a potent antidiuretic drug and that there have been reports of severe water retention with hyponatremia and convulsions, but these are infrequent [249, 253, 265-274]. Since the withdrawal of the nasal spray from many markets, reports of water-intoxication with desmopressin as the melt or tablet form, at correct doses, have been rare, it is important to stress that the drug should be correctly administered near bedtime as noted above, since every year there are reports of children taking it inappropriately in the morning.

Furthermore, earlier ICI-advice regarding a fairly rigid regimen of water restriction must be enforced for the two hours prior to bedtime and to allow one eight-ounce (300 ml) glass of water at dinner and nothing for the two hours prior to bedtime. [266, 271, 275].

The results of numerous clinical trials have shown that desmopressin is well tolerated even during long-term treatment and associated with a low risk of adverse events. [235]

Predictors of Response:
The highest response rate is in older children, with less severe bedwetting, nocturnal polyuria and larger functional bladder volumes. A low diuresis-volume, <60% of EBV overnight is highly predictive of desmopressin resistance. This is logical, since low diuresis-volume coincides with the presence of maximal concentrating activity of the kidney, where desmopressin is unlikely to have additional physiological value. [79,105,246, 251, 253, 264, 276].

However, relapse after short-term treatment is common. [251]. This suggests that desmopressin, by reducing the urine output overnight, reduces nocturnal enuresis but does not significantly affect the resolution rate over time above the spontaneous cure rate. Tapering during withdrawal might decrease relapse rates [263, 277]

Conclusion: Desmopressine treatment with the melt and tablet formula is a safe first line treatment of NE (LoE:1)

Recommendation:Desmopressine melt and tablet formula are recommended in the treatment of NE in children (GR:A)

9.5.2. Combined treatment with alarm and desmopressin

Combined treatment may be superior to the use of the alarm alone , especially for non-responders of each individual treatment. In this approach, treatments are started at the same time: the rapid action of dDAVP is believed to facilitate the child's adaptation to the alarm [278-283]. After 6 weeks the dDAVP is discontinued while the alarm treatment is continued until the child becomes completely dry.

Compared with either therapy alone, the combination is particularly effective in children with high wetting frequencies and behavioural problems.

Full-spectrum therapy, a combination of alarm, bladder training, motivational therapy and pelvic floor muscle training may even yield higher success rates[278, 284-287]. Since alarm plus Desmopressin was not more successful in the long-term, combination therapy cannot be recommended as a primary strategy in the vast majority of MNE patients. [288].

Conclusion: Combination therapy is effective in the treatment of NE (LoE:3)

Recommendation: Combination therapy is recommended in the treatment of NE in children (GR:C)

9.5.3. Anticholinergic / antimuscarinic drugs for OAB

Anticholinergic drugs are widely prescribed in monotherapy as well as in combination therapy. Oxybutynin, propiverine, tolterodine, and solifenacin have sufficient PK/PD data to be prescribed safely in children, while some others are under study. Paediatric labelling is mainly restricted to OAB in neurogenic and non- neurogenic bladder dysfunction and are often country dependent. None of the current OAB medications fulfills the criteria for evidence as first line therapy for nocturnal wetting in children, although there is some evidence for the treatment of daytime symptoms.

Since antimuscarinic drugs can in theory only be efficacious in children with monosymptomatic nocturnal enuresis, with underlying overactivity of the bladder, they cannot be considered as first line therapy. The observed responses might be related to considerable underdiagnosis of LUTS and non monosymptomatic nocturnal enuresis or isolated overactive bladder at night. [289]. Antimuscarinics are also indicated as treatment for combined day- and night-time incontinence [111, 290, 291] .

In general, antimuscarinic drugs are well tolerated but there are some side effects, namely vasodilation, dryness of the mouth, constipation, vertigo (rare), and symptoms of hyperactivity and concentration disorders, especially in children with ADHD. These side-effects are more predominant with oxybutynin than with the more contemporary anticholinergics. Use of antimuscarinics may lead to constipation that may aggravate detrusor overactivity and thus counteract the beneficial effects of the drug. Antimuscarinics may also result in increased residual urine volumes which may make it difficult for the child to empty prior to bedtime. Although there is no evidence in MNE populations, it is important to monitor post void residual and constipation in such patients following initiation of therapy with these agents.[7, 292]

The combination of alarm and anticholinergics should be considered if overactive bladder is suspected. If the alarm is set off several times per night, indicative of overactive bladder, this combination has been proven to be successful.

Conclusion: combination of an alarm and anticholinergics are effective in the treatment of children with NE with suspected bladder overactivity (LoE:3)

Recommendation: the combination of an alarm and anticholinergics is recommended in children with NE and suspected bladder overactivity (GR: C)

In those children who have NE due to isolated nocturnal detrusor overactivity, treatment with an antimuscarinic drug should be considered. Because it is impractical to perform cystometry at night in these children to make the diagnosis of detrusor overactivity/OAB, the clinical evidence for such a diagnosis is generally considered to be 1-2 wetting episodes per night , in the presence of desmo-

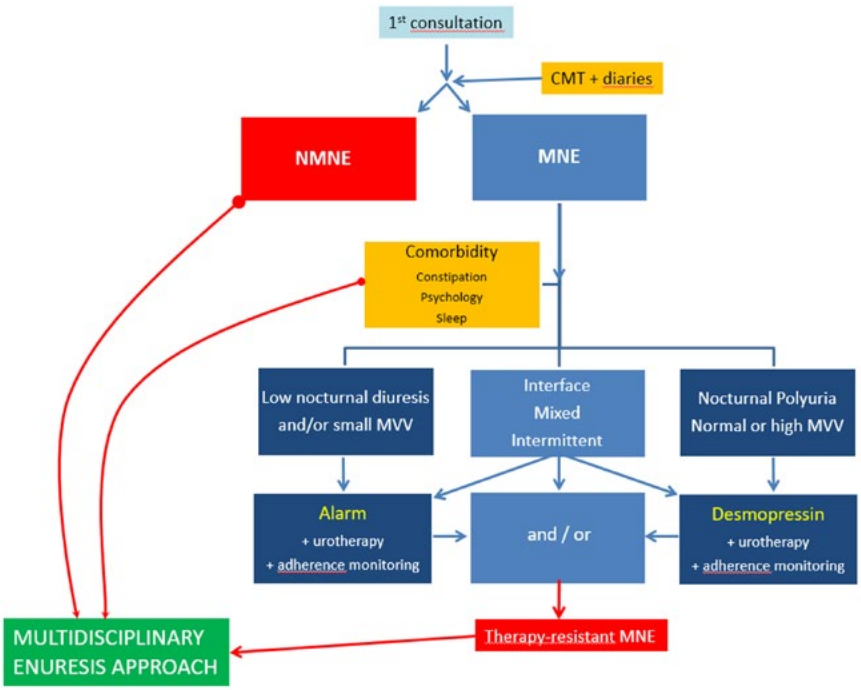

Fig. 3: Treatment algorithm for enuresis.

pressin therapeutic failure and/or the absence of nocturnal polyuria. [291,293]

Conclusion: single anticholinergic treatment is effective in children with NE and isolated nocturnal OAB (LoE:4)

Recommendation: single anticholinergic treatment is recommended in children with NE and isolated nocturnal OAD (GR:4)

9.5.4. Tricyclic antidepressants

Although tricyclic antidepressant drugs, imipramine in particular, have demonstrated efficacy in a number of children, most of the studies that recommend this drug are relatively old, and included patients that would be now likely be classified into both archetypes (NMNE/MNE). The major drawbacks to imipramine therapy are cardiotoxic side effects, in some cases even with therapeutic doses, and the possibility of death with overdose. [294].

Although treatment with tricyclic drugs is associated with a decrease of one wet night per week, the lasting cure rate is <20%[295] .

Only in selected cases (like adolescent boys with Attention Deficit Hyperactivity Disorder and persistent NE) or refractory cases should it be considered [296], but even in such circumstances, restriction to expert centres is recommended. Whether it is necessary to obtain a baseline ECG prior to the initiation of therapy remains debatable unless there is a family history of sudden death in which case it is mandatory.

Conclusion: tricyclic antidepressants are effective in the treatment of NE (LoE:1)

Recommendation: tricyclic antidepressants are recommended in the treatment of NE. Because of the potential cardiotoxicity their use should be limited to those cases refractory to all other therapy (GR:C)

9.5.5. Alternative regimens

Several other drugs, such as carbamazepine and NSAIDS (indomethacin, ibuprofen) have also been investigated. Based on study designs as well as on study outcomes, these drugs are not yet recommended for the treatment of MNE/NME [297-302] . Acupuncture, laser acupuncture and neuromodulation have also been suggested as treatment, but without sufficient evidence to be adequately assessed in the primary treatment of enuresis patients [303-308]

10. REFRACTORY MONOSYMPTOMATIC NE : [309]

About one third of children do not respond to treatment with alarm and/or dDAVP. The majority of these children are likely to have a small nocturnal bladder capacity and suffer from “detrusor dependent NE”. There are no large datasets using the latest ICCS standardisation to predict success-rates appropriately.

The majority of patients with MNE who are subsequently proven to be non- or partial responders are likely to have underlying bladder dysfunction, missed during the initial assessment, because 1) the intake evaluation was not performed appropriately, or 2) patients were classified according to the old ICCS standardisation, when according to the new ICCS-standardisation they would be considered as NME. In such refractory cases, a full intake screening should be redone. A history of diurnal incontinence, diurnal symptoms after the age of 3.5 years, too high or too low voiding frequency during the day, and postponing during normalized fluid intake are very suggestive for bladder dysfunction, as well as small enuresis volumes early in the night. Spontaneous low fluid intake is suggestive for a defence mechanism, and may mask OAB symptoms. These symptoms are often not mentioned by parents, and deserve repeated questioning or documentation in a bladder diary during a standardized fluid intake of 1.5ml/1.73m²/day. This provides additional information. Uroflow and bladder ultrasonography may also be useful. These children will benefit from a multidisciplinary approach and should no longer be treated exclusively by the primary care provider[310, 311].

In the absence of any bladder dysfunction we should concentrate on the desmopressin effect in differentiating different pathophysiologic characteristics that might be involved :

Anti-enuretic effect (= number of wet nights), the anti-diuretic effect (= nocturnal diuresis rate) and) concentrating capacity (= urinary osmolality) should all be evaluated.

Partial response to desmopressin in MNE (anti-enuretic effect) is related to persistent nocturnal polyuria on the wet nights[106]

Poor compliance should be excluded[205], including not taking the drug (consider letting the patient fill in a drug-diary and register the number of prescriptions /compliance)

In the diagnostic workup specific attention should be given to the following aspects:

-Does the child forget to void before sleeping, and already start the night with a filled bladder

-Can drinking overnight be excluded as a cause, as fluid intake overnight or even the hour before desmopressin administration reduces both the maximum and duration of anti-diuretic effect, as well as the concentrating capacity significantly. Intermittent polyuria might as well be related to the PK/PD characteristics of desmopressin [107, 244-247, 258]

The 3 formulations of DDAVP (tablet, melt and spray) have poor bioavailability, ranging respectively from 0,2-2%- 4%, but with a rather large SD resulting in high intra-individual variability. Only the melt has well established dose-response-data, proper pharmacodynamic and pharmacokinetic data in children. The melt showed superior PK and PD profile, better compliance and some indications of higher response rates. Before considering desmopressin resistance, a switch to the melt should be considered.

The child should take the drug just before sleeping time as the time to reach maximum concentrating capacity and anti-diuretic effect is 1-3 hours. Therefore, the drug should be taken at least one hour before the last void before sleeping) [110, 236, 244]

The tablet should not be taken at mealtime. DDAVP dosing should occur with an empty stomach , at least 2 hours after the last meal [110, 244, 245, 312]. However, such a dosing schedule (2 hours after the last meal, and 1 hour before sleep) is not realistic or practical in many children. This consideration favours the melt above the tablet. The melt study has demonstrated that, even in the therapeutic range of 120-240µg there are large standard deviations in maximal concentrating capacity and antidiuresis, as well as duration of

action. A better understanding of these PK/PD dynamics, can lead to more personalized approach to dosing. The PK/PD data demonstrate that at least 25% of patients might benefit from higher doses. Such patients can be identified by a pharmacodynamics test in an ambulatory setting in the individual patient (24h concentration-profile), especially in the older patients. Increasing the dose without this test is not recommended, because of the risk for toxicity.

In desmopressin refractory nocturnal polyuria with low urinary osmolality, diabetes insipidus (DI) should be excluded. X-linked DI in boys may not present with enuresis, but female carriers might have a more forme fruste pattern with enuresis as the predominant symptom. Many renal diseases (CKD, tubulopathies, renal dysplasia, uropathy, etc.) may present with enuresis. Hypertension, and especially nighttime hypertension coincides with nocturnal polyuria, and should be considered in refractory patients. Although there might be some anti-diuretic effect of desmopressin, these patients never reach maximum concentrating capacity. A desmopressin / vasopressin concentration test may be helpful if conventional diagnostic tools (ultrasound, lab) fail. It should be noted that the majority of studies on desmopressin in children with MNE, demonstrate that up to 25% of patients do not reach >850 mosmol/L after desmopressin. Although these patients do not fulfil the criteria of DI, there is a high prevalence of patients at the lower end of the normal range of concentrating capacity. Notably, a 20% decrease in concentrating capacity results in a 20% increase in diuresis and this may be the difference between continence and enuresis in many patients.

Desmopressin resistant nocturnal polyuria, with high urinary osmolality overnight might be correlated with high osmotic excretion overnight. This can be caused by an increased solute load only in the evening or during the preceding 24 hours [85, 86] . Sodium is the major osmotic agent [85, 97, 101, 313]. Although nutritional intake plays a major role, abnormalities of several circadian rhythms like prostaglandins [314-316], GFR [95, 97], blood pressure [94] and sleep pattern[129, 130, 134] have a significant impact in selected tertiary care patient populations. Extrapolation into the primary care enuresis patients remains premature. But these findings suggest a role for potential future treatment options. Some pilot studies evaluating the role of sodium restricted diet, diuretics (furosemide [101, 297, 317, 318]) , NSAID's and treatment of sleep disturbances (OSAS and melatonin) [75, 77, 319-322] have demonstrated some promising results. In the past, the role of calcium , and calcium restricted diet have been evaluated, [102, 103, 323], but other studies have suggested that such hypercalciuria might be a secondary phenomenon due to differences in diet[100, 109, 324].

Therapy resistance to conventional therapy can not only be related to underlying bladder dysfunction and/or renal response to desmopressin, but due to a number of other associated comorbidities (5). Identifying these, and addressing them if possible might increase the response rate. Constipation and faecal incontinence should be addressed before initiating other treatment for MNE but such conditions are often underestimated and underreported. Psychological comorbidities, as well internalizing as externalizing are more frequent in enuresis-patients. Attention deficit disorders, and autism are well studied and seem to have common pathways. A structured therapeutic approach is mandatory. Renal dysfunction, hypertension, diabetes mellitus and sleep disturbances have already been mentioned, but these should be treated appropriately. Many drugs interfere with the circadian rhythm of several biorhythms, including diuretics, steroids, cyclosporine A, neurotropic drugs and may be a possible trigger to set off enuresis in a sub-set of children.

Conclusion: individual analysis of the nocturnal diuresis parameters in refractory NE is necessary to optimise the treatment of the nocturnal polyuria (LoE:3)

Recommendation: in children with refractory NE, individual analysis of the nocturnal diuresis parameters is recommended (GR:C)

IV. CHILDREN WITH BOTH DAY AND NIGHT TIME INCONTINENCE

Children with lower urinary tract dysfunction (LUTD) may present with urinary incontinence, irritative or obstructive symptoms (urgency, straining during voiding), urinary tract infection (UTI), vesicoureteral reflux (VUR), and bowel problems (constipation, soiling) alone or in combination. Lower urinary tract (LUT) symptoms in school-aged children can be noted in as high as 20% of individuals and may present with a wide spectrum of severity [1]. They may just be slightly disturbing without any need for seeking professional help or have significant social consequences and sometimes clinical morbidity like UTI and VUR. This condition may also be associated with psychiatric, developmental disorders, and obesity. The most common symptom is day and night-time incontinence. There is high prevalence of constipation (30-50 %) among these patients with LUTD symptoms (LUTS). Urinary incontinence in children may also be caused by a congenital anatomical or neurologic abnormality, such as ectopic ureter, bladder exstrophy or myelomeningocele (MMC) as such and they are not within the scope of this chapter. In many children, however, there is no such obvious cause for the incontinence and they are referred to as having “functional incontinence”. This lower urinary tract dysfunction is not considered to be of any organic aetiology, but is often attributed to a developmental delay or problem. The most recent International Children’s Continence Society (ICCS) document suggests using the term daytime lower urinary tract (LUT) conditions to group together all functional bladder problems in children [2].

Normal storage and emptying of the bladder at a socially acceptable place and time is mostly achieved by age three to four. Children with LUT conditions would most commonly present with being still wet after the age of four often in the form of urge incontinence with or without weak stream, hesitancy, frequency and accompanied UTIs. Isolated night-time wetting without any day-time symptoms is known as ‘enuresis’ and considered as a different entity.

Bladder control is believed to be under the influence of the central nervous system. The pontine region is considered to be responsible for detrusor sphincter coordination while the cortical area is responsible for inhibition of the micturition reflex and voluntary initiation of micturition (detrusor over activity control). Formerly it was believed that bladder maturation followed maturation of cortical inhibition processes. Current understanding is that there is a dialogue between the cortex and pons resulting in bi-directional maturation of both and the coordinating influence on the bladder and the pons is also involved. This indicates that a condition such as detrusor overactivity would be the result of loss of cortical control or of a deficiency in cortical control, while dysfunctional voiding would be the result of non-maturation of the coordination. Detrusor overactivity should not be considered as a sole bladder-based problem but more a symptom of a centrally located dysfunction affecting bladder, bowel and even mood and behaviour [3,4,5]. Indeed, many studies indicate that there exists a link between lower urinary tract dysfunction and behavioural disorders such as ADHD (attention deficit / hyperactivity disorder) [6,7].

In the first few years of life there is an ongoing development in lower urinary system from an initially involuntary voiding pattern to a more socially conscious type of voluntary micturition control. During this ongoing evolution which includes the increase of functional bladder capacity and maturation of the detrusor-sphincter coordination a progressive development of the voluntary control over the infantile voiding reflex takes place. It is no surprise that during this complex evolution various derangements of lower urinary tract function may occur resulting with various LUT conditions with variable severity. The desire to void is a sensation which, in the developing child, is incorporated into daily life so that voiding takes place at an appropriate time and place. Variations with toilet training, developmental differences or psychological difficulties possibly have an impact on the results of training [8,9]. The positive reinforcement that the child receives by voiding even a small amount may lead to the development of an abnormal voiding pattern. The same may be true when children receive negative feedback related to voiding [8-12]. The issue remains to be controversial and the evidence is poor.

Urinary incontinence in children may be due to disturbances of the filling phase, the voiding phase or a combination of both. In the ICCS terminology document, these conditions are termed functional bladder disorders or Lower Urinary tract (LUT) conditions [2].

Filling-phase (storage) dysfunctions

In filling-phase dysfunctions, the detrusor can be overactive, as in OAB, or underactive, as in underactive bladder (UAB). Overactivity of the bladder is the most common problem which may lead to disturbances characterised by urgency, frequency and at times urgency incontinence. Some children habitually postpone micturition leading to voiding postponement. Therefore, holding manoeuvres such as leg crossing and squatting can often be seen in this group [5]. If not accompanied with an emptying disorder and residual urine, recurrent UTIs are not common. Constipation can be an additional aetiological factor, which needs to be assessed. In children with an underactive detrusor, voiding occurs with reduced or minimal detrusor contractions with post-void residuals (PVR). Urinary tract infections, straining to void, constipation and incontinence is common. Incontinence often occurs when the bladder is over-distended in the form of overflow incontinence.

Voiding-phase (emptying) dysfunctions

In voiding-phase (emptying), incomplete relaxation or tightening of the sphincteric mechanism and pelvic floor muscles results in staccato voiding pattern (continuous urine flow with periodic reductions in flow rate precipitated by bursts of pelvic floor activity) or an interrupted voiding pattern (unsustained detrusor contractions resulting in infrequent and incomplete voiding, with micturition in fractions). The general term for this condition is “dysfunctional voiding” and is associated with elevated bladder pressures and PVRs and UTIs are more common. Symptoms will vary depending on the severity of dyscoordination between bladder and the sphincter. Staccato

voiding is in less severe forms, and interrupted voiding and straining is in more severe forms. Children with dysfunctional voiding are also prone to constipation and soiling [13].

In incomplete emptying, high voiding pressures generated by the bladder working against a functional obstruction caused by non-relaxing sphincter may induce not only UTIs but also vesico-ureteric reflux (VUR). It is been shown that LUTD is more significant for the occurrence of UTI than VUR itself [15]. In the majority of children with dysfunctional voiding the recurrent infections disappear following successful treatment, which confirms the hypothesis that dysfunctional voiding is the main factor responsible for the infections. Spontaneous resolution of VUR may also be seen after successful treatment of dysfunctional voiding.

Storage and emptying dysfunctions can of course coincide and one may even be causative of the other. No evidence exists however for this last assumption. It has been postulated that detrusor overactivity may eventually lead to poor bladder emptying due to underactivity of the detrusor or severe dyscoordination between detrusor, sphincter and pelvic floor. However, the natural history of many of these children does not confirm this hypothesis, nor the early onset of severe pathology in some of them. Hoebeke et al. found no evidence for this dysfunctional voiding sequence: children with functional incontinence have different primary diseases, but all have a common risk of incontinence, UTI, VUR (15%) and constipation (17%) [14].

1. PREVALENCE

For more detailed information on the prevalence of daytime incontinence the Chapter on Epidemiology should be consulted. The main problem is that it is impossible to draw any conclusions from the presented data as different studies have used different definitions and criteria. Furthermore, it is virtually impossible to identify the prevalence of detrusor overactivity or dysfunctional voiding as the studies tended to look primarily at daytime versus night-time incontinence and made no effort to evaluate the type of daytime incontinence.

Daytime or combined daytime and night-time incontinence at least once a week seems to occur in about 2-7 percent of 7-year-old children and is more common in girls than in boys [15,16]. There are many studies in the literature looking at the prevalence of this condition and overall, the rates of prevalence vary from 1 to 20 percent depending on how the condition is defined. In general, for 6 to 7-year-old children the prevalence is around 5-10 percent, and rapidly decreases during the following years [15-19].

Sureshkumar et al. in a population-based survey of over 2000 new entrant primary school children [age 4-6 years] in Australia, noted an overall prevalence of daytime wetting of 19.2% defined as at least one daytime wetting episode in the prior 6 months with 16.5% having experienced more than one wetting episode and only 0.7% experiencing wetting on a daily basis [20]. Multivariate analysis showed that recent stress, a history of daytime wetting along the paternal line, and a history of wetting among male siblings were independent risk factors for moderate to severe daytime wetting. Because this was a cross-sectional study, recall bias may have resulted in an overestimate of the risk of daytime wetting being caused by such factors as emotional stress and family history. In addition, urine cultures were not obtained so occult UTIs could not be identified.

In a similar study looking at primary school students voiding disorders were detected in 175 (19.2%) of 907 children. One hundred and fifty-two (16.8%) had daytime urinary incontinence, and 131 (14.5%) had night-time incontinence. Voiding disorders decreased as the age increased. There was a significant relationship between voiding disorder and positive family history [21].

In another cross-sectional study looking at 2750 children aged between 11-14 years the overall prevalence of urinary incontinence was 8.6% and decreased with age [23].

Chung finds the percentage of OAB (16,6%) in 19,240 Korean children. In this study OAB was differentiated in ‘dry’ OAB and ‘wet’ OAB: children with OAB do not always have incontinence [22].

In a questionnaire-based study, supplemented by telephone calls, Hellstrom assessed the prevalence of urinary incontinence in 7-year-old Swedish school entrants [24]. Diurnal incontinence was more frequent in girls than boys, 6.7% vs 3.8%, respectively. Wetting every week was reported in 3.1% girls and 2.1% of boys. The majority of children with diurnal incontinence had concomitant symptoms: urgency was reported in 4.7% girls and 1.3% boys. Nocturnal incontinence combined with daytime wetting was equally common in males versus females, 2.2% versus 2%, respectively. At the age of 17 years daytime wetting, at least once a week, was found in 0.2 % of boys and 0.7% of girls. A limitation of this study is its dependency on recall. Children with daytime or mixed wetting were found to suffer from urgency in 50.7%, with 79.1% wetting themselves at least once in 10 days [25]. Urgency symptoms seem to peak at age 6–9 years and diminish towards puberty, with an assumed spontaneous cure rate for daytime wetting of about 14% per year [26].

In a cross sectional sample of 594 individuals 4 to 26 years old, Kyrklund (2012) described 4% of respondents with frequent UI, most < 12 years. Prevalence decreases enormously with age [27].

Most children are toilet-trained by the age of 3 years, although the mean age may range from 0.75 to 5.25 years, with girls being trained earlier (2.25 years) than boys (2.56 years) [28]. A 2008 Turkish study reported day dryness at a mean age of 28 months (29). This is confirmed by a 2015 Turkish study in 1500 children whose mean age of dryness was 29 months [30]. The age of commencing toilet training has increased [31]. This is thought to be associated with higher education levels in parents and the popularity of the child-oriented approach rather than parent-initiated methods. Children who exhibited elimination signals for voiding became dry sooner than those who did not show such signs. There is huge social and cultural variation in toilet training practices with some of the implicated issues being, availability of inside toilet, washable versus disposable diapers, working or home-based mothers, rural or urban location and use or not of punishment methods [29]. It appeared that initiating toilet training after 24 months of age may be associated with problems attaining and maintaining bladder control and that early training is not associated with bladder dysfunction [31,32]. A prospective study in 112 patients published in 2014 however showed problems in early training (<2 years) and in late training (>3 years) alike [33]. Da Fonseca found no association between children with combined bladder and bowel dysfunction and the time of toilet training compared to healthy children [34].

Swithinbank et al. found a prevalence of day wetting [including also “occasional” wetting] in 12.5% in children age 10-11 years which decreases to 3.0% by age 15-16 years [35]. Based on these findings, it seems that the prevalence of all kinds of daytime inconti-

nence diminishes by 1-2% per year from age 10-11 to age 15-16 years, while daytime incontinence, at least once a week, seems to diminish by 0.2% per year from age 7 to age 17 years. Because of treatment interventions the studies may not recount the true natural history.

A cohort study of all school children in the first and fourth grades in the city of Eskilstuna (Sweden), published in 2004, daytime urinary incontinence (at least once a month) was reported in 6.3% of the first graders and 4.3% of the fourth graders, while bedwetting (at least once a month) was reported in 7.1% and 2.7% and faecal incontinence in 9.8% and 5.6%, respectively. This study demonstrates that soiling and daytime urinary incontinence often coexist [36].

There has been ample amount of literature examining toilet training and dysfunctional elimination association and suggesting that late toilet training with bladder overactivity may be a leading factor. Bowel and bladder dysfunction in children may be due to delayed toilet training in children; however, there is no clear explanation how this happens. Some hypothesise that changing attitudes and practices towards toilet training make the completion of toilet training at a later age compared to previous generations. Concomitantly, there has been an increase in the incidence of paediatric bladder bowel dysfunction. One other theory suggests that the symptoms of dysfunctional voiding are more common when toilet training early, as immature children may be less likely to empty in a timely manner, or when training late due to (or in association with) constipation.

A meta-analysis reports the comprehensive search of current literature investigating the association between age at initiation of toilet training, approach used for toilet training, and bladder bowel dysfunction. A total of 10 studies with 24,121 participants (aged 5-17) were included for pooled analysis. Overall, the odds ratio (OR) with 95% confidence interval (95%CI) of lower urinary tract dysfunction in children who initiated toilet training at a younger age when compared to those who initiated toilet training at an older age, was 0.71 (0.63-0.81), (P < 0.001), irrespective of the approach used for toilet training. Subgroup analysis for day-time incontinence (persistent daytime wetting) was 0.77 (0.62-0.95), P =0.014; although the outcomes for enuresis fluctuated, favourable results were still observed in the earlier training group (OR:0.63, 95% CI:0.43-0.94, P = 0.023). Subgroup analysis for age at initiating toilet training vs LUT dysfunction also showed favourable results in children who were trained earlier, i.e., before 24 months (OR:0.77, 95% CI 0.63-0.94, P Z=0.009). Sensitivity analysis confirmed that the results were strong [37].

This meta-analysis presents preliminary findings that show that the incidence of bowel and bladder dysfunction may be decreased by initiating toilet training in children at a younger age prior to the age of 24 months [37]. Although the definition about the age of initial toilet training varied greatly in studies, findings from the current study suggested that the optimal time for initiating toilet training may be prior to the age of 24 months; if toilet training was initiated after 24 months or later, it may result in increased prevalence of LUT dysfunction. Since no RCTs studies were included in the current meta-analysis, well-designed longitudinal studies with larger sample size and from different cultural background are needed to confirm these results.

The natural history of detrusor overactivity in children is not well understood. It is no longer held that detrusor overactivity in children is idiopathic or due to a maturational delay but more likely to be associated with feed forward loops from the generation of a high-pressure system during voiding or filling. Both the interplay of neural drive with motor control and the dynamic nature of the growing bladder could be causative. This is in contrast to the adult population, where detrusor overactivity is considered a chronic condition, whose origin is unrelated to functional use. There is no long-term data to determine if childhood detrusor overactivity predicts detrusor overactivity as an adult. There is evidence that genetic influences affect adult urinary symptoms and that suffering lower urinary tract conditions in childhood increases the risk for these conditions in adult woman [38-41].

By the age of 5 years, unless organic causes are present, the child is normally able to void at will and to postpone voiding in a socially acceptable manner. After this age, night-time and daytime involuntary wetting become a social problem and a cause for therapeutic intervention. In children who present with a change in voiding habits, such as a new onset of voiding dysfunction, one should consider the possibility of child sexual abuse [41]. A more recent study found no significant differences in the presence of lower urinary tract symptoms between children and adolescents who had experienced sexual abuse and controls [33]. Nevertheless, this should be kept in mind, especially when invasive diagnostic and therapeutic procedures are contemplated. One may want to simply ask the parent or caregiver if there were any precipitating events or concerns that they feel may have led to the changes in the child's voiding habits. The appropriate individuals should be contacted if there is a high index of suspicion. Of adult women with complex urinary symptoms, a significant proportion report sexual abuse as a child.

2. CLINICAL ASSESSMENT

The evaluation of LUT conditions includes medical and voiding history (bladder diaries and structured questionnaires), a physical examination, a urinalysis, and uroflowmetry with post void residual (see the algorithm in table 1).

The upper urinary tract needs to be evaluated in children with recurrent infections and dysfunctional voiding. Uroflowmetry can be combined with pelvic floor electromyography to demonstrate over activity of the pelvic floor muscles during voiding. Because urodynamic studies are invasive and most often outcome will not alter treatment plan; they are reserved for patients with therapy resistant dysfunctional voiding and/or those not responding to treatment who are being considered for invasive treatment [42-46].

In addition to a comprehensive medical history a detailed voiding diary provides documentation of voiding and defaecation habits, frequency of micturition, voided volumes, number and timing of incontinence episodes, and fluid intake. A voiding diary should be done for at least 2 days– better 3 days, although longer observation periods are preferred. A voiding diary provides information about storage function and incontinence frequency, while a pad test can help to quantify the urine loss. In the paediatric age group, where the history is taken from both the parents and child together, a structured approach is recommended using a questionnaire. Many signs and symptoms related to voiding and wetting will be unknown to the parents and should be specifically requested, using the questionnaire as a checklist. Symptom scorings have been developed and validated [46-49] Although the reliability of questionnaires is limited, they are practical in clinical setting to check the presence of the symptoms and also have been shown to be reliable to monitor the response to treatment. History-taking should also include assessment of bowel function. For evaluation of bowel function in children, the Bristol Stool Scale is an easy-to-use tool [50].

Urinalysis and urinary culture are essential to evaluate for urinary tract infection (UTI). On urinalysis, the specific gravity (concentration) of the urine is noted, as is any evidence of underlying voiding problems based on the presence of hematuria, proteinuria, or glucosuria. Since transient voiding symptoms are common in the presence of UTI, exclusion of UTI is essential before further management of symptoms.

During clinical examination, genital inspection to see any pathologies like meatal stenosis or congenital abnormalities of the urethra and observation of the lumbosacral spine and the lower extremities are necessary to exclude obvious uropathy and neuropathy.

Uroflowmetry with post-void residual evaluates the emptying ability, while an upper urinary tract US screens for secondary anatomical changes. A flow rate which reaches its maximum quickly and levels off ('tower shape') may be indicative of overactive bladder whereas interrupted or staccato voiding patterns may be seen in dysfunctional voiding. Plateau uroflowmetry patterns are usually seen in anatomic obstruction of flow. A single uroflowmetry test may not be representative of the clinical situation and more uroflowmetry tests, which are all giving a similar result, are more reliable. Uroflowmetry examination should be done when there is desire to empty the bladder and the voided volume should at least be 50% of the age expected capacity ((age in years) + 1] x30 mL). While testing the child in clinical environment impact of the stress and mood changes on bladder function should also be considered.

In the case of resistance to initial treatment, or in the case of former failed treatment, re-evaluation is warranted and further urodynamic studies may be considered. Sometimes, there are minor, underlying, urological or neurological problems, which can only be suspected using urodynamic studies. In these cases, structured psychological interviews to assess social stress should be added [51-54].

In cases of febrile urinary tract infections vesico-ureteric reflux needs to be excluded either by VCUG or video urodynamic studies. With video-urodynamic studies, reflux may be observed along with bladder dynamics.

In the case of suspected anatomical problems which may cause infravesical obstruction such as posterior urethral valves, syringocoeles, congenital obstructive posterior urethral membrane (COPUM) or Moormann's ring, it may be necessary to perform further cystoscopy with treatment. If neuropathic disease is suspected, MRI of the lumbosacral spine and medulla can help to exclude tethered cord, lipoma or other rare conditions.

3. CONFOUNDING FACTORS: LOWER URINARY TRACT DYSFUNCTION, RECURRENT URINARY TRACT INFECTION AND VESICO-URETERIC REFLUX (VUR)

The relationship between detrusor dysfunction and VUR associated with a urodynamic anomaly was first described by Allen and Koff and has been confirmed by several authors [55-58]. Koff demonstrated that treatment of detrusor overactivity reduced the incidence of infection and resulted in a 3-fold increase in the rate of reflux resolution. In a study by Sillen of children with gross bilateral reflux, extreme detrusor overactivity without signs of bladder outlet obstruction was found in boys. Infant girls with gross bilateral reflux did not show the same degree of detrusor overactivity [50]. Other investigators assessing high grade VUR in new-borns noted similar findings. Van Gool et al. noted that 40% of 93 girls and boys evaluated for urgency incontinence and recurrent UTIs had reflux [59].

These studies in infants and the association of combined bladder and bowel dysfunction with reflux and infection in older children support the suggestion that, in some individuals, vesicoureteral reflux is a secondary disorder related more to abnormal detrusor function than to a primary anatomical defect at the ureterovesical junction. It has been shown that increased intravesical pressure, without reflux, may be detrimental for the upper tracts: renal scarring without reflux was recently described by Vega et al. [60].

Generally, high pressure during both storage and emptying do not always generate reflux but can easily do that in case of slight ureterotrigonal anatomic deficiency. In support of this concept is the common finding of vesicoureteral reflux in children with neuropathic bladders and detrusor-sphincter dyssynergia. In such children, the institution of clean intermittent catheterisation and anticholinergic therapy leads to the resolution of VUR in a large number of cases. It is believed that the decrease of detrusor overactivity and restoration of functional capacity in combination with regular and complete emptying of the bladder are the responsible co-factors [61]. If reflux continues to be a problem despite proper management of bladder pressures, anatomic correction could be warranted.

Koff et al. evaluated the effects of antimuscarinic therapy in 62 children with a history of recurrent UTIs, VUR and detrusor overactivity, and compared these children with an age-matched control group with a normal urodynamic study [62]. The overall small sample size and the small number of compliant patients limit the study, however, it did demonstrate a statistically significant difference in the resolution rate of VUR between the treated group and the control group. The overall infection rate was lower in the treated group (16%) compared to the non-medically treated group (63%) and the age-matched control group (71%)]. Several authors have documented the relationship between detrusor overactivity and dysfunctional voiding with recurrent UTIs .

Proposed aetiologies for the increased incidence of UTIs in these patient populations include a milk back phenomenon whereby bacteria in the proximal urethra are "milked back" into the bladder during contraction of the pelvic floor muscles. Alternatively, decreased blood flow and relative hypoxia during periods of increased detrusor pressure such as during involuntary detrusor contractions and voiding against functional obstruction, may induce transient bladder mucosal injury.

Constipation is prevalent among children with bladder symptoms, but often poorly identified by parents [63]. It is a risk factor for recurrent UTIs. Contrary to expectations, findings from the European Bladder Dysfunction Study suggested that symptoms of disordered defaecation did not influence the cure rate of treatment for bladder symptoms [64]. In a prospective non-randomised clinical series of day wetting children, a strong correlation was found between recurrent urinary tract infections, detrusor overactivity and detrusor-sphincter dysfunction [65]. In a study by Hansson et al. symptoms of detrusor overactivity, such as urgency and daytime incontinence were found in a high percentage of girls with asymptomatic bacteriuria [66].

In the majority of children with dysfunctional voiding the recurrent infections disappeared following successful treatment of the voiding dysfunction. This finding confirms the hypothesis that dysfunctional voiding is the main factor responsible for the infections (and to a lesser extent vice versa) [67,68]. Additionally, since such children typically have coexistent constipation, attempts at restoring normal bowel habits will also contribute to decreasing the risk of UTIs. At present, current opinion is that vesicoureteral reflux as such does not predispose to UTI: however, it may facilitate renal involvement [causing pyelonephritis] once bacteriuria has been established in the bladder. This concept has not been scientifically validated and the incidence of renal scars as a consequence of pyelonephritis is reportedly the same, regardless of whether reflux has been documented or not [69]. Those children with VUR in association with detrusor overactivity and/or voiding dysfunction may be at increased risk for upper tract damage given their increased risk of developing UTIs. With this in mind, aggressive treatment of the underlying filling/voiding disorder, the addition of prophylactic antibiotics, and attention to their bowel habits should be given in an effort to decrease the risk of UTIs in this higher risk group [70-73].

In a recent retrospective study evaluating a large group of children with LUT conditions it was shown that in patients who had urinary tract infection the presence of reflux increased the rate of renal cortical abnormalities [74].

4. CLASSIFICATION

Numerous classifications have been used for children who present with varying degrees of 'functional' urinary symptoms, unrelated to apparent disease, injury or congenital malformation. In 2016, the International Children's Continence Society (ICCS) released a standardised terminology to provide guidelines for the classification and communication about LUTS in children [2].

Symptoms are classified according to their relation to the voiding and or storage phase of bladder function. Classification in a clinical setting may have its difficulties because of overlapping conditions and sometimes may not be really needed. Both invasive and non-invasive tools may be needed for better classification. Most often a non-invasive approach in the clinical setting will help classification, as such, use of invasive tools like video-urodynamics are rarely needed.

In addition to obtaining a comprehensive history, observing micturition and examining the child forms the basis of assessment: the information derived from a 48-hour bladder diary, stool record, voiding uroflowmetry and lower urinary tract ultrasonography is also essential in making the initial diagnostic classification [38,67].

Screening for psychological conditions with questionnaires is recommended, as 30-40% of children with daytime urinary incontinence are affected by comorbid emotional or behavioural disorders [75].

Urodynamic investigations elucidate the basis of clinical findings but are first line evaluation techniques only in tertiary referral centres where children have not responded to previous treatment or have symptoms suggestive of neurological involvement or anatomical anomalies.

The ICCS has classified daytime LUT conditions into groups that currently align with understanding of underlying pathophysiology.

The groups commonly overlap and allocation is based on the 4 symptoms of urinary incontinence, frequency of volitional voiding, micturition volumes and fluid intake.

- Overactive bladder (OAB) including urgency incontinence
- Dysfunctional voiding
- Underactive bladder

In general, classifying according to those 3 groups is essential for planning treatment.

The symptom-specific conditions as listed below are also important for planning specific treatment.

- Voiding postponement
- Vaginal reflux
- Giggle incontinence
- Extraordinary daytime urinary frequency
- Elimination syndrome, now called Bladder Bowel Dysfunction

The term 'non-neurogenic dysfunction' is commonly encountered in the literature and describes the whole spectrum, from simple bladder overactivity to severe cases with deterioration of the upper tracts. The fact that a neurologic deficit is not demonstrated at the time of evaluation, does not exclude the possibility that a neurological abnormality was present at the onset of the problem. It has been postulated that detrusor overactivity may eventually lead to poor bladder emptying due to underactivity of the detrusor or severe dyscoordination between detrusor, sphincter and pelvic floor. However, the natural history of many of these children does not confirm this hypothesis, nor the early onset of severe pathology in some of them. Hoebeke et al. found no evidence for this dysfunctional voiding sequence: children with functional incontinence have different primary diseases, but all have a common risk of incontinence, UTI, VUR [15%] and constipation [17%] [14].

4.1. Overactive bladder in children

The term overactive bladder (OAB) is used to describe the symptom complex of urinary urgency, which may or may not be associated with urgency incontinence and is not a direct result of known neurological damage in association with urinary frequency. Recent suggestions describe OAB as a symptom of corticocentral dysfunction that affects multiple systems rather than a dysfunction isolated to the urinary bladder [69]. Urgency syndrome is characterised clinically by frequent episodes of an urgent need to void, countered by contraction of the pelvic floor muscles (guarding reflex) and holding manoeuvres, such as squatting and the Vincent curtsey sign. The term urgency refers to a sudden compelling desire to void that is often difficult to defer, unlike the need to void which is experienced by all individuals and may be intense if one holds one's urine for a prolonged period. The symptoms are thought, at least in part, to arise from detrusor overactivity during the filling phase, causing urgency. These detrusor contractions are countered by voluntary contraction of the pelvic floor muscles to postpone voiding and minimise wetting. Where present, the detrusor contractions can often be demonstrated urodynamically, as can the increased activity of the pelvic floor muscles during each contraction.

The voiding phase is essentially normal, but detrusor contraction during voiding may be extremely powerful. The flow rate reaches its maximum quickly and may level off ('tower shape'). Such strong bladder and pelvic floor muscle contractions have been postulated to result in damage to the bladder mucosa increasing the risk of UTIs. In addition, these children may note suprapubic or perineal pain. A cohort of patients presenting with night-time pain syndromes based on pelvic floor spasms was described by Hoebeke et al. [77].

Overactive bladder should also be considered in “continent” children with recurrent UTIs and vesicoureteral reflux. Depending on fluid intake and urine production, the complaints of incontinence become worse towards the end of the day, due to loss of concentration and fatigue and may also occur during the night. Children usually diminish their fluid intake to minimise wetting, and therefore incontinence may not be the main complaint or symptom, but on careful questioning urgency becomes apparent.

Frequent voluntary contractions of the pelvic floor muscles may also lead to postponement of defaecation. Constipation and faecal incontinence (soiling) are often found in children with detrusor overactivity [78]. The constipation is aggravated by the decreased fluid intake. Constipation contributes to an increased risk of UTIs and may exacerbate the detrusor overactivity. An investigation of the natural history of combined emptying dysfunction of bladder and bowel, using an elimination score in women with and without urogynaecological problems, demonstrated that childhood lower urinary tract dysfunction may have a negative impact on bladder and bowel function in later life [80].

Urinary symptoms and faecal problems often go hand in hand, epidemiological data show that urinary incontinence is found more often in girls, where defaecation problems are more often found in boys. A clear explanation is not yet found.

A careful history, physical examination and scrutiny of the child’s bladder diary will identify symptoms of bladder overactivity. Urine flow rate registration and post-void residual urine measurement help to identify co-existing dysfunctional voiding. Thus, in most children, invasive studies such as urodynamic studies are not indicated as part of the initial evaluation. Such studies are reserved for those children with a question of an underlying neurological defect and those who fail to improve with medical and behavioural therapy, especially if invasive therapies are being considered. Those children with a history of recurrent UTIs should undergo assessment with a renal/bladder ultrasound and depending on the age of the child and the severity of the UTI(s), a voiding cystourethrogram (VCUG) to assess reflux. [81,82]. By adopting a structured approach to history and physical examination, the diagnosis can be made in most children without the need for invasive diagnostic procedures.

4.2. Dysfunctional voiding

Dysfunctional voiding refers to an inability to fully relax the urinary sphincter or pelvic floor muscles during voiding. There is no identified underlying neurologic abnormality. Children with dysfunctional voiding usually present with incontinence, urinary tract infections and constipation and demonstrate an intermittent, or fluctuating pattern referred to as staccato flow (by ICCS definition) during repeated uroflowmetry.

No clear data are available on the possible causes of dysfunctional voiding. It may be that bladder overactivity eventually leads to overactivity of the pelvic floor muscles, with subsequent insufficient relaxation during voiding [83]. Alternatively, poor relaxation of the pelvic floor muscles during voiding may be a learned condition during the toilet training years, adopted following episodes of dysuria due to UTI, or constipation or occurring secondary to sexual abuse [84]. The child’s environment, in particular toilet conditions and privacy issues, can trigger or exacerbate voiding anomalies [85]. In some girls, anatomical anomalies of the external urethral meatus seem to be associated with a higher incidence of dysfunctional voiding. The urine stream may be deflected anteriorly and cause stimulation of the clitoris with subsequent reflex activity of the bulbocavernosus muscle causing intermittent voiding [86]. Since no true structural obstruction can be identified the intermittent incomplete pelvic floor relaxation that occurs during abnormal voiding is termed a functional disorder.

Abnormal flow patterns seen in children with dysfunctional voiding:

- Fluctuating (Staccato) voiding: continuous urine flow with periodic reductions in flow rate precipitated by bursts of pelvic floor activity. Voids are commonly prolonged and incomplete.
- Interrupted voiding: characterised by unsustained detrusor contractions resulting in infrequent and incomplete voiding, with micturition in separate fractions. Bladder volume is usually larger than age-expected capacity. Residual urine is often present resulting in increased UTI incidence. Bladder overactivity commonly accompanies this but it may also be absent [79, 86]

Sustained alteration of voiding is associated with subsequent filling phase anomalies such as phasic bladder overactivity and inappropriate urethral relaxation [87]. Urinary tract infections and kidney damage are common sequelae [88]. Over time, routine incomplete bladder emptying may possibly progress to bladder over-distension associated with chronic urinary retention and poor bladder emptying due to bladder underactivity.

Urinary symptoms associated with dysfunctional voiding range from urgency to complex incontinence patterns during the day and night [84]. Children with dysfunctional voiding have a higher rate of recurrent urinary tract infections than children with no voiding abnormality and demonstrate increased incidence of higher grades of VUR [90]. Symptoms are significantly more common in children with Attention Deficit Disorder than in ‘normal’ children [91].

Signs of dysfunctional voiding reflect initial “compensatory” overactivity of the bladder along with poor emptying ability. They may include small bladder capacity, increased detrusor thickness, decreased detrusor contractility, impaired relaxation of the external urinary sphincter/ pelvic floor during voiding, weak or interrupted urinary stream and large post-void residual volumes of urine. There may also be ultrasound abnormalities, secondary vesicoureteric reflux, faecal incontinence or constipation [92-94].

4.3. Bladder underactivity

Children with bladder underactivity may demonstrate low voiding frequency and an inability to void to completion using detrusor pressure alone. Voiding is of long duration, low pressure, intermittent and often augmented with abdominal straining.

Children with this condition usually present with urinary tract infections and incontinence. Urodynamically, the bladder has a larger than normal capacity, a normal compliance and reduced or no detrusor contraction during voiding, and is then termed detrusor underactivity. Abdominal pressure is the driving force for voiding. The previously used term ‘lazy bladder’ is incorrect and is no longer used.

A correct diagnosis can only be made by urodynamic evaluation. Renal function studies, renal ultrasound and VCUG should be performed to assess the extent of renal damage and reflux. Long-standing overactivity of the pelvic floor may in some children be responsible for decompensation of the detrusor, leading to an acontractile detrusor. However, no data are available to support this theory.

4.4. Voiding postponement

Voiding postponement is a condition in which children habitually postpone imminent micturition until overwhelmed by urgency, resulting in urgency incontinence [94]. A study comparing children

with typical OAB to those with voiding postponement revealed a significantly higher frequency of clinically relevant behavioural symptoms in postponers than in children with OAB, suggesting that voiding postponement is an acquired or behavioural disorder [95]. The rates of Oppositional Defiant Disorder (ODD) are especially high. Some children with voiding postponement have abnormal uroflow patterns [96].

Voiding postponement can develop out of previous OAB, but can represent a separate disorder. Also, voiding postponement can induce OAB. Therefore, different aetiologies need to be considered.

Only 20% exhibit a fluctuating voiding pattern. It remains to be determined whether voiding postponement can develop in the setting of a perfectly normal urinary tract or whether OAB is a necessary precursor.

4.5. Giggle incontinence

In some children giggling can trigger partial to complete bladder emptying well into their teenage years, and intermittently into adulthood [97,98]. The condition occurs in girls and occasionally in boys and is generally self-limiting. The aetiology of giggle incontinence is not defined. Urodynamic studies fail to demonstrate any abnormalities, there is no anatomic dysfunction, the upper tracts appear normal on ultrasound, the urinalysis is normal and there are no neurological abnormalities [92,93]. It is postulated that laughter induces a generalised hypotonic state with urethral relaxation, thus predisposing an individual to incontinence, however the effect has not been demonstrated on either smooth or skeletal muscle. It has also been suggested that giggle incontinence is due to laughter triggering the micturition reflex and overriding central inhibitory mechanisms. One small study hinted at an association with cataplexy (associated involuntary truncal body movements) and narcolepsy (a state of excessive daytime sleepiness), suggesting involvement of central nervous structures, however with only 7 subjects in this study, further evidence is needed [98-104].

4.6. Vesicovaginal entrapment

Urinary leakage that occurs in girls a short time after voiding to completion, that is not associated with any strong desire to void, may be the result of vesicovaginal reflux [105]. Urine may become entrapped in the vagina during voiding due to labial adhesions, a funnel shaped hymen, or an inappropriate position on the toilet. The classic presentation is that of a girl who does not spread her legs apart during voiding and who is not sitting all the way back on the toilet seat, but who is rather sitting near the end of the toilet seat tilting forward. Obesity may be an associated risk factor.

4.7. Bladder and bowel dysfunction

This is a term used to describe the association of any bowel and bladder dysfunction (BBD) (11).

The genitourinary tract and the gastrointestinal system are interdependent, sharing the same embryologic origin, pelvic region and sacral innervation. Although children with voiding disturbances often present with bowel dysfunction, until recently this co-existence was considered coincidental. However, it is now accepted that dysfunction of both systems, in the absence of anatomical abnormality or neurological disease, is inter-related. The common neural pathways, or the mutual passage through the pelvic floor musculature, may provide a theoretical basis for this relationship, as may the acquisition of environmental and developmental learning. The latter can be influenced by episodes of urinary tract infection, constipation, anal pain or trauma, childhood stressors, reluctance to toilet and poor toilet facilities [106].

There is also evidence to suggest that in severe cases symptoms may have a neurological basis.

BBD is seen more frequently in girls than boys and is significantly associated with the presence of both VUR and UTI [107]. VUR is slower to resolve and breakthrough urinary tract infections are significantly more common in children with BBD when compared to those without the diagnosis. Infections do not ameliorate with antibacterial prophylaxis. Age of first febrile UTI does not appear to be an aetiological factor [97], however, recurrence of UTI in children older than 5 years is associated with the presence of BBD [108-110].

Abnormal recruitment of the external anal sphincter during defaecation or at call to stool is considered causative, in that it elicits concomitant urethral sphincter and pelvic floor co-contractions. Thus, in both systems a functional obstruction to emptying is generated. In the case of the urinary system, high pressures generated by the detrusor muscle to overcome a decrease in urethral diameter can stimulate detrusor hypertrophy, detrusor overactivity, and lead to incompetence of the vesicoureteric junctions. In the early stages of defaecation disorders, bowel emptying is incomplete, infrequent and poorly executed. As the dysfunction progresses stool quality becomes abnormal, the child develops distension of the rectum and descending colon, seems to lose normal sensation and develops faecal retentive incontinence. If constipation was not present as a predisposing factor, it rapidly develops [111].

Children with BBD commonly complain of daytime urinary incontinence, non-monosymptomatic nocturnal enuresis, recurrent urinary tract infections, imperative urgency to void (OAB) and exceptional urinary frequency. On investigation, they are often noted to have poor voiding efficiency, vesicoureteric reflux, constipation, faecal incontinence, no regular bowel routine and infrequent toileting. The incidence of children with elimination syndrome and sub-clinical signs and symptoms is unknown.

It is important to differentiate between functional constipation and non-retentive faecal incontinence, as the treatment differs. The ICCS has provided documents for both disorders [111,112].

Assessment follows the same process as for other aspects of paediatric bladder dysfunction, with the addition of a 2-week bowel diary and relevant symptom score. The inclusion of an ultrasound rectal diameter measurement when assessing the bladder, has been shown to be discriminative for children with constipation. Urinary flow curve, perineal EMG and post void residual urine estimate, when considered in isolation, are not conclusive for the diagnosis of BBD. There is no evidence to suggest that anorectal manometry is warranted as a first line investigation in these children. Recently a symptom scale for BBD has been developed providing objective assessment for diagnosis and quantification of severity [113-115].

Conclusion: In the evaluation of children over 5 years of age with LUTS voiding diary, stool pattern evaluation, thorough physical examination to exclude neurogenic pathology or anatomic problems, urinalysis and uroflowmetry combined with post void residual determination are essential.

5. MANAGEMENT

The treatment of LUTD involves a multimodal approach, utilizing strategies such as behavioural modification (urotherapy), anticho-

Table 1: **Management Algorithm: Children with LUTS over 5 years of age**

Diagnostic Work-up
Voiding diary 2 full days minimum
Bristol stool scale
Questionnaires (optional)
To evaluate voiding and bowel habits, wetting severity/frequency, fluid intake, quality of life
Physical exam
To exclude neurogenic pathology or anatomic problem (meatal stenosis, labial fusion)
Urinalysis
To exclude presence of UTI or any other pathology (DM, DI)
Uroflowmetry and PVR determination (USG or bladder scan)
To evaluate urine flow and emptying efficacy
USG (optional).
To determine bladder wall thickness, upper tract changes, signs of constipation
Urodynamic studies
Not required unless refractory to management
VCUG
Only required if recurrent febrile UTI is present
Management
If UTI is present treat UTI first
If constipated treat bowel first with dietary changes and laxatives.
Urotherapy is initial therapy in all cases to maintain controlled fluid intake, regular and efficient bladder emptying
Medical treatment (anticholinergics: if OAB symptoms dominate and persist despite urotherapy.
Antibiotic prophylaxis; in case of recurrent UTI
Biofeedback is optional as first line therapy as part of urotherapy program; otherwise it recommended use if refractory to urotherapy.
Neurostimulation or Botulinum toxin A injection to detrusor is suggested if refractory to urotherapy and medical treatment but still experimental.

linergic medication and physiotherapy; along with addressing underlying and potentially complicating conditions such as constipation and urinary tract infections. In a recent publication EAU-ESPU provided guideline recommendations for daytime lower urinary tract conditions in children [116].

Behavioural modification, mostly referred to as urotherapy, is a term, which covers all non-pharmacological and non-surgical treatment modalities. It consists of rehabilitation of lower urinary tract and aims to normalise micturition in order to prevent further functional disturbances. This includes standard instructions in proper hydration and bowel management; timed voiding and basic relaxed voiding education. The child and family are educated about normal bladder function and responses to urgency. Urotherapy may often need to be combined with medical treatment including anticholinergics and antibiotics. Voiding regimens are instituted and UTIs and any constipation are treated using antibiotics and laxatives. Treatment is aimed at optimising bladder emptying and inducing full relaxation of the urinary sphincter or pelvic floor prior to and during voiding.

Recurrent urinary infections and constipation should also be addressed and prevented during the treatment period. In the case of combined bladder and bowel dysfunction it is advised to treat the bowel dysfunction first [117] as LUTS may disappear after successful management of bowel dysfunction.

Additional strategies as below may be needed for cases which do not show satisfactory response to urotherapy and who have some conditions which may need specific treatment.

- Physiotherapy which includes pelvic floor muscle awareness practices with/without sessions of biofeedback, visualisation of uroflow curves and/or pelvic floor activity and relaxation.
- Clean intermittent self-catheterization for large post-void residual volumes of urine despite urotherapy and biofeedback.
- Antimuscarinic drug therapy if bladder overactivity is present.
- If the bladder neck is associated with increased resistance to voiding, alpha-blocker drugs may be introduced.

Most often these complex patients would need urodynamic studies to delineate the underlying problem that may need specific treatment.

Treatment efficacy can be evaluated by improvement in bladder emptying and resolution of associated symptoms. Controlled studies of the various interventions are needed. As with detrusor overactivity, the natural history of untreated dysfunctional voiding is not well delineated and optimum duration of therapy is poorly described. A high success rate has been described for urotherapy programs, independent of the components of the program [117-118]. However, the evidence level is low as most studies of urotherapy programs are retrospective and non-controlled. Some recent controlled studies show efficiency of urotherapy over pharmacologic treatment and suggests its use as the initial treatment [119].

Treatment strategies may vary according to subgroups as listed below.

5.1. Overactive bladder in children:

Treatment involves a multimodal approach, involving strategies such as behavioural modification, antimuscarinic medication and neurostimulation. Underlying and potentially complicating conditions such as constipation and UTI are managed prior to intervention.

Conclusion: multimodal approach is effective in the treatment of the overactive bladder in children (LoE:3)

Recommendation: it is recommended to treat children with overactive bladder with a multimodal approach (GR:C)

5.2. Dysfunctional voiding:

Symptoms are often refractory to standard therapy of hydration, bowel management, timed voiding and basic relaxed voiding education. Effective intervention requires combination therapy, generally with a sizeable investment of time over a long period. Treatment is aimed at optimising bladder emptying and inducing full relaxation of the urinary sphincter or pelvic floor prior to and during voiding. Strategies to achieve these goals include pelvic floor muscle awareness and timing training, repeated sessions of biofeedback, visualisation of uroflow curves and/or pelvic floor activity and relaxation, clean intermittent self-catheterisation for large post-void re-

sidual volumes of urine, and antimuscarinic drug therapy if detrusor overactivity is present. If the bladder neck is implicated in increased resistance to voiding, alpha-blocker drugs may be introduced. Recurrent urinary infections and constipation should be treated and prevented during the treatment period.

Treatment efficacy can be evaluated by improvement in bladder emptying and resolution of associated symptoms [94]. Controlled studies of the various interventions are needed. As with bladder overactivity, the natural history of untreated dysfunctional voiding is not well delineated and optimum duration of therapy is poorly described.

Conclusion: treatment focussing on the full relaxation of the urinary sphincter and the pelvic floor is effective in dysfunctional voiding (LoE:4)

Recommendation: in case of dysfunctional voiding relaxation treatment of the urinary sphincter and the pelvic floor are part of the treatment (GR:C)

5.3. Detrusor underactivity:
Treatment is aimed at optimising bladder emptying after each void. Clean intermittent (self) catheterisation is the procedure of choice to promote complete bladder emptying, in combination with treatment of infections and constipation [which may be extreme in these patients]. Intravesical electrostimulation has been described, but is not recommended as a routine procedure for children.

Conclusion: Clean intermittent catheterisation can be used effectively in the treatment of detrusor underactivity but the level of evidence is low (Lo4)

Recommendation: In cases of detrusor activity, intermittent catheterisation can be used as a treatment option (GR:C)

5.4. Voiding postponement:
Urotherapy focused on behaviour modification and timed voiding is the mainstay of treatment.

Conclusion: urotherapy is effective in the treatment of voiding postponement (LoE:4)

Recommendation: urotherapy is recommended in the child with voiding postponement (GR:C)

5.5. Giggle incontinence:
Positive results have been reported with conditioning training, methylphenidate and imipramine [98,104]. Others have tried antimuscarinic agents and alpha-sympathomimetics. There is no acceptable evidence that any form of treatment is superior to no intervention.

Conclusion: conditioning training, methylphenidate, imipramine, antimuscarinics and alpha-sympathomimetics are not superior to no intervention in the treatment of giggle incontinence (LoE: 3)

Recommendation: conditioning training, methylphenidate, imipramine, antimuscarinics and alpha-sympathomimetics can be used in the treatment of giggle incontinence but with limited results (GR:D)

5.6. Vesicovaginal entrapment:
Changes in voiding position and treatment of labial adhesions will usually lead to resolution of the urine leakage.

Conclusion: correction of the voiding position and treatment of labial adhesion are effective as a treatment for vesicovaginal entrapment (LoE:4)

Recommendation: in cases of vaginal entrapment, attention should be paid to correction of voiding position and treatment of labial adhesions (GR:C)

5.7. Bladder and bowel dysfunction:
Treatment aims at assisting a child to become clean and dry in the short term, by retraining appropriate bladder and bowel awareness and teaching optimal toileting skills. As bowel dysfunction is more socially isolating than urinary incontinence, and in the light of evidence that amelioration of underlying constipation can relieve bladder symptoms, most clinicians begin with treatment of the bowel. Strategies include disimpaction [if needed], prevention of stool reaccumulation, and post-prandial efforts to empty the bowel while maintaining optimal defecation dynamics [114]. Once stools are being passed regularly, treatment focuses on teaching awareness of age appropriate fullness in the bladder, and training unopposed emptying (without straining or pelvic floor muscle recruitment), at pre-scheduled times. Pelvic floor awareness training and biofeedback therapy are integral.

There are few studies of the efficacy of treatment in children with BBD. Several authors have evaluated the outcome of constipation management on bladder symptoms; however the baseline characteristics of subjects were not described adequately enough to allow a clear diagnosis of BBD [78, 113]. A review on the effectiveness of biofeedback for dysfunctional BBD reports that 80% of children benefited from biofeedback but that the level of evidence was low due to poor study designs [112, 115]

Despite early successful treatment of LUTD there is evidence that there is a high recurrence rate of symptoms in the long term which necessitates chronic follow-up [120] and thus many patients may present later in adulthood with different forms of LUTD [121].

Conclusion: biofeedback is effective in the treatment of bladder and bowel dysfunction (LoE: 3)

Recommendation: biofeedback is recommended in the treatment of bladder and bowel dysfunction (GR:C)

Treatment:
Treatment aims at assisting a child to become clean and dry in the short term, by retraining appropriate bladder and bowel awareness and teaching optimal toileting skills. It has been shown that a full rectum can result in bladder over- or under-activity [122], and the fuller the rectum the larger the post void residual urine [123]. Functional constipation can often be missed, but it is essential in the light of evidence that amelioration of underlying constipation can relieve bladder symptoms, beginning with treatment of the bowel. Strategies include disimpaction [if needed], prevention of stool re-accumulation, and post-prandial efforts to empty the bowel while maintaining optimal defaecation dynamics [124] The aim therefore is active and ongoing (as relapse is common) bowel management to optimise bowel evacuation and reduce any faecal incontinence. The next aim is optimising age-appropriate bladder storage, blad-

der sensation and awareness and unopposed, relaxed and complete bladder emptying. Strategies to do this are described below.

Conclusion: Amelioration of underlying constipation can relieve bladder symptoms (LoE:4)

Recommendation: constipation should be treated prior to bladder dysfunction treatment (GR:C)

6. PRINCIPLES OF NON-PHARMACOLOGICAL TREATMENT OF ALL DIFFERENT STATES

Urotherapy is the term for all non-surgical and non-pharmacological interventions and is the first-line therapy for children with bladder and bowel dysfunction. It is cognitive and behavioural in nature, and undertaken by a range of clinicians with different skill sets – doctors, nurses, physiotherapists and psychologists [125].

It is classified as standard or specific urotherapy [126]. Standard urotherapy involves age-appropriate information and demystification regarding urinary and gastrointestinal tract functions, instructions on how to resolve bladder and bowel symptoms, behavioural modifications including regular bladder and bowel habits, timed voiding, fluid and dietary choices, pelvic floor muscle awareness and posture for relaxed voiding and defaecation, family documentation of interventions and symptoms and clinical support and follow-up. Specific urotherapy involves pelvic floor muscle training, electrical neuromodulation, alarm therapy and clean intermittent catheterisation. Additional treatment involves pharmacotherapy, psychotherapy and cognitive behavioural therapy, either alone or in combination.

6.1. Standard urotherapy

Initial intervention for overactive bladder (OAB), voiding postponement (VP) and dysfunctional voiding (DV) uses a non-pharmacological approach. The main objectives of treatment are to normalise the bowel and defaecation pattern, normalise bladder storage and emptying and pelvic floor activity, and cure the incontinence, infections and constipation. Initial treatment for most children with LUTS includes a regular drinking and voiding regime. For many children who present with symptoms of OAB, as well as a voiding/drinking schedule, treatment focuses on both the involuntary bladder contractions and the child's awareness of these. Children learn to recognise the desire to void and to suppress this by normal central inhibition instead of resorting to holding manoeuvres to generate urethral compression. Children with DV learn to initiate voiding with a completely relaxed pelvic floor and to pass urine in association with a bladder contraction rather than via generation of increased abdominal pressure. Dietary changes and bowel regimens are used to treat the constipation. In children with OAB and DV, pelvic floor muscle relaxation can be impaired during voiding. Physiotherapy is concerned with re-training of specific muscle groups. Adjunctive physiotherapeutic input offers children different strategies to achieve pelvic floor relaxation during micturition.

Antibiotic prophylaxis may prevent recurrent UTIs, however, data to support this is limited. A combination of bladder training programmes and pharmacological treatment, aimed specifically at reducing detrusor contractions, is often useful and sometimes necessary also.

If children do not respond to these interventions, then specific urotherapy may be instituted (see below).

A Danish report of the outcome of standard urotherapy in 240 children with daytime incontinence noted achievement of dryness in 126 children (55%). Alarm therapy has traditionally been used for the treatment of nocturnal enuresis but has been used in management of daytime wetting. When a timer watch was utilised as a reminder to void at regular intervals 70% of children became dry. Predictors for dryness included a low voiding frequency, larger volumes voided in relation to age-expected storage and fewer incontinent episodes per week [127]. There is evidence that for children who are therapy-resistant, timed voiding assisted by a timer watch added to urotherapy is effective [128].

Another study found that following a 3-month training programme, 42.8% of day wetting children were cured at 1 month, 61.9% by 6 months, and 71.4% by 1 year [129]. Allen et al. [130] reported that urotherapy patients who had good compliance with timed voiding were significantly more likely to improve their continence than those with poor compliance. It has recently been highlighted however, that there is frequently conflict between school rules, routines and toilet facilities and the urotherapy programme components. Adaptive coping techniques added to urotherapy training may enhance gains in dryness.

Several centres offer intensive urotherapy called voiding schools or even inpatient rehabilitation. A prospective evaluation of 38 Belgian children who underwent this approach showed improvement in 90% of the children with 42% becoming dry, whilst no child on the waiting list improved during the 6 months [131]. Long-term follow-up of 75 incontinent children 16-22 years after they underwent intensive urotherapy showed a good result in 84% and the authors concluded that if the original outcomes of paediatric intensive inpatient urotherapy were good, they tend to remain so over time in most patients [132].

Although there are many studies reported in the literature assessing the effects of various forms of therapy on daytime incontinence and urinary symptoms, many of these are case series rather than being randomised or controlled trials. The paucity of studies evaluating standard urotherapy initiatives has precluded double-blinded trials of novel and multimodal interventions. Whilst clinically important benefits are commonly described, and there are some studies comparing urotherapy with or without pelvic floor muscles training, with or without anticholinergics, with or without voiding re-education and uroflowmetry, with or without timer watch and others, variations in design and delivery of interventions, patient numbers, objective outcome measures and length of follow-up are sub-optimal. A recent Cochrane review concluded that most of the evidence for these interventions was of very low or low certainty [133]. However, Schafer et al. reviewed studies and concluded that standard urotherapy is effective for treating daytime urinary incontinence [134]. Another recent review concluded that standard urotherapy applied as first line treatment in BBD in children resulted in positive outcomes in symptom reduction and improvement in uroflowmetry parameters [135]. Some authors contend that in less severely affected children a thorough explanation of the underlying causes and the expected progress of resolution is sufficient treatment [136]. Buckley et al. comment that treatment choices must take into account not only a comprehensive assessment, but also the child and carers' capaci-

ties and commitment, supports available to the child and family and the resources of the health setting the child attends [123].

Conclusion: Standard urotherapy is effective as a treatment of daytime incontinence (LoE:3)

Recommendation: Standard urotherapy is recommended as a first line treatment of daytime urinary incontinence (GR:C)

6.2. Specific urotherapy

6.2.1. Pelvic floor muscle training.

In contrast to adult incontinence, little is known about pelvic floor muscle (PFM) function and training interventions in children. There are many reasons for this, including the lack of a gold standard of measurement of PFM function, not being able to be invasive and therefore using surrogate measures, for example, superficial perineals to measure Levator Ani, or the external anal sphincter to represent urethral sphincter function. These may or may not be adequate. Furthermore, a range of clinicians, trained or not in muscle re-education, participate in this work and studies reflect poor methodology or report none at all [137].

In this arena, PFM awareness (contraction vs relaxation) is primarily used to facilitate defaecation and treat DV. In the latter, the aim is to achieve relaxed unobstructed voiding and complete bladder emptying. In most instances it is not difficult for a trained therapist to teach this and feedback about performance to the child is given immediately. The aim is for the child to internalize the sensation and have sufficient awareness to practice correctly, and to apply such techniques during initiation of the void and throughout voiding. How to teach PFM awareness to a particular child depends on the motor learning needs of that child which vary with many factors, including age, sensori-motor awareness and cognitive ability.

Biofeedback is a technique in which physiological activity is monitored, amplified and conveyed to the person as visual or acoustic signals, thereby providing the patient with information about unconscious physiological processes. It is a technique which may be used, in this case, to facilitate muscle training, not as a treatment in itself. Biofeedback is mainly utilised for the management of the voiding phase (DV due to pelvic floor muscle overactivity) [138]. This is often undertaken with electromyography (EMG). EMG needs to be used in trained hands as there are many pitfalls of its use and what is seen on one day cannot be measured again, or may not reflect what happens on another day [139].

Training with biofeedback can be used as a single treatment or in conjunction with a comprehensive rehabilitation program. To assist the child to recognise detrusor contractions it may be performed by a cystometrogram during which the child is taught to recognise and inhibit involuntary detrusor contractions by watching the pressure curve during cystometry. This is invasive and a time-consuming process with limited application as a routine treatment.

Real-time uroflow can also provide indirect/surrogate feedback of the child's ability. The child sits on a toilet with a flow transducer (with or without EMG), watching the flow curve, and attempts to empty completely in one relaxed void. In the absence of real-time uroflowmetry post-void feedback can be given by the shape of the uroflow or post void residual. Ultrasound may be used to determine the post-void residual and demonstrate complete emptying.

Transabdominal or transperineal ultrasound can also give direct feedback to the child as the movement of endopelvic fascia and the effect on the bladder neck can be seen as the child contracts and relaxes the pelvic floor. Its use for PFM measurement and training has been validated in adults and is applicable to children [140].

Rectal balloon training has repeatedly been shown not to be effective routine treatment in children with bladder dysfunction [141] or defaecation difficulty [142]. For constipation and defaecation dysfunction there are studies reporting that in addition to standard medical care, the success of a physiotherapeutic approach as adequate toilet posture, abdominal musculature (involved in increased intra-abdominal pressure), PFM/sphincter/abdominal muscle dyssynergia and defaecation dynamics, rectal sensation and perception are comprehensively re-trained [143, 144].

The results of biofeedback are commonly reported as case series rather than RCT, and often the interventions are multifactorial. Results are generally positive but overall may not be superior to high quality standard urotherapy, and whether it is biofeedback, the added input of a clinician, or the effect on the bladder/bowel or reinforcement of other urotherapy advice has not been elucidated.

Long duration follow-up, whilst desirable, confounds results of interventions in children who are continually growing and maturing. Hellstrom et al. reported results of a 6-week bladder rehabilitation programme inclusive of biofeedback [145] and noted that at 3 years, 71% of the children with detrusor overactivity, 70% of those with dysfunctional voiding and 73% of those with a combined disturbance had a normal micturition pattern. The potential for bias from intercurrent events and interventions precludes statements about the efficacy of biofeedback alone.

Buckley found in a recent Cochrane review that in 11 qualifying studies no clear evidence was available to suggest that biofeedback was effective in treating children with bladder or bowel dysfunctions with no differences being found at 3-, 6- and 12-months post intervention [133]. Janet Chase stated that "Without a complete published description of interventions, clinicians and patients cannot reliably implement interventions that are shown to be useful, and other researchers cannot replicate or build on research findings". For this reason the Template for Intervention Description and Replication (TIDieR) checklist and guide has been developed and future studies should adhere to the twelve items [146].

Conclusion: Pelvic Floor muscle training is an effective treatment of dysfunctional voiding (LoE:3)

Recommendation: Pelvic floor muscle training ie recommended to treat dysfunctional voiding in children (GR: C)

6.2.2. Clean intermittent (self) catheterisation

In children with an underactive detrusor, bladder emptying may be achieved with timed and double voiding. If this does not adequately empty the bladder clean intermittent self-catheterisation (CISC) may be tried. This requires careful guidance for both the child and the parents. Sometimes it is necessary to give the child a suprapubic catheter for a while and gradually prepare him/her to accept CISC. Once the infections have cleared and the child is continent it will become easier for both the parents and the child to accept. The frequency of CISC depends on the severity of the problem and may vary between four times a day and once a day before going to bed.

Conclusion: Clean intermittent catheterisation can be used effectively in the treatment of detrusor underactivity but the level of evidence is low (Lo4)

Recommendation: In cases of detrusor underactivity with significant PVR intermittent catheterisation can be used as a treatment option (GR:C)

6.2.3. Electroneurostimulation

Electroneurostimulation (ENS) has been used in adults for a variety of lower urinary tract symptoms and its use has been reported in children for many years also. ENS has been used to influence childhood bladder and bowel symptoms (both neurogenic and non-neurogenic) using surface or skin electrodes, anal electrodes, percutaneously with needle electrodes, intravesical and implanted electrodes. Current is delivered from different stimulation devices with varying waveforms, frequencies and intensities.

Electrical current directly stimulates nerves and muscles with an immediate effect, and use of electrical stimulation in this way is often referred to as functional electrostimulation (FES). For example, FES can be used to stimulate muscles to improve function or to increase awareness, including the pelvic floor or abdominal musculature. Once neural efficiency has improved, training is augmented by active muscle training.

Neuromodulation implies that the application of electrical current alters neurotransmission patterns over time and usually with a carry-over effect. Borch et al. found no immediate bladder effect of sacral TENS in a group of children with OAB [147]. However, Dombek et al. did find a significant immediate effect in 77% of a group of children with neurogenic bladder dysfunction [148]. In LUTS, ENS has been shown to enhance beta-adrenergic activity, reduce cholinergic activity in the bladder, alter other transmitters such as GABA, nitric oxide and serotonin and raise endorphins and enkephalins in cerebrospinal fluid [149]. Although the exact mechanisms are not fully understood changes in the brain have been demonstrated. There are therefore local, spinal and supraspinal effects. Recently, a functional MRI study on 10 healthy adults, comparing sacral versus thoracic TENS showed activity in anterior cingulate cortex (ACC) and the dorsal lateral prefrontal cortex (DLPFC) were significantly increased during sacral TENS compared to rest. Thoracic TENS did not increase connectivity between the ACC and DLPFC when compared to rest [150].

Looking at TENS with non-invasive transcutaneous electrodes, the majority of studies have been done to treat OAB with electrodes positioned over the second and/or third sacral foraminae. Initially this was used for treatment-resistant OAB with a 16.6% cure rate and a 43% improvement rate after 12 weeks [151], but now is used as first line treatment. A prospective study of 69 children where sacral neurostimulation was used as first-line treatment, showed 55.1% complete resolution of symptoms after 20 sessions [152]. Other good success rates have been demonstrated in many case series and also randomised controlled studies investigating BBD (see Table 2). A current review reports the overall success rate with sacral TENS as first line treatment was 1.92 times that of children undergoing standard urotherapy alone (RR: 1.92, 95% confidence interval [CI: 1.02, 3.61]) and 1.56 for those undergoing either urotherapy alone or with pharmacotherapy [153]. Reported changes in bladder function with neurostimulation include: significantly increased bladder capacity, decreased severity of urgency, improved continence, and decreased frequency of urinary tract infections. Significant improvement in urodynamic parameters of bladder compliance, number of involuntary contractions, and bladder volume at first detrusor contraction have also been noted.

Other administrations of current to treat OAB have been with different electrode placement or type, or different current waveform. Examples are posterior tibial nerve (PTNS) (ankle) or plantar nerves stimulation with non-invasive electrodes (sole of foot) [154, 155]. In one RCT when transcutaneous PTNS was compared to sham there was a 71.42%:12.5% complete incontinence improvement respectively and AVV, MVV and NE improved significantly in the test group only ($p < 0.001$) [154]. Abd El-Moghny used intra-anal stimulation to successfully treat refractory MNE [156]. Cultural differences may determine whether this is seen as invasive or not. Different current has also been used, usually as interferential therapy (IFT) to treat constipation ,and both bladder under- and over-activity (see Table 2).

Use of neurostimulation in children with neurogenic LUT dysfunction has been reported with varying results and in 2 RCT's using transcutaneous stimulation in children with myelomeningocele one showed no significant differences in incontinence (TENS compared to sham) [157], and one that did (IFT compared to sham) [158].

Four forms of invasive ENS techniques have been reported.

Percutaneous PTNS using a needle electrode close to the medial malleolus, usually performed once per week for 30 minutes has been reported since 2002 [159]. It is used to inhibit detrusor function although has been reported in group of children with a variety of neuropathic and non-neuropathic LUTD, with symptom improvement better in the non-neuropathic group ($p=0.002$) and with reportedly good tolerability by children [160]. Barrosso et al. carried out a prospective study comparing PTNS with sacral TENS for the treatment of OAB. Children having TENS had a 70% cure rate compared to 9% of the PTNS group ($p=0.02$) but there was no statistical difference on DVSS ($p=0.55$) [161]. There is one RCT using PTNS in refractory MNE in which there was a symptomatic and urodynamic improvement in the PTNS group of 78.6% (which fell to 42.9% at 3 months) versus 14.3% in the control group [162].

Recently a pilot study on percutaneous (needle) sacral stimulation has been carried out on eighteen children (aged 4- 14 years) with OAB who underwent weekly treatment for 20 weeks. There were significant reductions in urinary urgency, incontinence, urinary tract infection and enuresis [163].

Intravesical electrical stimulation (IVES) involves introducing a cathode on a catheter into the bladder and an anode over the abdominal wall. Initially this was done on an outpatient basis and then progressed to a home-based treatment as the children were catheterising anyway because of idiopathic or neuropathic detrusor underactivity. One NRCT showed normalising of voiding in the former group in 84% children and 40% in the latter [164]. Hagerty reported 22 years of experience in neuropathic IVES in 392 children. With a mean of 6.6 years follow-up, nearly 80% had a 20% increase in bladder capacity with a, bladder pressures less than 40 cm H_2O and 61% developed or sustained bladder sensation [165]. Choi reported on 10 years' experience on IVES and UD patterns in children with spina bifida [166]. Bladder capacity increased especially if IVES was started before 18 months, detrusor sphincter dyssynergia resolved in 55.66% and in the acontractile detrusor group, contraction ability increased in 48%. Intravesical stimulation is rarely indicated but more studies are needed as treatments for bladder underactivity are few.

A recent review states “Neuromodulation is a promising tool in the management of constipation refractory to medical treatment and faecal incontinence in children” [167]. One randomised placebo-controlled trial using interferential current transcutaneously 3 times weekly, showed significant improvements in colonic transit times, decreased soiling and abdominal pain and increased quality of life in children with severe constipation [168]. Daily home treatment showed further improvements [169, 170]. Follow up on these children for an average of 3.5 years has shown that these improvements were maintained [171]. Kajbafzadeh et al. treated 30 children aged 3-12 years with neurogenic bowel dysfunction randomising them into physiotherapy plus sham or physiotherapy plus real IFT. There was a significant improvement in anorectal manometry measurements ($p<0.05$) and increase defaecation frequency ($p< 0.005$) in the real IFT group [172]. Sharifi-Rad randomised children with constipation into receiving physiotherapy or physiotherapy plus IFT [173]. Both groups improved in defaecation frequency but the IFT group had better results at 6 months ($p=0.005$). Sacral TENS has been used to treat constipation and it was reported that after the treatment 85.7% of the children’s constipation symptoms had improved according to the Rome III criteria (174). Certainly, anecdotally many clinicians note an improvement in bowel function when treating OAB in this way. Lecompte reports a small study of children with congenital abnormalities and faecal incontinence treated with PTNS with some good results as well [175].

Different modes of application have been trialled in mostly small studies with in children. There is minimal standardisation of populations, application parameters or outcome measures, and short periods of follow up. Thus, evidence is largely drawn from low quality studies with considerable risk of bias. A recent Cochrane review found that comparing TENS vs sham more children with day wetting receiving active TENS may achieve continence but there is low-certainty evidence [133]. Clearly neurostimulation in children warrants larger, controlled and randomised studies. Despite the slow pace of research, the reviewers of the articles mentioned above agree that there is a positive role for neurostimulation in children with LUTD and bowel dysfunction, and that it is adjunctive to other interventions, with no known predictors of efficacy now, but also rare and minor adverse events.

Sacral nerve stimulation with implantable electrodes, although still not approved in children is gaining importance in the treatment of children with refractory non- neurogenic and neurogenic lower urinary tract dysfunction and bowel bladder dysfunction.

Different neuroanatomical pathways have been described as targets for invasive sacral neurostimulation. The third sacral (S3) nerve root remains the main access point used for neurostimulation treatment but also the stimulation of the pudendal nerve has been reported.

In a first step a tined quadripolar stimulator lead is placed under fluoroscopic guidance and under general anaesthesia and connected with an external pulse generator. Unilateral stimulation of S3 has to be achieved. After a successful trial period a pulse generator is implanted.

In 2004 Guys et al. reported a prospective randomised controlled study on the benefits of sacral neuromodulation in 32 patients suffering from neurogenic bladder dysfunction, mainly due to spina bifida. 21 patients received an implant. 9 patients reported improvement in intestinal transit, 5 had total disappearance of urinary infection and 6 had persistent sensation of a full bladder. No one in the control group reported improvement. Three cases needed revision surgery because of lead migration, faulty connection or wound infection [176].

The same group published in 2010 the results of a multicentre, open label, randomised, crossover study in 33 children older than 5 years with mainly neurogenic pathology, suffering mixed urinary and faecal incontinence in 19, urinary incontinence in 9 and faecal incontinence in 5. The only urodynamic parameter that showed a significant change was the cystometric bladder capacity.

A retrospective study by F. Sharifiaghdas on the other hand only showed significant decreased detrusor overactivity but no significant positive effect on maximum cystometric capacity. [177]. The overall clinical response rate was more than 75%. For urinary incontinence the response rate was 81% and for faecal incontinence it was 78% [178]

Nearly the same results were mentioned in a retrospective study by AL Groen et al. :18 patients, of which 5 with neurogenic bladder, showed a good short term (78%) and long term (73%) response . [179]

Neurostimulation has also been successfully used in the treatment of bowel bladder dysfunction and refractory faecal incontinence and constipation.

In a prospective study M. E. Dwyer followed up 105 children with BBD. Ninety-four percent of the patients experienced improvement of at least 1 symptom after implantation of a sacral neuromodulator. Ten percent showed complete resolution of all preoperative symptoms. Symptom resolution was observed in 41% of the children suffering incontinence and 40% of those who were constipated.[180]

In a prospective cohort study in 30 children and adolescents (10-20 year) suffering from refractory constipation, A.A van der Wilt et al. showed a positive test stimulation in 27. In these 27 who underwent a stimulator implantation 42.9% showed durable improvement of the symptoms [181].

A prospective study by M.D. Mason et al. in a group of 30 children with refractory bowel bladder dysfunction, showed that all patients had a significant improvement in quality of life and symptom scores, and those with detrusor overactivity on preoperative urodynamics had a significantly greater improvement in symptom scores.[182]

Schober et al. described a case of refractory bowel bladder dysfunction in a patient with caudal regression and partial sacral agenesis in which they used pudendal neuromodulation (PNM) They placed the quadripolar tined electrode into Alcock’s canal adjacent to the pudendal nerve. During the stimulation trial episodes, faecal incontinence decreased significantly and bladder spasms completely resolved. Two months after implantation of the Implantable Pulse generator urodynamic testing showed a good compliance, and no more bladder overactivity [183].

Although many studies report promising results the majority also report a high complication rate, especially infection, lead migration and fracture of the lead.

A systematic review by R. Iacona et al. illustrated that both non-invasive and invasive neurostimulation are effective in the treatment of constipation and faecal incontinence in children. The main disadvantage of invasive neurostimulation is the high complication rate of 17- 53% and a reoperation rate of 11-50% [184].

In a retrospective study by M.E. Fuchs et al. on 63 children who underwent SNM, 49% because of primarily bowel symptoms and 51% for primarily bladder symptoms the incidence of reoperation was studied. 25% needed reoperation because of infection, lead breakage or migration. According to this study there is no correlation between age, gender or BMI and the complications, in contrast to former studies on smaller groups [182, 185].

As mentioned, many patients with an implant will develop post-implant complications. Up to 53% will develop pain at the implant site and 3-38% will lose effective stimulation. C.R. Powell focussed on a standardised troubleshooting algorithms to overcome these problems and to avoid surgical intervention. Changes in stimulation effect often can be overcome by reprogramming the device. Even in cases of lead migration or a fractured lead, reprograming can offer, in some cases, a solution [186].

Another important issue is the fact that an implanted neurostimulator possibly interferes with the follow-up of patients with medullary or spinal pathology as an MRi may not be performed because of the metal components of the stimulator [184]. However, newer iterations of the device are now MRI compatible.

Table 2: Non invasive ENS in children with non-neurogenic or functional bladder or bowel dysfunction RCT"s since 2009
TENS transcutaneous electrical stimulation. IFT interferential therapy. OAB overactive bladder. MNE monosymptomatic nocturnal enuresis. PFMT pelvic floor muscle training. ES electrical stimulation. PT physiotherapy.

Author and year of publication	Population	Design	N	Mode of application	Outcome measure
Hagstroem 2009	5-14 years Day wetting	TENS vs sham TENS	25	Sacral	Sig decrease daily incontinence episodes in active group vs sham (p=0.05)
Clarke 2009	8-18 years severe refractory constipation	IFT vs sham IFT	42	Quadripolar anterior abdominal wall and T10-L2	Scintigraphic transit studies sig improved in real IFT group (p 0.0001)
Lordelo 2010	Over 4 years, mean 7 years OAB	TENS vs sham TENS	37	Sacral (real) Scapular (sham)	62% cured test group. None in control (p<0.001)
De Oliviera 2013	Over 6 years Primary MNE	Urotherapy vs urotherapy +TENS	45	Sacral	Sig > in in dry nights in TENS group 61.8% vs 37.3% controls (p=0.0038)
Sillen 2014	5-12 years Day wetting	TENS + urotherapy vs urotherapy alone	62	Sacral	Reduction in wetting episodes in both groups – no sig difference
Reis 2014	5-16 years Day wetting + enuresis	PFMT (EMG) +urotherapy vs TENS + urotherapy	78	Sacral	60.6% complete resolution symptoms TENS vs 54.9% PFMS group (p=0.483)
Kajbafzadi 2015/1	Children with underactive bladder	Physiotherapy + IFT vs Physiotherapy alone	36	IFT quadripolar symphysis pubis and ischial tuberosities	IFT vs control, sig >se in voiding freq (p<0.002), sig <se bladder capacity (p<0.01), >se in Qmax (p=<0.05)
Kajbafzadi 2015/2	6-14 years Primary NE	Urotherapy (standard) vs urotherapy (standard) + IFT	54	IFT quadripolar symphysis pubis and ischial tuberosities	Sig decrease in wet nights in IFT group compared to controls at 2 months and 1 year (P=0.003 and P=0.03, respectively
Quintiliano 2015	4-17 years Urinary urgency +/- day wetting	Anticholinergics + sham TENS vs TENS + placebo	28	Sacral (real) Scapular (sham)	Both groups sig improvement in symptoms. Real TENS no side effects and improved bowel function
Patidir 2015	Mean age 8 years Refractory OAB day wetting	TENS vs sham TENS (no stimulation)	40	Tibial (transcutaneous)	Test group vs sham 71.42%:12.5% complete incontinence improvement AVV, MVV and NV improved significantly in test group only (p < 0.001)
Borch 2017	5-14 years Urge incontinence	Anticholinergics + sham TENS vs TENS + placebo vs TENS + anticholinergics	66	Sacral	TENS+anticholinergic 83% >ed treatment response than either monotherapy (p+0.05). Combined also < wet days, < severity and < voiding frequency, and TENS < PVR risk compared to anticholinergics

Author and year of publication	Population	Design	N	Mode of application	Outcome measure
Jorgensen 2017	7-11 years MNE	TENS vs sham TENS	47	Sacral	No sig. changes in no of wet nights, nocturnal urine production, MVV or voiding frequency
Abd El-Moghny 2018	8–12 years refractory PMNE	behavioural therapy and PFM training alone or added intra-anal BFB or added intra-anal ES	90	Intra-anal	3 groups had sig. improvement in first void of am, reduced wet nights. Greater improvements in ES group.
De Paula 2018	3-18 years OAB day wetting and 7 with enuresis	Tens + urotherapy vs sham +urotherapy	16	Sacral (real) Scapular (sham)	Sacral TENS – sig. improvement urgency as well as an increase in dry (p = 0.03). No difference was noted regarding day wetting.
Sharifi-Rad 2018	5-13 years Constipation	Physiotherapy + IFT vs physiotherapy with sham IFT	90	IFT Quadripolar anterior abdominal wall and posterior paraspinalT10-L4	Frequency of defaecation >ed in both groups. At 6 months better in IFT group (P= 0.005)
Ladi-Seyedian 2019	5-13 years Non-neuropathic urinary incontinence	Standard urotherapy vs physiotherapy vs physiotherapy+ IFT	46	IFT Quadripolar anterior abdominal wall and paraspinal T12 and L4	At 6 and 12 months UI sig decreased in PT + IFT group (P<0.04 and P=0.05 respectively)
Ladi-Seyedian 2020	5-10years BBD	Physiotherapy vs physiotherapy + IFT	34	IFT Quadripolar anterior abdominal wall and paraspinal T12 and L4	Significant more children receiving PT+IF [11/17 (64.7%)] had full response versus PT: P= < 0.03.
Abdelhalim 2020	7-14 years PMNE	Sacral TENS vs IFT	52	Sacral TENS S3/4 IFT quadripolar pubic symphysis to ischial tuberosity	No of wet nights, reduced significantly (P < 0.05) in both groups, in favour of IFC group

The restricted lifespan of the battery, 3 to 9 years depending on the stimulation program, is another limiting factor, implicating necessity of multiple operations in future. However, new rechargeable implants have a much longer battery life, potentially up to 15-20 years.

Compared to other treatment modalities, the cost-effectiveness of sacral neuromodulation, certainly in children is an important consideration. A study by H.S. Harvey et al showed that in adult women suffering refractory urgency urinary incontinence, SNM and BTX 200 units are both effective treatment modalities but that cost-effectiveness of SNM is much lower than BTX 200 Units [187].

General limits of the evaluation of results for invasive SNS are the small number of patients in all series, the heterogeneity of the study populations, the general absence of RCTs, the different ways to evaluate results and different clinical protocols. For all these reasons SNM in children still needs further studies (controlled and randomised).

Due to the uncontrolled design the level of evidence is low. Experience from adults treated with SNM suggests future positive development in children, in well-defined cases, to be likely.

Conclusion: non-invasive ENS is effective in the treatment of children with non-neurogenic LUTS. It is also effective in the treatment of bowel and bowel-bladder dysfunction (LoE:3)

Recommendation: non-invasive ENS is recommended as a treatment option in children with non-neurogenic LUTS and in those suffering bowel and bowel-bladder dysfunction (GR:C)

6.2.4. Alarm therapy

Alarm therapy has traditionally been used for the treatment of nocturnal enuresis as it is the most effective treatment with the best long-term results with approximately two thirds of children becoming dry. When appropriate, the alarm is considered as first line treatment for enuresis. (See above) Alarm therapy can also be used for daytime wetting but not often. Only one randomised clinical trial has been published to establish the efficacy of this form of treatment. Halliday et al. compared a contingent alarm which sounded when the child wets with a noncontingent alarm system (which sounded at intermittent intervals to remind the child to void) [188]. Forty-four children participated in the study, 50% were assigned to each form of therapy for a 3-month period. Success was measured as 6 consecutive weeks without daytime wetting. Nine children in the non-contingent group and 6 children in the contingent group had persistent wetting. Although the risk of persistent wetting with the contingent alarm was 67% of the risk of persistent wetting with the noncontingent alarm, the difference in the reduction in wetting between the groups was not significant (RR 0.67, 95% CI 0.29 to 1.56). In a retrospective review by Van Laecke et al., a cure rate of 35% after the use of a daytime alarm was described [189]. Due to the retrospective design of the study the level of evidence is low.

Conclusion: alarm therapy is effective in the treatment of daytime incontinence in children (LoE:3)

Recommendation: alarm therapy can be used in the treatment of daytime incontinence (GR:3)

6.3. Group training

Group training programmes have been developed for children with treatment-resistant incontinence. The program includes provision of information, coaching regarding drinking and voiding habits, relaxation and stress-reduction techniques, as well as cognitive-behavioural therapy (CBT). The training proved to be effective in pre-post analyses [190].

6.4. Conclusion

Many clinical studies describe combinations of therapies rather than single interventions, which makes it difficult to evaluate the results. Most studies only state the clinical responses, and do not provide information on urodynamic parameters or muscle measurements before and after treatment. A 'normal' flow curve may not mean normal voiding if no information is provided on post-void residual urine. In most papers the inclusion and exclusion criteria are not clearly documented, and it may very well be that the more difficult patients with both storage and voiding dysfunction were included in the study population. Furthermore, different series may describe different groups of patients due to poor definitions and an inadequate classification system. Again, we recommend the Template for Intervention Description and Replication (TIDieR) checklist guide future studies [146].

7. PHARMACOLOGICAL TREATMENT

7.1. Antimuscarinic therapy

Antimuscarinic therapy remains one of the common forms of therapy for overactive bladder / detrusor overactivity. Its use is predicated on the concept that parasympathetic mediated stimulation of muscarinic receptors in the bladder causes detrusor overactivity, which is responsible for the symptoms of overactive bladder. Antimuscarinic agents have been demonstrated to increase bladder capacity, increase bladder compliance and decrease detrusor contractions in neurogenic detrusor overactivity. Detrusor overactivity is believed to play a role in many children with functional incontinence, vesicoureteral reflux and urinary tract infections [191]. More commonly, pharmacotherapy is instituted when behavioural therapy has failed to achieve a satisfactory outcome. Some clinicians use pharmacological therapy as first line in children with moderate to severe daytime incontinence [73].

Despite the frequent use of anticholinergic therapy, often in conjunction with a behavioural therapy regimen, the outcome of pharmacological therapy for daytime urinary incontinence is "unpredictable and inconsistent" and there are few randomised studies available to assess drug safety and efficacy in children.

The following antimuscarinics are briefly discussed:

- Oxybutynin: approved for use in children FDA EMA
- Propiverine: approved for use in children EMA
- Tolterodine: tested phase 3 clinical trials, not approved for use in children
- Solifenacin: tested phase 3 clinical trials, awaiting approval for use in children
- Terodiline: investigated in a randomised placebo controlled trial, withdrawn because of serious cardiac side effects.
- Trospium chloride: approved for use in children 2 years and older FDA EMA
- Fesoterodine: used in small series in children, but not approved for use in children

Oxybutynin

Currently the pharmacological therapy most widely used in children with detrusor overactivity is oxybutynin [192]. In 2002, a long-acting formulation, Oxbutynin XL, was approved by the FDA for use in children [193]. Historically, oxybutynin use has been limited by its adverse effect profile with such side effects as dry mouth, constipation, facial flushing and CNS effects. The incidence of side effects seems to be dose-related, both for oral and intravesical administration [194]. The CNS effects are related to the ability for oxybutynin and its metabolites to cross the blood brain barrier. Oxybutynin XL utilises a novel delivery system, which results in absorption in the large intestine, thereby bypassing the first pass metabolism in the liver. This leads to a decrease in the amount of active metabolite [produced in the liver]: resulting in a more favourable tolerability profile. The delivery system requires an intact tablet and thus it cannot be cut or crushed to facilitate swallowing. Another method of delivery of oxybutynin is intravesical therapy. This method of delivery also avoids the first pass effect and leads to increased amounts of oxybutynin available compared to immediate release oxybutynin. Its use in the neurologically intact patient is limited by the need for catheterisation [194].

Transdermal delivery of oxybutynin is another approach to avoid the first pass metabolism through the liver. Limited small studies have been reported with children and the localized skin irritation and continued adherence of the transdermal patch limit its utilisation.

There are only a few studies and only one randomised and double blinded, assessing the efficacy of oxybutynin in detrusor overactivity (DO) in children. In the European Bladder Dysfunction study, 97 children with DO on cystometrogram, received oxybutynin or placebo: the placebo effect of 45% was equal to the effect of oxybutynin chloride [195].

Curran et al. in a retrospective review of 60 patients assessed the efficacy of several agents, primarily oxybutynin in children with non-neurogenic detrusor overactivity, confirmed by urodynamics, who were refractory to behavioural therapy. Some children were treated with combination therapy. Eighty percent had complete resolution or a significant improvement in their urinary symptoms. The authors noted an average time to resolution of symptoms of 2.7 years (range 0.2 to 6.6), however patients were not followed frequently [196]. In a study by Van Hoeck et al. holding exercises with and without oxybutynin showed no beneficial effect on bladder volume. [197].

Conclusion: Oxybutynin is an effective treatment in children with incontinence due to detrusor overactivity (LoE:3)

Recommendation: Oxybutynin is recommended in the treatment of daytime incontince in children with bladder overactivity. Attention should be paid to adverse effects (GR:B)

Propiverine

Propiverine is the second antimuscarinic drug approved by the EMA for use in children. A randomised, double-blind, placebo-controlled phase 3 trial with propiverine in children aged 5-10 yr. was reported in 2008. Of 171 randomised children, 87 were treated with propiverine and 84 with placebo. The primary efficacy outcome, decrease in voiding frequency, was -2.0 episodes for propiverine versus -1.2 for placebo; p=0.0007. Superiority could also be demonstrated for increase in voided volume (31.4 vs. 5.1ml; p<0.0001) and reduction in incontinence episodes (-0.5 vs. -0.2) episodes per day; p=0.0005. This clinical trial showed superior efficacy of propiverine over placebo and good tolerability for the treatment of children suffering from DO and urinary incontinence. [198,199] This is the first study with level of evidence 1 that demonstrated a beneficial effect of anticholinergic therapy in children.

A retrospective study published in 2012 on 68 children with OAB, reported a response rate of 86.8% [200].

Conclusion: propiverine is effective in the treatment of daytime incontinence in children (LoE: 1)

Recommendation: propiverine is recommended as therapy for urinary daytime incontinence (GR: B/C)

The following antimuscarinics are not approved for use in children, and may only be used off-label.

Tolterodine

Tolterodine is a non-selective antimuscarinic used for the treatment of overactive bladder and detrusor overactivity in adults. It is the first antimuscarinic agent designed specifically for use in detrusor overactivity and is felt to be “bladder selective”. Its affinity for the bladder compared to other organ systems has been suggested to account for a favorable tolerability profile. The chemical nature of tolterodine makes it less likely to penetrate the blood brain barrier, which is supported by EEG studies [201]. The delivery system of the long acting preparation is such that the capsule may be cracked and “sprinkled” on food. Tolterodine has not been approved for use in children but there are several studies, which evaluated its safety and efficacy in children with detrusor overactivity. Hjålmas reported the results of an open label, dose escalation study using immediate release tolterodine in 33 children [202]. Doses ranged from 0.5 mg po BID to 2 mg po BID for 14 days. The results demonstrated a 21% (23% with 2 mg po BID) mean decrease from baseline in micturition frequency and a 44% mean decrease from baseline for the number of incontinence episodes in children treated with 1 mg and 2 mg po BID. Bolduc et al. reported on a prospective crossover study of 34 children followed for > 1 year who were crossed over from oxybutynin to tolterodine because of adverse effects with oxybutynin [203]. Detrusor overactivity was confirmed in 19/20 who had urodynamic studies performed prior to therapy. Children received either 1 mg or 2 mg po BID and the median treatment period was 11.5 months. Efficacy was assessed by a questionnaire and was comparable for oxybutynin and tolterodine. Sixty-eight percent noted a > 90% reduction in wetting episodes at 1 year and an additional 15% noted a > 50% reduction in wetting episodes. Fifty nine percent reported no side effects with tolterodine and 18% reported the same side effect as with oxybutynin, but felt it was less severe. Eight patients (24%) discontinued tolterodine.

Munding et al. reported on the use of tolterodine in children with “dysfunctional voiding” manifested as daytime wetting, frequency or urgency [204]. There was no documentation of uroflow studies to make the diagnosis of “dysfunctional voiding” and from the symptoms these children appeared to have detrusor overactivity. Children were started on behavioural modification for 4-6 weeks and pharmacological therapy was instituted if they failed or had only slight improvement with behavioural therapy. A minimum of 1 month’s follow-up was needed for inclusion, but the mean follow-up was only 5.2 months. Doses ranged from 1 mg po BID to 4 mg po BID. Assessment of results was made by telephone survey. Thirty-three percent had > 90% reduction in daytime and night-time wetting episodes and 60% had > 50% reduction. Four patients (13.3%) had side effects, constipation in 2, dry mouth in 1 and diarrhoea in 1.

Reinberg et al. performed an open label parallel group retrospective study of the efficacy and safety of immediate release and long acting tolterodine and extended release oxybutynin [205]. Children started out with the lowest possible dose, 2 mg tolterodine and 5 mg oxybutynin and titrated up according to response and side effects. Children were arbitrarily assigned to therapy based on the formulary restrictions of the health plan and there was an uneven distribution of patients in the treatment groups. Final dose and duration of treatment were not noted. Study nurses asked about side effects and a voiding diary was used to assess efficacy. The authors concluded that extended release tolterodine (p<0.05) and oxybutynin (p<0.01) were more effective than immediate release tolterodine in improving urinary incontinence symptoms and that extended release oxybutynin was more effective than extended release tolterodine in resolving diurnal incontinence (p<0.05) Long term tolerability of tolterodine extended release in a large paediatric population has been shown [206].

Conclusion: Tolterodine is effective and safe in the treatment of overactive bladder in children (LoE:3)

Recommendation: Tolterodine is recommended as a therapy for overactive bladder in children. The is off-label (GR:C)

Solifenacin

Solifenacin is an antimuscarinic agent used in children with OAB: Hoebeke et al. published results on 139 children with therapy resistant OAB, with favourable results, and few side effects, in 2009 [207].

Bolduc et al. conducted a prospective, open label study, and published their results in 2009: 72 children enrolled, 45 with non-neurogenic DO. Continence improved in all patients, including 24 who were dry, and 42 and 6 who were significantly and moderately improved, respectively [208].

Long term use showed that high subjective and objective success rates were maintained over a longer follow-up [209].

Conclusion: Solifenacin is effective in the treatment of overactive bladder in children (LoE:2)

Recommendation: Solifencin is recommended as treatment of overactive bladder in children . The use is off-label in non-neurogenic children(GR:B)

Terodiline

One of the drugs which has been investigated in a randomised placebo controlled trial was terodiline [210,211]. Because of serious cardiac side effects terodiline has been withdrawn from the market and is of only historical interest.

Trospium chloride
Trospium chloride has been used in small series in children. It is currently available in a twice a day dosing formulation that can be used in children. For adults a once daily preparation is available. In the adult population, there is a 16% intra-individual variability in bioavailability and 36% inter-individual variability. Absorption is affected by food intake. Trospium's chemical structure make it unlikely to penetrate the blood brain barrier as supported by EEG studies. Lopez Periera et al. evaluated the use of trospium in 62 children with documented detrusor overactivity and absence of 'detrusor sphincter dyssynergia' [212]. Children were randomly assigned to 10, 15, 20 or 25 mg of trospium administered in 2 divided doses or placebo. Fifty-eight children were evaluated. Response rates were assessed by incontinence episodes and urodynamic parameters. Overall, 32% had an excellent response, 42% a good response and 8% a fair response. Detrusor overactivity completely resolved in 35%. Four children had medication related adverse effects including headache, dizziness, abdominal cramps and dry mouth.

Conclusion: trospium chloride is effective as therapy for overactive detrusor in children (LoE:3)

Recommendation: trospium chloride is recommended for the treatment of overactive detrusor in children. The use is off-label in non-neurogenic children (GR:C)

Fesoterodine
Fesoterodine is approved for adults, and is reportedly safe and effective. A post marketing surveillance study in Korea with 2978 adults with OAB scored on efficacy showed amelioration in 91% [213]

Comparison with solifenacin showed no difference in efficacy, but more side effects with fesoterodine [214].

Expert opinion is that fesoterodine has a similar tolerability and side effect profile to other antimuscarinics and is, therefore, unlikely to revolutionise the treatment of the overactive bladder [215].

In children, the only study done is a dose-escalating study of the pharmacokinetics and tolerability, showing steady-state plasma 5-hydroxy-methyltolterodine exposures similar to those in adults. The doses given were well tolerated. Only 10 children with non-neurogenic bladder and OAB were included [216].

Darifenacin
Darifenacin is approved for use in adults as well. Although already mentioned in 2004 to be promising, in children, up to date no studies have published [217].

Combination therapy
Some authors have tried combinations of anticholinergics for refractory OAB: Bolduc et al. treated 33 children with a combination of oxybutynin and solifenacin or tolterodine with good success [218, 219].

Fahmy et al. enrolled 72 children in a prospective study where trospium chloride was added to oxybutynin in refractory OAB: 68% showed improvement, 22,2% were completely dry [220].

7.2. Beta3-adrenoceptor agonists
Mirabegron is the first of a new class of drugs for the treatment of OAB. Stimulation of β3-adrenoreceptors results in relaxation of the detrusor smooth muscle and improves bladder compliance and bladder capacity. Randomised controlled trials in adults show that mirabegron decreased the number of micturitions and incontinence episodes in a 24-hour period compared with placebo. Mirabegron is approved for use in adults [221,222].

A small number of studies have been published in children. A prospective off-label study in 58 children with refractory OAB or with significant side effects with at least two different antimuscarinic agents were recruited. Continence improved in 52 of 58, with 13 being completely dry. Eight patients reported mild or moderate side effects. Absence of a placebo group is a limitation of the study [223].

Phase 3 studies with mirabegron are currently ongoing in children with neurogenic bladder, but not yet in neurologically normal children. A recent study evaluating the pharmacokinetics (PK) of mirabegron in children demonstrated that single, weight-adjusted paediatric mirabegron doses were successfully predicted by population PK modeling to achieve drug exposures comparable with steady state in adults [224]. Miabegron has been FDA approved only for the treatment of neurogenic detrusor overactivity in children aged 3 years and older

Conclusion: Mirabegron is effective in the treatment of children with overactive bladder (LoE:3)

Recommendation: Mirabegron is recommended for the treatment of overactive bladder in children. The use is off-label in non-neurogenic children (GR:C)

7.3. Botulinum Toxin
Botulinum toxin is used in children, mainly with neurogenic detrusor overactivity. Botulinum toxin has recently been approved by the FDA (February 2021) for the treatment of neurogenic detrusor overactivity (NDO) in paediatric patients 5 years of age and older who have an inadequate response to or are intolerant of anticholinergic medication. The safety and efficacy of OnabotulinumtoxinA was evaluated in a 48-week prospective, multicenter, randomised, double-blind study in children (aged 5-17 years) with NDO and urinary incontinence [225]. This phase 3 study of more than 100 pediatric patients demonstrated that the intradetrusor administration of OnabotulinumtoxinA of 200 Units (not to exceed 6U/kg) was well tolerated and effective for the treatment of NDO in children. The reduction in daytime urinary incontinence along with a lowered maximum bladder pressure and increased bladder capacity at week 6 (primary timepoint) were the main significant clinical benefits.

In children, botulinum toxin is injected in 20 spots along the detrusor wall. Although the dosage in children varies in different published studies, the FDA labelling is approved for dosing of up to a maximum of 200 U and not to exceed 6U/kg [225]. The results last about 6-9 months.

There is no approved study by the FDA or EMA for the usage of botulinum toxin in non-neurogenic detrusor overactivity in children. One prospective uncontrolled study by Hoebeke et al. in 21 children showed beneficial effects of botulinum toxin in 70% of children with therapy resistant detrusor overactivity [226].

Urodynamic assessment demonstrated improvement after botulinum toxin A in detrusor contractions and bladder capacity in a prospective study with 13 children [227]. Leon et al. published an even smaller prospective uncontrolled series in 2014 on 8 children with favourable results [228]. Other published studies are all retrospective: A retrospective study in 30 patients by Blackburn et

al. published in 2013 and a retrospective study in 57 patients by McDowell published in 2012 demonstrated a good response [229, 230]. Injection of botulinum toxin into the external sphincter is also possible, but the results are more variable and last only 3-4 months [231]. Radojici et al. describe excellent results in the treatment of dysfunctional voiding. In 20 children, good results were described for 17 patients [232]. In a retrospective study by Franco et al. similar results were described in 16 children, however using a higher dosage [233].

These results are confirmed by 't Hoen et al., and by Vricella et al., but the effect in their series was longer: they report safe and persistent satisfactory results during an average of 13 months in 18 of 20 patients and 15 months in 8 of 12 patients respectively with therapy-refractory dysfunctional voiding [234,235].

Less invasively, botulinum toxin can be administered electromotively: a small study in 15 children showed that this type of administration is feasible, safe, and results in considerable improvement on urinary incontinence [236].

Conclusion: Botulinum toxin is an effective therapy for detrusor overactivity in children (LoE:3)

Recommendation: Botulinum toxin is recommended as treatment for detrusor overactivity in children.The use is off-label in non-neurogenic children (GR:C)

7.4. Alpha-adrenergic blockers

Treatment of the overactive pelvic floor and sphincter is much more difficult. Treatment with alpha-adrenergic blockade seems promising, but from the presented studies it is difficult to draw firm conclusions, as most series are small, not randomised and describe a mixed patient population [237-239].

In a more recent uncontrolled study by Donohoe et al. a total of 26 patients with primary bladder neck dysfunction (20 males, 6 females, mean age 12.8 years) were treated with alpha-blockers. Mean average and maximum uroflow rates improved from 5.5 to 12.6 cc per second and from 10.3 to 19.7 cc per second, respectively, while mean EMG lag time decreased from 24.4 to 5.7 seconds and post-void residual urine volume from 98.9 to 8.9 cc (all p <0.001). Mean follow-up was 31 months and no major adverse side effects were observed [240]. Further randomised controlled studies are needed to define the place of alpha-blockers.

Conclusion: alpha-adrenergic blockers are effective in the treatment of primary bladder neck dysfunction in children (LoE:3)

Recommendation: alpha-adrenergic blockers are recommended for treatment of primary bladder neck dysfunction in children (GR:3)

Because there is much variability in presenting symptoms as well as the underlying pathology an individual approach is advisable: a step by step algorithm has been developed by Marschall-Kehrel, which seems to deal with many of these variables [241].

Conclusion: a step by step algorithm is an effective tool for an individual approach of children suffering urinary incontinence (LoE:3)

Recommendation:the use of recommended for the treat a step by step algorithm is recommended for the treatment of urinary incontince (GR: B/C)

The limited number of identified randomised controlled trials does not allow a reliable assessment of the benefits and harms of different methods of management in children. Further work is required in this difficult clinical area. The establishment of outcome measures is needed, to facilitate randomised controlled trials of routine therapy. Interventions that would benefit from further investigations include: bladder and voiding education, bladder retention training, bowel management, hypnotherapy and alternative therapies, psychology, prophylactic antibiotic medication, neuromodulation, biofeedback therapy and pelvic floor muscle awareness and specific relaxation. Only then can the efficacy of new interventions be measured in children with detrusor overactivity or dysfunctional voiding.

Development of less invasive methods of diagnosis and treatment should therefore be encouraged.

V. NEUROGENIC DETRUSOR-SPHINCTER DYSFUNCTION

1. INTRODUCTION

Neurogenic detrusor-sphincter dysfunction (NDSD) develops in response to a congenital or acquired lesion in the spinal axis at any level below the pons. These lesions result in various lower urinary tract dysfunctions which may be manifested as urinary incontinence, urinary tract infections (UTIs), vesicoureteral reflux (VUR), and renal damage, either on the basis of scarring from infection or as a result of high resting storage pressures. While we commonly place a greater emphasis on the management of incontinence in these patients because it affects their quality of life in the present, **the primary goal of their management must be to preserve a safe low pressure lower urinary tract**. Failure to do so can result in an obstructive uropathy that over the long term leads to renal failure, dialysis, and transplantation. The statistics are sobering; approximately 25% of young adults with spina bifida shows signs of renal insufficiency, and up to 5% have required transplantation [1, 2]. What makes this a particularly difficult problem to manage is that the resulting renal failure develops insidiously with the average age of transplant being 27 years of age (Figure 1).

The problem is further compounded by the lack of an accurate measure of the GFR in these patients [3-5]. This is because the equations to estimate GFR from a creatinine value are based on healthy individuals; they do not take into account the diminished muscle mass seen in these patients and the challenge of measuring an accurate height in patients who may be wheelchair dependent or have severe scoliosis. By the time the creatinine begins to rise, a substantial loss of GFR has occurred. The majority of these patients who present in renal failure do so long after they have left pediatric care; this can diminish the sense of urgency we must have to optimise lower urinary tract function early in life by teaching

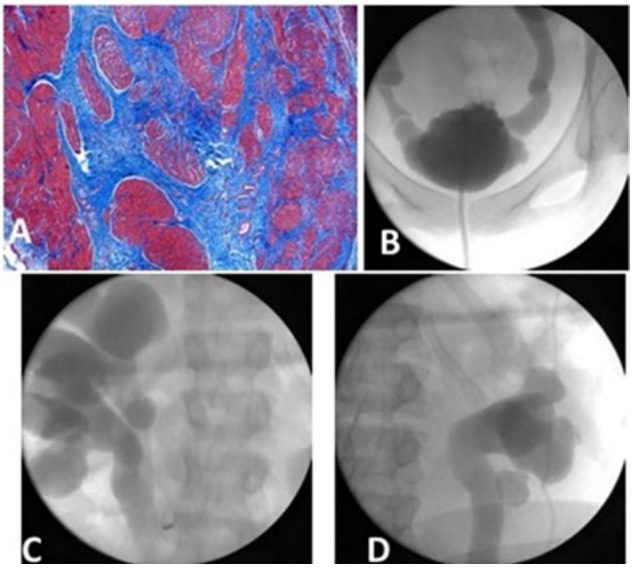

Figure 1 – This patient developed end stage renal disease in her 20s as a result of her neuropathic hostile bladder. Bundles of collagen (blue) are seen among sparse smooth muscle (red) (A). The bladder is small and non compliant (B) and there is massive reflux into the upper urinary tract (C&D)

families and children the importance of learning and adhering to a regimen of clean intermittent catherisation (CIC) [6, 7]. In the ideal setting, patient management should be driven by the scientific principles that describe the physiology of the lower urinary tract and well done clinical trials; but the reality is that managing the social aspects of this condition are as important if not more important than the science alone. **The old adage that is better to be a safe wet, than a dangerous dry remains true**.

Sixty years ago these children rarely survived past infancy. The first major advance for the care of children with spina bifida was the introduction of shunting to manage hydrocephalus [8]. As these children survived beyond infancy, it became apparent that the urinary tract would prove to be a source of major morbidity unless it could be successfully managed [9]. Reflux and recurrent urinary tract infections were noted by the early practitioners of paediatric urology, but urodynamics for children were not available at that time. This resulted in the adoption of urinary diversion with ileal conduits or ureterostomies. The vesicostomy was adopted as a means to drain the lower urinary tract and preserve the upper tracts, and continues to be used today [10, 11]. Such an approach would have preserved the renal function of the patient shown in figure 1 who now suffers the double burden of incontinence and renal failure. A major advance in the management of these children was the introduction of CIC [3, 4]. In reintroducing CIC to modern medicine, Lapides created the possibility for bladder preservation or continent reconstruction. Clearly preservation of the native bladder is the optimal outcome, although it is important to note that even in these cases, malignancies in later life have been described in the absence of augmentation [12]. Numerous approaches to the surgical reconstruction of the lower urinary tract have been described over the past half century. In recent years, the application of robotic assisted reconstruction has begun to take hold. But no matter which of the many reconstructive techniques is selected, **the approach to continence for these children must begin with an assessement of the child's motivation and the total commitment of a motivated and well informed family**. Given the potential for complica-

tions with such surgery and the need for fastidious adherence to CIC and followup visits, a failure to properly select and educate the patient and family can set up the potential for decisional regret [13]. But when patients and families are properly selected, the surgical creation of continence (by whichever method is used) offers the patient an enhanced quality of life [14].

It is worth distinguishing between a neurogenic and a neuropathic bladder. A neurogenic bladder arises from an anatomically defined neurologic deficit such as spina bifida, spinal cord injury (from trauma or compression by tumors), sacral agenesis, or following surgical excision of a sacrococcygeal teratoma. In contrast a neuropathic bladder may arise from posterior urethral valves, connective tissue disorders (such as Ehlers Danlos syndrome), mutations in smooth muscle actin (which results in hollow visceral myopathy) [15], recurrent infections, or behavioural issues. Some cases resist such a categorisation, of which Hinman's Syndrome is one such example [16]. While the Hinman Syndrome was originally felt to fall into the "behavioural" category, Ochoa described several familial cohorts of patients with classic detrusor sphincter dyssynergia some of whom went on to develop renal failure [17, 18]. These patients had no obvious neurologic finding to explain this. This cohort was studied extensively and led to the discovery of mutations in the heparanase 2 gene as the genetic etiology [19]. Deletion of heparanase 2 in mice produces a voiding phenotype of retention, with a higher leak point pressure [20]. Taken together, these findings suggest that even a normal spinal MRI does not rule out a neurologic etiology for detrusor sphincter dysynergia. Another example would be mitochondrial disorders which might cast an effect on the nervous system as well as the smooth muscle of the bladder and bowel [21].

The most common cause of NDSD in children is neurospinal dysraphism which presents across a spectrum ranging from myeloschisis to myelomeningocele. In the neonatal phase many of these infants appear to void and bladder scanning may show that they do empty. However over time, a different picture emerges and the bladder begins to show the strain of being subjected to high pressure voiding and worse yet, high pressure storage. This transition which can occur silently will be detected only through videourodynamics which play a role in the identification of the hostile bladder. Typically the neonate with spina bifida will undergo a videourodynamic study around 3-4 months of age and about 20% of these studies will show fairly normal findings. But with time the urodynamic findings are likely to change as a result of high pressure voiding due to NDSD which can result in bladder wall fibrosis and a loss of bladder compliance which is often accompanied by the onset of reflux. This change in urodynamics serves to point out the need for fastidious follow up of these patients. A carefully done video urodynamic evaluation with a systematic analysis of the individual components of the study can be used in conjunction with a scoring system to predict which patients are at risk of upper tract damage [22]. A classic paper suggested that upper tract changes are more likely to occur once a passive leak point pressure of 40 cm H2O is recorded [23], although today there is a growing awareness that this number is likely to be much lower especially when patients are followed over many years. This pathophysiology makes sense given the established relationship between bladder pressures, and those recorded in the upper urinary tract in clinical [24, 25] as well as investigative [26] settings.

The past half century has seen a remarkable improvement in the management of patients with spina bifida, which in part is the result of better management of the lower urinary tract. However sophisticated our current urodynamics systems look, evocative cystometry has some significant limitations. This is in part due to the higher than normal fill rates used, and a common failure to measure and account for natural urine production during the study. In addition, the study is usually done with a patient supine as opposed to standing or sitting. Microelectronics and nanotechnology offer the promise of prolonged (and perhaps even permanent) ambulatory monitoring that will give more accurate measurements of the physiology of the lower urinary tract in real time [27, 28]. Application of these new technologies in this patient population will represent a significant advance and allow for better stratification of patients to identify those at risk of upper tract decompensation. Another area of need is in the interpretation of VUDS or UDS. There is significant interobserver variability in the interpretation of VUDS or UDS [29, 30]; we can anticipate the application of machine learning and artificial intelligence to help improve the accuracy of these studies which will offer a clinical benefit to the patient, and to research groups trying to assess outcomes [31]. No matter which new tools and technologies are introduced, the goals remain the same; to preserve renal function, and to achieve continence at an appropriate age.

2. PRESENTATION OF NEUROGENIC DETRUSOR-SPHINCTER DYSFUNCTION IN CHILDREN

The most common reason for NDSD in children is spinal dysraphism which arises due to incomplete closure of the vertebral column and malformation of the embryonic neural tube. The closure of spinal canal in utero takes place in a cranial to caudal direction and is complete by 35 days of gestation. The failure of mesodermal in-growth over the developing spinal canal results in an open lesion most commonly seen in the lumbosacral area. The degree of this closure deficiency contributes to a variable presentation of neural injury with varying degrees of LUTD and lower extremity problems. **The type and degree of detrusor sphincter dysfunction is poorly correlated with the type and spinal level of the neurologic lesion**. The process of spinal closure is in part folic acid dependent. Maternal dietary supplementation with folate in advance of conception has been shown to reduce the incidence of spina bifida [32, 33]. In the US alone, dietary folate supplementation has been estimated to prevent some 670 births with spina bifida resulting in a 603 million dollar lifetime health care savings for each birth year cohort [34]. There is a poorly understood genetic component, as the incidence of SB is increased if there is a family history. A patient with spina bifida has about a 4% chance of having a child with spina bifida [35]. Application of copy number variant analysis and or whole exome sequencing in these patients should allow for identification of the genes or gene networks that contribute to this closure and hopefully allow for new approaches to prevention [36].

Myelodysplasia, also commonly known as **spina bifida** (SB), is a general term that describes incomplete closure of the vertebral column and malformation of the embryonic neural tube. A wide spectrum of lesions are seen ranging from a failure of fusion of the vertebral bodies with a herniation of the dura with or without neural elements within the sac (meningocele), or a lipomeningocele in which fat is also contained within the meningocele. The most common and most dangerous form is myelomeningocele in which there is a herniation of the spinal cord out onto the back and there is no dura or skin covering the neural placode. In addition to the danger of sepsis posed by exposed neural elements, these lesions are often associated with hydrocephalus which necessitates placement

Figure 2 – Examples of the kind of sacral spinal findings on physical exam that should trigger suspicion for a tethered cord and lead to an MRI of the spine. However tethering can be seen even in the presence of a normal physical examination.

of a shunt to prevent herniation. These diagnoses are most likely to be made in utero, or in the newborn nursery. The neurologic lesions are variable and will be effected by the degree to which the neural elements are extruded. Although we can assess the vertebral level of the lesion, this does not correlate well with the neuro-urologic outcomes. In general however the lower the level of the lesion, the less the need for shunting, and the better the neurodevelopmental outcome. Even after a foetal or neonatal closure, the spinal cord can retether producing changes in gait or the urodynamics [37].

In occult myelodysplasia, the lesions are not overt and often with no obvious signs of neurological lesion which explains why these lesions are not diagnosed in the neonatal period. A tethered spinal cord with or without an associated lipoma is the most likely finding in this scenario, and with spinal MRI this diagnosis can now be made with accuracy. While it is true that a cutaneous lesion over the sacral area may be seen in a substantial percentage of these cases (Figure 2), there are many cases that have absolutely normal sacral anatomy . Lesions that arouse suspicion may include a dimple, skin tag, hair tuft, vascular malformation, or lipoma; a study in 70 such infants found a low lying conus in 20% [38]. Many older children present with a normal spinal exam, but worsening gait and new onset bowel/bladder symptoms. They may also present with back pain, a loss of perineal sensation, or a complaint of sexual dysfunction. In a child with recalcitrant bowel bladder dysfunction and a normal sacral examination, it is reasonable to consider an MRI to rule out a cord tether, but it must be recognized that the yield is low [39].

Sacral agenesis is a rare congenital anomaly that involves absence of part or all of one or more sacral vertebrae. Perineal sensation is usually intact and lower extremity function is usually normal and the diagnosis is made when a flattened buttock and a short gluteal cleft is seen on physical examination [40]. Most of these patients will require CIC for continence.

Cerebral palsy patients may also present with varying degrees of LUTD usually in the form of overactive detrusor and wetting. Many of these patients can achieve continence with the use of anticholinergics and timed voiding. Their voiding phenotype does not seem as severe as that seen in patients with spina bifida. This likely is a reflection of the prolonged exposure of the spinal cord elements to amniotic fluid throughout gestation. In contrast, patients with cerebral palsy have normal foetal development until later in the pregnancy when the asphyxia occurs.

Imperforate anus is a rare anomaly and presents with a closed rectum that does not open onto anal skin verge. Traditional thinking was that the incidence of tethered cord was associated with the level of the imperforate anus with a higher incidence of tethering noted if the fistula developed above the levators. However in one series, tethered cords were observed in 35% of patients who were imaged routinely with MRI and the level of the fistula did not matter [41]. These children should all be imaged with a spinal sonogram in the newborn nursery prior to the calcification of the vertebrae. Some series suggest that the tethering does not impact bowel continence and advocate observation [42], while others suggest prophylactic detethering [43]. In another large series, 36% of all patients were shown to have a tethered cord, and if the fistula ended at the bladder neck, this defined a subset at high risk for bowel bladder control [44, 45]. Early detection of this problem in imperforate anus patients is important to improve the child's chance of maintaining healthy kidneys and allows for proper counselling of the family. In the absence of this knowledge they will be more likely to embark upon toilet training and encounter frustration. The sooner a family understands their child has a neurogenic bladder and/or bowel, the better the outcome.

Sacrococcygeal Teratoma presents as a mass arising from the sacrum that is a benign tumor which responds well to excision. In highly selected cases they are amenable to treatment in utero. The lesions can achieve enormous size, and the resection can be accompanied by significant bleeding. Surprisingly many of these children void with low residuals, but a significant cohort are left with a flaccid or underactive bladder [46]. Some of these children valsalva void on their own with a low enough residual that they can stay continent and infection free. For others, CIC will be required.

Inflammatory Diseases such as transverse myelitis and multiple sclerosis are seen in childhood, although they are a rare etiology of NDSD.

Spinal cord injury, tumors, and spinal infarcts are also rare causes of NDSD in childhood. The higher up along the spinal cord that these lesions are found, the greater the likelihood of autonomic dysreflexia.

3. CLASSIFICATION: PATTERN RECOGNITION

Over the past century, multiple classification systems were proposed for categorisation of the neurogenic bladder. They have typically been based on the localisation of the lesion and the findings of the neurourologic examination. In children, the spinal level

and extent of congenital lesion is poorly correlated with the clinical outcome. Urodynamic and functional classifications have been more practical for defining the extent of the pathology and planning treatment in children.

A more simplified classification system is built around the two great dividing points in lower urinary tract function; a failure to store or a failure to empty. The benefit of this approach is that using the tool of video urodynamics, one can readily categorise the majority of these patients into functional physiologic categories. Under normal conditions, the detrusor and sphincter are two units working in a coordinated manner to allow for bladder filling without any rise in pressure, and bladder emptying with low voiding pressures. A successfully executed urodynamic study should be to evaluate the passive filling properties of the bladder and delineate the relationship of sphincteric function during a bladder contraction. The individual performing paediatric video urodynamics must be patient and willing to allow for time for slow filling (which should not exceed 4% of expected bladder capacity/min). Ideally, the surgeon who is considering a patient for a continence procedure will perform the study personally. The goal is to allow the patient an opportunity to recreate their symptoms (incontinence) in the laboratory setting. This might even call for the patient to "stand" by tilting the urodynamics exam table so as to understand how the effect of gravity impacts on the function of the outlet. The physician might also ask the patient to cough or strain in an effort to measure the gradient across the bladder neck and external sphincters. Equally important during the study is the patient's response to filling and their reporting of any sensation or discomfort. All of this data is important to document in the record while the study is underway. **Attempts to interpret a "cold study" hours or days later result in a loss of valuable data**. We have found that recording our interpretations into an electronic flow sheet during the actual study is incredibly helpful because this serves as a checklist to help standardise the study but also because it can allow for retrieval of physiological parameters that were stored in a consistent manner [47]. Such a system might also be applied for multi institutional studies that rely upon urodynamics as an outcome. Urodynamic evaluation (preferably in combination with fluoroscopy) makes pattern recognition possible.

Four major types are usually used to describe the detrusor-sphincter dysfunction:

1. Detrusor overactivity with overactivity of the sphincter (mostly dyssynergia),
2. Detrusor overactivity with normal or underactivity of the sphincter,
3. Detrusor underactivity with sphincter overactivity
4. Detrusor underactivity with sphincter underactivity.

Besides these 4 patterns, one can use the ICS classification: overactive detrusor, underactive detrusor, overactive sphincter and underactive sphincter. Sometimes this is more helpful, as the detrusor may be overactive during filling, but underactive during 'voiding'.

The urodynamic investigation is considered normal when there is suitable age appropriate capacity, a normally compliant bladder with no overactivity and normal innervation of the sphincter with normal sacral reflexes and an increase in pelvic floor activity during filling and no activity during voiding. Presence of detrusor overactivity during filling with or without decreased capacity and compliance, is usually seen when there is an upper motor neuron lesion and this is usually accompanied by overactivity of the sphincter and failure to relax during voiding. A lower motor neuron lesion is considered when the voiding detrusor contractions are weak or lost and the sphincter is underactive. **Urodynamic investigations make it possible to establish a personalised management plan for each individual patient**. Current urodynamic technique has some definite limitations, but managing these patients on clinical symptoms alone is akin to flying an airplane without instruments. A metanalysis of 49 studies suggests the value of urodynamics in predicting upper urinary tract damage in patients with neurogenic lower urinary tract dysfunction [48]. Only 1 of these 49 studies was a randomised controlled trial, 9 were prospective, and the overwhelming majority were retrospective in nature. The number of patients in the series reviewed ranged from 9 to 249 with followup ranges from 3 to 10 years (the majority of studies did not include the mean followup time). Not surprisingly the level of evidence was overwhelmingly at a 3, but as Musco et al. pointed out the evidence strongly favours the use of urodynamics in the management of the child with a neurogenic bladder. They also offer suggestions as to how to better record data to allow for better meta analyses of combined series in the future [48].

Conclusion: Urodynamic investigation is essential in the diagnostic workout and the follow-up of a neurogenic bladder (LoE:3)

Recommendation: urodynamic investigation is recommended in the diagnostic workout and the follow-up of a neurogenic bladder (GR:B)

The combination of an overactive detrusor and sphincter is potentially dangerous because of the high intravesical filling pressures, which will put the upper tract at risk (vesicoureteral reflux and hydronephrosis as seen in Figure 1) [22]. In contrast, the combination of an underactive detrusor and a paralysed sphincter is relatively safe, providing a low-pressure reservoir [23, 49, 50].

Conclusion: the urodynamic result of the combination of an overactive detrusor with an overactive sphincter is potentially dangerous. The combination of an underactive detrusor and paralysed sphincter is relatively safe for the upper tract (LoE:2)

Recommendation: it is recommended to evaluate for the possibility of the urodynamic finding of the combination of an overactive detrusor with an overactive sphincter as it is potentially dangerous for the upper urinary tract (GR:B)

4. PRENATAL DIAGNOSIS AND FOETAL SURGERY

In utero intervention holds the promise of reversing some of the sequelae and improving outcome in SB patients. To prospectively evaluate the value of intrauterine surgery, a randomised controlled trial was established in 3 centres. The endpoints of this Management of Myelomeningocele Study (MOMS) included foetal and infant mortality, the need for a ventriculoperitoneal shunt at 1 year of age, and the evaluation of mental and motor development at 30 months of age. Prenatal surgery for myelomeningocele decreased the incidence of ventriculoperitoneal shunting and improved neuromotor functioning, but was associated with maternal and foetal risk [51]. MOMS's experience permitted to define technical differences between prenatal and postnatal defect closure, identifying some potential pitfalls useful in order to reduce complications [52]. Different surgical approaches have been utilised, both open and endoscopic, in order to improve results [53]. After the MOMS study, foetal myelomeningocele repair became a care option for prenatally diagnosed spina bifida [54]. Foetal repair unchanged CIC re-

quirements at 30-month follow-up but showed improved outcomes (less trabeculation and open bladder neck) compared with postnatal repair [55]). Long-term follow-up of bladder function is unknown [56] despite some encouraging reports [57]. Careful counselling is required for the high risk of persistence of neurogenic bladder dysfunction, requiring CIC in 50% of cases. Although most children use diapers or CIC, children who underwent prenatal closure may be more likely to void volitionally [58], but long-term follow-up is required [59,60], including repeated urodynamic studies. In conclusion although the risk for maternal deaths or complications (uterus rupture mainly) are low as rates of adverse neonatal outcomes, the evidence to suggest prenatal surgery is still really low and it should only be done in high volume designated centres.

Conclusion: prenatal surgery in myelomeningoceles performed in high volume designated centers has a positive effect on bladder function (LoE:3)

Recommendation: prenatal surgery in myelomeningocele is recommended to preserve bladder function when performed in high volume designated centers (GR:C)

5. MANAGEMENT

The main aim in management of NDSD in children is to ensure and maintain a reservoir with normal age-matched capacity and good compliance that can be emptied completely at low pressures and at regular intervals. How to perform the management of a potential NDSD is still debated: some are advocating a proactive management versus others suggesting an expectant one [61]. Nevertheless, it is generally agreed that urological care should be initiated soon after a child with SB is born and is to be maintained throughout childhood. In the first years of life, the kidneys are highly susceptible to back pressure and infection. Bladder drainage is essential during and after the closure of the spinal defect in early life. Following the closure, within a few weeks emphasis will be on documenting the pattern of neurogenic detrusor- sphincter dysfunction and assessing the potential for functional obstruction and whether there is vesicoureteral reflux [49]. Ultrasound studies and a VCUG or video-urodynamics to exclude reflux must be performed soon after birth. Measurement of residual urine during both ultrasound and cystography should also be done. These studies provide a baseline for the appearance of the upper and lower urinary tracts, can facilitate the diagnosis of hydronephrosis or vesicoureteral reflux and can help identify children at risk for upper urinary tract deterioration and impairment of renal function. Regarding the time for first urodynamic evaluation, urodynamics should be performed after the so called phase of spinal shock, approximately 3 months after postnatal closure of spinal defect. In children treated prenatally, urodynamics could be performed earlier, such as in the first month of life, because the spinal shock, related to the spinal procedure, occurred early in foetal life [62].

With respect to evaluating the bladder function, 2 general scenarios are common. One group of patients will have an overactive sphincter and develop high detrusor leak point pressures greater than 40 cm H2O and are therefore at risk for upper tract damage. The other group will have underactive sphincter resulting in free urine flow at low pressures into the diaper with little risk to the upper tract. In newborn and infants urodynamics may be difficult to perform, due to a high risk of artifacts, as well as difficulties in interpretation, with poorly defined normative values. The standards of International Children Continence Society should be applied and reported [63]. Urodynamics should be repeated at regular intervals, in combination with evaluation of the upper tracts [64]: such studies should be obtained after 6 months if at risk based on the initial UDS study and clinical parameters, or can be delayed until 1 year of age if the child is low risk. When urodynamic findings are inconsistent with observed deleterious findings of the upper urinary tract (increased dilatation at ultrasound) natural filling cystometry or repeated conventional urodynamics or videourodynamics, could be useful [61].

Conclusion: a strict urodynamic evaluation is essential in the workup and follow-up of a child with a neurogenic bladder. (LoE:2)

Recommendation: it is recommended to perform the initial urodynamic investigation 3 months after postnatal closure, and repeat these studies after 6 months if at risk on the initial UDS or at the age of 1 year in the low risk case (GR:B)

Overwhelming experience gained over the years with early management of the neurogenic bladder in infants has led to a consensus that such children do not develop upper tract deterioration when managed early with CIC and antimuscarinic medication [65-67]. Therefore, initial treatment should consist of oral or intravesical antimuscarinic drugs in combination with clean intermittent catheterisation, to start soon after birth in all babies and especially in those with signs of possible outlet obstruction [68-71]. The volume of urine collected with CIC and severity of urine leakage in between CIC will provide more information about the characteristics of bladder storage and drainage.

Conclusion: early start of anticholinergics and CIC in children with neurogenic bladder is effective to prevent deterioration of the upper tract (LoE:2)

Recommendation: early start of anticholinergics and CIC is recommended in the treatment of neurogenic bladder (GR:B)

The early initiation of intermittent catheterisation in the newborn period, makes it easier for parents to master it and for children to accept it as they grow older [72,73]. With early management, not only are upper tract changes fewer, but also bladders are better protected and incontinence rates are much lower.

It has been suggested that increased bladder pressures due to detrusor-sphincter dyssynergia cause secondary changes to the bladder wall. These fibro-proliferative changes may cause loss of elasticity resulting in a small non-compliant bladder with progressively elevated pressures. It is believed that early institution of intermittent catheterisation and anticholinergic drugs may prevent this in some patients [65,72,74] (Level of evidence 3)

Retrospective evaluation of patients has also shown that significantly fewer bladder augmentations were required in patients with early start of CIC [71,72]. (Level of evidence 3)

The main disadvantage of CIC is bacteriuria which is found in 60% of the patients, but symptomatic UTIs are less common (20%) with CIC when compared to the group without CIC (40%). Symptomatic urinary tract infections defined as foul smelling urine, suprapubic pain with or without an accompanying fever. Patients on CIC are less likely to develop symptomatic UTIs than those who are off a CIC regimen. There is no evidence that maintaining these adult patients on antibiotic prophylaxis confers a benefit and this increases the likelihood of resistant strains of bacteria [75]. The use of nightly bladder irrigations has been shown to lower the incidence of blad-

der stones and UTIs [76] Since the risk of reflux is similarly low with CIC, the renal scar rates are lower.

CIC alone, when begun in infancy can achieve continence at a rate of 60 %. When combined with newer and more potent antimuscarinic drugs continence rates approach 75-80%. [77-80]

Due to high risk of latex sensitivity in the NDSD population, non-latex catheters are recommended. Hydrophilic-coated catheters have become more popular as they are more practical to use and are associated with less pain during use. In a randomised trial comparing hydrophilic-coated catheters to uncoated catheters, there was a reduction in microscopic haematuria and better overall satisfaction with the hydrophilic-coated catheters [81].

A Cochrane review examined sterile versus clean catheterisation technique, coated (pre-lubricated) versus uncoated (separate lubricant) catheters, single (sterile) or multiple use (clean) catheters, self-catheterisation versus catheterisation by others, and any other strategies designed to reduce UTIs with respect to incidence of symptomatic UTI, haematuria, other infections, and user preference, in adults and children using CIC [82]. This review found a lack of evidence to state that the incidence of UTI is affected by any of these parameters. Another review failed to show that single use hydrophilic-coated catheters decrease the incidence of symptomatic urinary tract infection, when compared to clean multiple use polyvinylchloride catheters [83]. Current data does not show a real difference [84], so the evidence to suggest one specific catheter type, technique, or strategy is weak and choice of catheters and regimens should be made on an individual basis. (Level of evidence 3)

Overnight catheter drainage was introduced by Koff [85] to manage valve bladder syndrome, and serves to take pressure off the upper and lower urinary tract in children with NDSD [86 -88] This will allow for bladder wall reperfusion, as well as for the release of volume as all resistance is eliminated. Institution of overnight catheter drainage may make it possible to avoid augmentation with bowel in a bladder with borderline capacity. This method has been applied to patients with native bladders as well as those with augmented bladders. Anecdotal evidence suggests that overnight drainage has led to fewer perforations of augmented bladders. (Level of evidence 4)

Because it is well known that detrusor overactivity in NDSD is dangerous for the bladder wall as well as the upper urinary tract and that anticholinergic/antimuscarinic medication can reduce high intravesical pressure, when an overactive bladder is demonstrated, anticholinergics are commonly recommended even during the first months of life [67,71,72]. At present oxybutynin, tolterodine, trospium, propiverine and solifenacin are the most frequently used anticholinergic drugs to treat detrusor overactivity in children.

The clinical efficacy and side effects from anticholinergics are related to the receptor subtype present in the target organ. There are several muscarinic receptor subtypes throughout the body: M1, M2, M3, M4, and M5. The predominant muscarinic subtype in the bladder is the M2 receptor (66%); however, it is the M3 receptor subtype (33%) that is more important for detrusor activity [89].

Some clinical studies are available, but not many randomised placebo-controlled studies have been performed in children [65,90-92].

Oxybutynin was the first anticholinergic agent to undergo broad investigation in children with NDSD. It is the first FDA approved anticholinergic for paediatric use in NDSD, and it is still the most frequently used in paediatrics, with a success rate close to 90% [93]. The dosing of oral and intravesical oxybutynin is 0.2 mg/kg/dose every 8 hr. Despite its high efficacy, oxybutynin has major side effects, which include dry mouth, constipation, blurred vision, headache, somnolence, learning disability, flushing, constipation and dry itchy skin.

If children are unable to tolerate oral oxybutynin, other modes of delivery can help reduce side effects. The intravesical route does not rely on gastrointestinal absorption and therefore largely avoids the hepatic metabolite, N-desethyloxybutynin. This compound is an active metabolite with similar pharmacological properties to oxybutynin, increasing the potential for adverse effects [94]. Intravesical oxybutynin use has been recommended in children suffering oral side-effects [95]. A meta-analysis involving intravesical oxybutynin in children with NBD supports its efficacy in lowering the mean maximum detrusor pressure while increasing bladder capacity, but side effects are nevertheless present, although fewer than with oral oxybutynin. Incontinence has been shown to be improved significantly in most studies, with “dry and improved” rates ranging from 61% to 83% [96,97]. The transdermal route is an alternative route with similar benefits as intravesical treatment as it circumvents the production of N-desethyloxybutynin [98]. The main limitations with transdermal delivery are local skin site irritation and the necessity for continual skin adherence. Oxybutynin side effects on the central nervous system are debated [99]. In contrast to what was expected the study of Giramonti et al. showed that long-acting oxybutynin and tolterodine did not have a deleterious effect on children’s attention and memory. They mentioned that other cognitive functions can be affected.[100]

A prospective controlled trial evaluating trospium in children reported that trospium is effective and safe in correcting detrusor overactivity in children but this study did not include patients with a neurogenic bladder [101]. Tolterodine has also been evaluated in patients with neurogenic bladder and found to increase functional capacity in a one-year trial [102] In this particular trial oral and extended-release formulations were tested and found to be effective. Interestingly the functional volume measured at urodynamics increased in the younger patients and did not change in the adolescents. Despite this, both groups reported improved dry intervals and the mean catheterised volumes increased in all subjects. Adverse effects were noted in 7/42 patients who enrolled in the study and were mild including dry mouth and exacerbation of constipation. Two patients withdrew consent and 10 no longer met enrolment criteria leaving 30 patients for the final analysis. These authors had also carried out exploratory studies to assess the optimal dosing strategy [103]. These details serve to point out just how difficult it is to perform a carefully monitored drug trial in this patient population. Similar findings were reported in an earlier trial in patients with overactivity and a neurogenic bladder though this study looked at efficacy defined by urodynamics and the endpoint was assessed at 3 months [104]. Tolterodine has similar efficacy and tolerability to oxybutynin in children with NDSD and the extended-release formulation of tolterodine was as efficient as the immediate release form with the advantages of being a single dose and less expensive [105].

Two open label baseline controlled trials showed that once-daily solifenacin oral suspension in children with neurogenic overactive bladder produced increases in mean cystometric capacity and gains in bladder compliance [106]. Side effects in these studies were few, and lower than those observed with oxybutynin. In a randomised trial solifenacin was superior to placebo for mean voided volume (primary efficacy endpoint) and was well tolerated in

children with detrusor overactivity [107]. Propiverine seems to be effective too [108].

Mirabegron is a beta3 agonist which induces relaxation of the detrusor smooth muscle, and has been studied in refractory cases. In one report 37 patients under age 18 whose neurogenic overactivity was refractory to oxybutynin were started on mirabegron and urodynamic end points were measured showing significant increases in bladder capacity and a decline in end filling pressure [109]. Another report with 66 patients reports similar urodynamic outcomes with dual therapy [110] . Mirabegron added to solifenacin was also shown to be a safe alternative for children with refractory overactive bladder. Dual therapy is well tolerated and the adjusted dose regimen appears safe in this first paediatric study [111]. These encouraging results with mirabegron have led to a pharmacokinetics trial seeking to better define dose adjustments for the paediatric population [112]). This had led to the FDA issuing an approval for mirabegron for paediatric use in case of NBD in March of 2021.

Based on the data available in children with neurogenic bladder overactivity, use of anticholinergic drugs is the mainstay of medical treatment.

Conclusion: anticholinergics are effective to reduce the storage pressure and increase the voided volume in children with NDSD (LoE:2)

Recommendation: anticholinergics are recommended to reduce the storage pressure and increase the voided volume in children with NDSD (GR:B)

Cognitive changes with anticholinergic usage have been described in recent years and are a source of concern for providers and patients. There is a growing literature to suggest that anticholinergic medication must be carefully monitored in geriatric patients some of whom may experience cognitive decline [113,114]. Furthermore this may be related to oxybutynin which has a lower molecular weight and a greater propensity to cross the blood brain barrier [115]. In contrast anticholinergics with a higher molecular weight are less likely to cross the blood brain barrier and are associated with fewer such effects. The challenge in the interpretation of these findings is the co-morbidities that are present, or may be evolving in these patient populations. A new study reported that the dementia risk was higher in older patients prescribed anticholinergics when compared to a β-3 agonist [116]. However fewer studies have been done to evaluate anticholinergic effects on cognition in children. The effect of oxybutynin was studied in children, and at 16 weeks was not found to have any effects on cognitive performance [117]. In a more recent open label study looking at a 42 week trial of solifenacin in patients with spina bifida ranging from 6 months to 18 years, there were gains in cognitive performance that were age appropriate [106]. Oxybutynin has traditionally been used in infants with spina bifida whose urodynamics show low bladder capacity, overactivity, or poor compliance. In a small series of patients 3 to 4 months old who started early treatment (capacity <50% of estimated bladder capacity, overactivity, or poor compliance), 20% stopped the medication due to retention or allergic reaction but 5% of patients stopped the medication due to parental reports of changes in their child's affect [118]. This cognitive outcomes data has led to a call for caution in the use of anticholinergics in children, for the lifetime consequences of chronic use are not defined [119]. These concerns should also point out the future need for developmental testing to assess the effects of these medications in children as most outcomes analysis have focused only on the urodynamics parameters.

The use of medication in children with neurogenic bladder to facilitate emptying has not been studied well in the literature. Few studies investigating the use of alpha-adrenergic blockade in children with neurogenic bladder report good response rates but they are non-controlled studies and long-term follow-up is lacking [120-121]. Studies with selective α1-blockers (doxazosin) in children with NDSD and increased leak point pressure (LPP) did not show any evident efficacy [122-123].

In neurogenic bladders that are refractory to antimuscarinics and remain in a low capacity and high-pressure state, or when antimuscarinics side effects are relevant, injection of onabotulinumtoxin-A (BTX-A) into the detrusor has been proven to be effective and safe [124-125]. Initial promising results in adults have initiated its use in children [143]. In a recent systematic review examining 12 series (all non-randomised and only 2 with a control group) injection of BTX A in therapy resistant bladders caused a significant improvement in terms of continence, maximum detrusor pressure, maximum cystometric capacity, and bladder compliance [126]. This treatment seems to be more effective in bladders with evidence of detrusor overactivity, while non-compliant bladders without obvious detrusor contractions are unlikely to respond to this treatment [126,127]. Other series have also noted that BTX is less effective for fibrotic bladders with no overactivity noted on the urodynamics [128]) . Repeated bladder injections of BTX-A during time have been demonstrated to be effective and safe [129-132].

Conclusion: onabotulinumtoxin-A is an effective treatment of overactive neurogenic bladder (LoE:2)

Recommendation: onabotulinumtoxin-A is recommended to treat neurogenic detrusor overactivity.in children. (GR:B)

Dosage of BTX-A in children should be determined by body weight, and timing adjusted with caution regarding total dose if also being used for treatment of spasticity, and minimum age [133] In most published studies, the dose of BTX-A is 10 U/kg up to a maximal dose of 300 U involving 30 trigone sparing injections of 10 U/kg/ml in the detrusor. BTX-A seems to reach efficacy levels at 2 weeks and maximum effects within a month. Duration of the BTX-A effect ranges from 3 to 8 months depending on short-term versus long-term repeated injections [134]. Recently on the basis of results of a multicentre international phase III study, a recommended dosage of 200 U, not exceeding 6U/kg has been suggested [135]. Few adverse events have been reported in children, but the need for CIC after injection is an important consideration and is higher with higher dosage [136].

BTX-A injection into the urethral sphincter has been shown to be effective in decreasing urethral resistance and to improve voiding [137]. A meta-analysis of BTX-A injection into the sphincter in adults with spinal cord injury has shown its effectiveness in reducing post-void residual urine and demonstrating a statistically significant reduction in detrusor pressure and urethral pressure 1 month post injection [138]. Current evidence is insufficient to recommend its routine use in decreasing outlet resistance, but it could be considered as an alternative in refractory cases [139]. The transient sphincteric pharmacological denervation then could be useful in selected cases, when CIC is not well accepted by patients or families [140]

Conclusion: BTX-A injection in the urethral sphincter is effective to treat the overactive neurogenic sphincter (LoE:3)

Recommendation: BTX-A injection in the urethral sphincter is recommended to treat the overactive neurogenic sphincter (GR:B)

Intravesical electrical stimulation of the bladder was introduced more than four decades ago and it has been tested in some open clinical trials in children since 1984 [141]. Its practice is limited to a few centres who have reported varying results. The only randomised controlled trial looking at this mode of therapy has failed to show efficacy [142]. Furthermore, this type of treatment is time consuming, requiring very dedicated personnel, rendering it unattractive for most treatment centres as well as for patients.

Nerve stimulation via the percutaneous, sacral or transcutaneous route has been also studied in the treatment of patients with a non-neuropathic bladder [143]. Although transcutaneous nerve stimulation has been found to be effective in treating overactive bladder disorders in chronic pelvic pain/painful bladder syndrome and in children with non-neurogenic lower urinary tract disorders; its effectiveness has not been established for children with NDSD [144-146]. In a report of a prospective study, in which sacral nerve modulation was conducted in children with NDSD, comparison of urodynamic variables revealed no statistically significant difference except that functional bladder capacity was better in the oxybutynin group and leak point pressure was better in the sacral neuromodulation group [147]. Better results have been reported in children with acquired neurologic dysfunction, as in myelitis, and partial spinal cord injury [148].Although nerve stimulation has good evidence for its efficacy in non-neurogenic bladder overactivity, both in children and adults, there is no clear evidence for its effectiveness in neurogenic overactivity in the paediatric population. Its use remains investigational and must be limited to well selected cases and centers [149-150].

Most children with a neurogenic bladder also have constipation and this is managed most commonly with laxatives, such as mineral oil, combined with enemas to facilitate removal of bowel contents. Faecal incontinence in these children is frequently unpredictable; it is related to the loss of lower bowel sensation and function, altered reflex activity of the external sphincter and the consequent failure to fully empty the rectum [151].

A regular and efficient bowel emptying regimen is often necessary to maintain faecal continence and this may have to be started even at a very young age. With antegrade or retrograde enemas, most of these children's constipation can be managed and they may attain some degree of faecal continence [152-153].

With availability of retrograde devices with a balloon on the rectal catheter to prevent leakage of solution, retrograde enemas have become more efficient and more popular in comparison to antegrade enemas [154,156-158]. Bowel management must be defined individually for each patient and careful follow-up is required in order to improve efficacy. Today conservative management is commonly offered before surgery (ACE stoma, Cecostomy button)[155].

Conclusion: bowel management is essential in the treatment of children with a neurogenic bladder (LoE:2)

Recommendation: bowel management is recommended in children with neurogenic bladder (GR:B)

Biofeedback training programmes to strengthen the external anal sphincter have not been shown to be more effective than a conventional bowel management programme in achieving faecal continence [159]. Electrostimulation of the bowel may also offer a variable improvement in some patients [160].

Conclusion: electrostimulation is an effective method of bowel management in children with neurogenic bladder (LoE:3)

Recommendation: electrostimulation is recommended for bowel management in children with neurogenic bladder (GR:D)

Urinary tract infections are common in children with neurogenic bladders. In the absence of reflux, patients with urinary tract infections should be treated if symptomatic. There is strong evidence not to prescribe antibiotics to patients with asymptomatic bacteriuria [161-163]. Bacteriuria is seen in more than half of the children using clean intermittent catheterisation (CIC), but this is not an indication for treatment. While there is not consensus for prevention, diagnosis and treatment [164], there is a common view to avoid continuous antibiotic prophylaxis, in order to reduce risk of bacterial resistance [165]

Conclusion: continuous antibiotic prophylaxis is to be avoided in children with neurogenic bladder (LoE:3)

Recommendation: continuous antibiotic prophylaxis is not recommended in children with neurogenic bladder (GR:B)

Patients with vesicoureteral reflux and frequent urinary tract infection require prophylactic antibiotics to reduce the incidence of pyelonephritis, which can potentially lead to renal damage [166]. Since vesico-ureteral reflux in NDSD is often secondary, reflux management must always be associated with NDSD treatment. Videourodynamics is the gold standard for a correct diagnosis, defining the presence of high or low bladder pressure in case of high-grade reflux. Endoscopic treatment alone has a high failure rate [167] and a combined endoscopic treatment with BTX-A [168] or button cystostomy [169] has been suggested. The role of reimplantation with or without augmentation or augmentation alone is debated [170-171]

Sexuality is not an issue in early childhood, but becomes progressively more important as the patient ages [172]. This issue has historically been overlooked [173]. Patients with myelodysplasia have sexual encounters, and studies indicate that at least 15-20% of males are capable of fathering children and 70% of females can conceive and carry a pregnancy to term. Therefore, counselling patients regarding sexual development is important in early adolescence, and fertility must be preserved [174-176].

Summary:

Children with a good response to antimuscarinic treatment and an overactive sphincter may be continent between catheterisations. Bladder pressure and (normal) development of the upper tracts will determine whether additional treatment is necessary. Children with therapy resistant overactivity of the detrusor, or small bladder capacity and poor compliance will usually need additional surgical treatment such as bladder augmentation [177-179].

Children with detrusor overactivity but with underactive sphincters will be in a better shape in terms of protecting their upper tracts, but they may be severely handicapped because of their incontinence. Initial treatment will be intermittent catheterisation (as it may reduce the degree of incontinence and offers a much better control over urinary infections) in combination with antimuscarinic drugs. Urodynamics or videourodynamics will be

helpful in order to better understand how to correct incontinence. At a later age the outlet resistance may be increased to render them continent [180]. There is no medical treatment of proven efficacy that increases bladder outlet resistance. Alpha-receptor stimulation of the bladder neck has not been very effective. Thus, surgical procedures need to be considered for maintaining continence [181-185]. To avoid negative influence on the upper urinary tract, bladder neck surgery should only be considered in cases with an adequate bladder capacity and compliance. Bladder neck closure is the last option and has to be considered when all other procedures failed and in very selected cases [186-187]

It is important to establish adequate bowel emptying before attempting to correct bladder dysfunction surgically or medically.

Patients with a neurogenic bladder require lifelong supervision; monitoring of renal function is extremely important. Periodic investigation for upper tract changes, renal function and bladder status is mandatory [188]. Therefore, repeat urodynamic studies are needed more frequently at younger ages and less frequently as time progresses. A repeat urodynamic study is warranted when the patient has a change in symptoms or undergoes any neurosurgical procedure. In case of any apparent changes both in the upper and lower urinary tracts or any changes of neurological symptoms, a more detailed examination including urodynamics and MRI of the spine is indicated. Renal failure usually progresses slowly but may occur with startling rapidity.

VI. SURGICAL MANAGEMENT OF URINARY INCONTINENCE IN CHILDREN

1. INTRODUCTION

The principles for managing incontinence in childhood are much the same as those for adults – although the application and interpretation may differ. The basic principles can be outlined as follows:

1. Achieve and maintain continence
2. Preserve the upper tracts
3. Achieve maximum effect with the least invasive treatment
4. Consider the long-term effects

Many patients do not require surgical intervention and the first 2 criteria can be achieved with a combination of medication and inter-

mittent catheterisation. However, if these measures fail then surgical intervention becomes important.

The choice of surgical procedure needs to be based on the age and wishes of the child and/or parents, their medical history, relevant investigations (eg. Urodynamics) and other comorbidities or physical limitations. A multidisciplinary approach is often important to ensure optimal decision making.

Surgery may be indicated in patients with conditions (congenital or acquired) affecting bladder storage, the sphincter mechanism or the ability to void urine. There are a range of different procedures to improve all of these. It is important that where possible parents and their child understand the potential outcomes. It can be difficult to convey the important 'trade-offs' that may follow – for instance that 'dryness' may not be the same as continence and that the creation of a safe bladder may be at the cost of spontaneous emptying. Many procedures require adjuncts such as catheterisation or medication, along with life-long follow-up.

Therefore, an operation forms part of a contract between the surgeon, initially the parents and subsequently the patient to remain engaged with this in order to achieve the best outcome. It is absolutely key for everyone to understand that this operation often represents the beginning of a pathway of care and not the end. Many families will have only previously seen surgery where it is used as a 'cure' (eg for cancer, a hernia or broken bone) where there is often a finite conclusion to treatment that is facilitated by surgery. For our patients surgery forms a major part of treatment and the aim is a significant improvement in function, but they will often remain under the care of a surgeon for life and may well need further treatment and/or surgery.

In order to operate on patients with an incompetent bladder neck there are some fundamental principles. The majority of procedures employed to reconstruct a bladder neck require the creation of a fixed resistance, creating enough of an outlet obstruction to render a patient dry. For the majority of patients, dryness under these circumstances may well come with the sacrifice of spontaneous voiding at low pressure – for the majority self-catheterising may be the better option.

The management of complex congenital anomalies generally happens in a field with a dearth of high-grade evidence – the conditions are rare; patients require an individual treatment and expertise and treatment approaches vary. The concentration of treatment in specialist centres may improve the variability, but we are still considerably short of high evidence levels to direct surgical treatment. Therefore, graded recommendations for specific procedures cannot be provided.

There are no randomised controlled trials (level 1 and 2 evidence). Based on the available literature most studies have a level of evidence 3-4 and grade of recommendation C or D.

1.1. Abnormalities of storage

Bladder Exstrophy: The incidence of bladder exstrophy is 1 per 30,000 live births. (male to female ratio 3:1). Closure of the bladder is generally performed within the first days of life; many centres use pelvic osteotomies to facilitate reconstruction of the abdominal wall and aim to improve ultimate continence (1-3) Some children will develop more or less normal capacities. Even after successful closure there will be some children who end up with poorly compliant small bladders, requiring subsequent bladder augmentation or urinary diversion (eg. Mitrofanoff, ileal conduit or ureterosigmoidostomy) (4-7). Patients with a good bladder plate who develop sufficient bladder capacity after successful primary closure and epispadias repair may achieve acceptable continence without the need for bladder augmentation and intermittent catheterisation (8-10).

Bladder neck reconstruction may be undertaken at the time of bladder closure or at a later stage. Some data suggest that early reconstruction may facilitate normal bladder function, but should be attempted only at centres experienced with such surgery (11-12). Published data for continence show a considerable range 43 to 87% (13,14) – the reasons behind such variability are not clear.

Cloacal Exstrophy: The incidence of cloacal exstrophy is 1 per 200,000 live births. This is a much more complex deformity that requires an individual approach. Most of these children have additional anomalies including neurological, the upper urinary and gastrointestinal tracts - all may add to the challenges of urinary tract reconstruction. Before reconstructive procedures are considered, a careful, multidisciplinary evaluation is needed.

Bladder Agenesis or Duplication are both extremely rare. Agenesis is rarely compatible with life. In patients affected by bladder duplication, other associated congenital anomalies are common, including duplication of external genitalia or colon.

Abnormal bladder function, in combination with other anomalies are usually the result of a neurological deficit, there may also be bladder outlet obstruction. Sacral anomalies are frequently seen with cloacal malformations and imperforate anus (15-18).

Posterior urethral valves may lead to a small, poorly compliant bladder, the obstruction results in detrusor hypertrophy and surrounding fibrosis (19,20). Even following valve ablation (and thus removal of the obstruction), there is no guarantee that these bladders will return to normal function (21,21).

1.2. Abnormalities of sphincteric function

Primary Epispadias (without exstrophy): has an of incidence 1 in 60,000 live births, male to female ratio: 3-5:1. All patients with bladder exstrophy also have complete epispadias.

In male patients with complete epispadias and in all affected females, the sphincteric mechanism is deficient resulting in complete incontinence. Reconstruction of the bladder neck is performed, either, at the time of epispadias repair or at a later stage. The bladder function may or may not be normal in these patients (23,24).

Urogenital Sinus Anomaly occurs exclusively in phenotypic females. The incidence is 1 in 50,000 live births. In patients with classical urogenital sinus or cloaca, the sphincteric mechanism is insufficient and due to associated neurological abnormalities the bladder function may be abnormal.

Ectopic ureteroceles protruding into the urethra may be responsible for a partial defect of the bladder neck. In these rare cases, sphincteric incontinence may be the result.

Secondary Abnormalities in Sphincter Function associated with spina bifida and other neurological disorders are important. The sphincter may be overactive (like in detrusor-sphincter dyssynergia) or underactive. An overactive sphincter leads to secondary bladder wall changes (increased collagen type III with decreased compliance) and, most worryingly, obstructive nephropathy. Continence can be achieved with antimuscarinic drug treatment or bladder augmentation (using the overactivity of the sphincter for continence).

In cases of sphincter incompetence, there are a variety of surgical interventions to enhance continence. In general, all patients with a neurogenic bladder need clean Intermittent catheterisation (CIC). In patients reliant upon wheelchair mobility a suprapubic channel can be created (Mitrofanoff) to facilitate CIC.

Bypass of the sphincter mechanism

Ectopic Ureter - Instead of the ureter draining into the bladder, it opens into the urethra (below the sphincter), vaginal vestibule or uterus. Ectopic ureters occur more frequently in girls and most commonly drain the upper moiety of a duplex system (25). When the upper pole ureter drains into the mid or distal female urethra or outside the urinary tract (i.e. vulva or vagina), an upper pole nephrectomy or ipsilateral uretero-ureterostomy will cure the incontinence.

If an ectopic ureter is associated with a simplex system, the ipsilateral trigone is usually asymmetrical and poorly developed. This can lead to continuous incontinence (with a deficient sphincter).

In patients who have bilateral ectopic ureters and simplex systems, the trigone and bladder neck are functionally abnormal and treatment includes surgical reconstruction of the bladder neck. The bladder is typically hypoplastic, and achieving a functional bladder capacity may require additional procedures (eg augmentation) combined with ureteric reimplantation (26-28).

Urethral duplication. Most patients with urethral duplication will leak urine from the abnormal meatus during voiding. In rare cases, when the accessory urethra is attached above the sphincter ie it is a conduit without any continence mechanism, continuous leakage may be present (29).

Vesicovaginal fistulae. Acquired fistulae may be traumatic or iatrogenic, following procedures on the bladder neck.

2. EVALUATION AND DIAGNOSIS

A detailed history and physical examination (this is so often missed and can provide very clear information) in combination with imaging studies and urodynamic evaluation are the cornerstones for successful management. Imaging studies will define anatomical abnormalities responsible for and associated with incontinence. Ultrasonography of bladder and kidneys as well as a voiding cystourethrogram are the basic studies. In infants and small children sacral ultrasonography can demonstrate normal position and mobility of the spinal cord. The scout film of the contrast voiding cystourethrogram (VCUG) assesses the lower spine and sacrum, intersymphyseal distance, and constipation. The contrast films will show bladder configuration, presence of vesicoureteral reflux, incomplete voiding, bladder neck competence, urethral anatomy and vaginal reflux. MRI and CT scans/urograms can be helpful in defining spinal abnormalities as well as congenital abnormalities in the urinary tract.

In addition to anatomical imaging studies, functional studies eg. urinary flow studies, urodynamics (cystometrography and when needed, sphincter electromyography) are useful for all patients with neurogenic incontinence. These studies are also valuable following surgery in some cases of bladder exstrophy and after posterior urethral valve resection to define the mechanism of any continued incontinence. However, in many patients much useful information on the function of the lower urinary tract can be obtained with very basic studies including ultrasound and cystometry.

3. INDICATIONS FOR SURGICAL PROCEDURES TO CORRECT URINARY INCONTINENCE

3.1. Storage function

Augmentation cystoplasty is indicated, once appropriate conservative treatment has failed, when reduced capacity, raised end-fill cystometric bladder pressures, reduced compliance and intractable detrusor overactivity (most commonly neurogenic) are present. Each of these scenarios may be congenital, (as part of a condition) eg. myelomeningocele, bladder exstrophy or posterior urethral valves or acquired, eg. scarring following previous surgery, reduced capacity following bladder neck reconstruction or following an infective condition eg bilharzia (where it is either endemic or may be imported with migrant populations).

Published data support aggressive early intervention with CIC and anticholinergic therapy to improve bladder compliance and avoid the need for augmentation cystoplasty (30,31).

A recent survey reported that there has been no change in augmentation rates over a 5-year period: but there was significant inter-institutional variability (32).

3.2. Sphincter function during storage

Many of the conditions described are complex and will affect both bladder and sphincter function – both need assessing and both may require intervention. Conservative measures to improve sphincter function have limited value and surgery is often the only available treatment. The surgical options for the bladder outlet can be categorised into the following:

- Bladder neck reconstruction with urethral lengthening procedures
- The use of native tissue to support the urethra – autologous fascial sling, colposuspension
- Insertion of an artificial urethral sphincter
- Bladder neck closure and creation of a continent catherisable channel (other forms of urinary diversion are also discussed)

The last option clearly involves the need for clean intermittent catherisation (CIC) - patients undergoing any of the other options also need to be prepared for the fact that CIC may be necessary.

3.3. Urinary diversion

If bladder outlet surgery fails or urethral catheterisation is not possible – urinary diversion becomes necessary. Some patients prefer catheterising through a continent stoma rather than through the sensate urethra. The continent stoma (Mitrofanoff principle) may be combined with bladder augmentation and/or bladder neck reconstruction or closure. Further options in this group include a ureterosigmoidostomy (Mainz II) with the anal sphincter becoming the continence mechanism and colon acting as the storage reservoir. Historically, an ileal conduit has been used; this is rarely used as part of modern paediatric urology.

4. BLADDER RESERVOIR CONSTRUCTION

4.1. Ureterosigmoidostomy

This type of continent urinary diversion may be utilised in reconstruction for bladder exstrophy, an incontinent urogenital sinus or

the traumatic loss of the urethral sphincter. As this reconstruction is totally dependent on the normal function of the anal sphincter, contraindications include incompetence of the anal sphincter (therefore it is not suitable for neuropaths), anal prolapse, previous anal surgery and irradiation. These reservoirs have a strong association with metabolic anomalies (hyperchloraemic metabolic acidosis and (rarely) hyperammonaemia) (33), renal insufficiency is also a relative contraindication.

The creation of a low-pressure rectal reservoir is superior to simple ureterosigmoidostomy because the augmented or reconfigured rectal bladder achieves lower pressure storage and accordingly, enhances continence.

The most commonly employed is the recto-sigmoid pouch (Mainz II) in which there is an antimesenteric opening of the recto-sigmoid (which is configured in a 'u'-shape) and a side to side detubularisation anastomosis. Normal calibre ureters are reimplanted with a standard submucosal tunnel (Goodwin, Leadbetter). If the ureter is dilated, a serosa lined extramural tunnel may be more appropriate (34,35).

Data from D'elia et al., showed the outcome of low-pressure rectal reservoirs to be excellent; with day and night continence better than 95% and complications related to the surgical procedure range from 0 -10% with the Mainz II, other techniques have been described but complications appear higher (up to 34%) (36). Late complications for the Mainz II pouch range from 6-12.5%. Early complications include pouch leakage while late complications are mainly related to the ureteric implantation; including stenosis or pyelonephritis secondary to reflux. Metabolic acidosis also occurs, 69% of the patients had a capillary base excess of –2.5 mmol/L and used oral alkalinizing drugs to prevent hyperchloraemic acidosis.

Regular life-long follow-up is important to survey the upper tracts and monitor for/treat metabolic acidosis. There is a documented risk of malignancy at the ureterointestinal anastomosis, so flexible sigmoidostomy should be performed annually beginning at postoperative year 10 (30,37-40). It is valuable to consider this reconstruction in a resource-limited environment where stoma bags and/or catheters are difficult to obtain or expensive. The risks described are important but on balance may be more acceptable than the pre-existing condition or the need for expensive (or unavailable) bags/catheters.

Conclusion: ureterosigmoidostomy is an effective technique for continent urinary diversion (LoE:3)

Recommendation: ureterosigmoidostomy is a recommended type of continent urinary diversion in selected patients (GR:B)

4.2. Bladder augmentation, bladder replacement and continent urinary diversion using intestine

Indications for augmentation or substitution cystoplasty, with or without the creation of a continent urinary diversion, are the anatomical or functional loss of normal bladder function. The main goal of this surgery is to relieve high pressure and improve a low-capacity bladder; creating a continent reservoir with low storage pressures that can be emptied regularly. It is particularly important that the patients understand that spontaneous voiding will not be possible after such surgery and lifelong intermittent catheterisation will be required.

Before deciding on what type of procedure can be performed some significant factors must be considered. These include:

1. The motivation, physical and mental capacity of the patient to undertake intermittent catheterisation.
2. Previous surgery (on urinary tract and bowel – particularly availability of sufficient, healthy bowel).
3. Renal function
4. The presence of reflux
5. Continence vs outlet resistance
6. Preferred method of drainage eg. urethra vs continent catheterisable channel

The different technical approaches to augmentation/substitution cystoplasty may be dependent on a variety of factors – including the clinical presentation of the patient:

- Augmentation cystoplasty may be reasonable if there is a bladder plate, a competent sphincter and/or bladder neck, and a catheterisable urethra,
- Augmentation cystoplasty with additional bladder outlet procedures such as bladder neck reconstruction and/or urethral lengthening are required when both the bladder and outlet are deficient. This is most commonly exemplified in spina bifida or bladder exstrophy.
- Augmentation cystoplasty with surgical closure of the bladder neck may be required primarily, or as a secondary procedure (ideally as an option of last resort). By definition, urinary diversion in the form of a continent stoma will be required. However, most urologists prefer to leave the bladder neck and urethra patent as a safety valve. If the bladder is ever allowed to overfill, urethral leakage should occur (reducing the risk of bladder rupture) and it should also allow urethral catheterisation if catheterisation of the channel fails.
- Augmentation cystoplasty with a continent stoma is utilised primarily following failure of previous bladder outlet surgery or urethral damage – preventing urethral catheterisation. An abdominal wall continent catheterisable channel may be particularly beneficial to the wheelchair bound spina bifida patient who may have considerable difficulty with urethral catheterisation and may be dependent on carers to catheterise. Although the urethra may not be formally closed, it is essential that there is sufficient outlet resistance to prevent urethral leakage.
- Substitution cystoplasty with normal voiding in children is usually an unrealistic expectation (of course there are rare, anecdotal, exceptions). Fortunately, there are very few indications for a total cystectomy in childhood. This type of bladder replacement is much more common in adult urology and is most commonly associated with urological malignancy.

The main contraindications for augmentation or substitution cystoplasty are the inability to perform self-CIC and the anticipation of poor patient compliance. Impaired renal function, generally with a creatinine above 2 mg/dl or a creatinine clearance below 40 ml./min/1.73 m2, constitutes a relative contraindication to enterocystoplasty because of the risk of metabolic complications. However, in a situation where the bladder has caused such renal failure, there is a need for a safe reservoir to avoid further decline in renal function. As a matter of principle the shortest segment of bowel with the least dwell time (ie contact time between urine and bowel) should be the preference – this needs to be carefully balanced against acceptability to the patient and likely compliance with drainage. The stomach with its excretion of acid may be (but is rarely) used with a low creatinine clearance possibly in preparation for transplantation. It is, however, not wise to use stomach in any voiding patient or one with any questions of an incompetent bladder outlet because of

the severe skin irritation that the acid urine may produce (haematuria-dysuria syndrome).

4.3. Which intestinal segment should be utilized?

4.3.1. Stomach

Stomach has limited indications primarily because of the complications related to acid secretion. It may be used in patients with significantly reduced renal function (41- 43).

Additionally, when no other bowel may be available, such as after irradiation or in the presence of a short bowel syndrome, as in cloacal exstrophy, this may be a salvage option.

4.3.2. Ileum / Colon

Clinically, these two intestinal segments appear equally useful. In children, sigmoid colon is widely used. Its use is contraindicated in those who have been treated for imperforate anus. Urological reconstruction using the ileocaecal region may be associated with diarrhoea. Use of this segment should be avoided in patients with a neurogenic bowel (eg. myelomeningocele) or who have had previous pelvic irradiation. The ileum can be satisfactorily used for augmentation cystoplasty: however, because of its smaller diameter a longer segment of ileum is required to create a comparable reservoir to that created from colon. Ileum can be reconfigured into a 'u'-shape to form a double or cup-cystoplasty. Colon has greater flexibility for ureteric implantation and creation of a continent catheterisable channel.

4.3.3. General principles

There are some important principles to consider when using bowel in the urinary tract:

- use the minimal amount of bowel needed and if possible 're-use' segments that have been used previously,
- a low-pressure large capacity reservoir is essential – this is best achieved with detubularisation of any intestinal segment.
- for colonic reservoirs, a sigmoid segment of 20-30 cm is generally satisfactory. A slightly longer segment of ileum is generally used. The length of the segments can be scaled down in smaller children. It is important to ensure that there is at least 200 cm of bowel left in continuity to avoid short-gut syndrome. If necessary, seek specialist imaging and advice prior to operating if there is doubt about the length of bowel available.
- the jejunum is contraindicated for reconstruction of the urinary tract because of its metabolic consequences (hyponatraemia, hypercalcaemia, and acidosis).
- an anti-reflux ureteric anastomosis to the reservoir is important if there is no urethral outlet. If the system has an intact urethra (ie a safety valve) or an incontinent stoma (ileal conduit) then the risk of ureteric stricture outweighs the risk of stricture (44,45).
- a reliable continence mechanism is a priority.
- to reduce the risk of stone formation only resorbable sutures and staples should be used in bladder augmentation and reservoir construction.

4.3.4. Bladder augmentation techniques

1. When performing gastric augmentation, a 10-15 cm wedge-shaped segment of stomach is resected. Most commonly this is based on the right gastroepiploic artery but may be based on the left. The segment is easily brought down to the bladder via the retroperitoneal space, along the great vessels.
2. A large or small bowel segment is opened on the antimesenteric border and detubularised prior to anastomosis to the bladder. The anastomosis of the intestinal segment to the bladder remnant, and to itself, is usually carried out with a running layer of inverting, absorbable sutures.
3. The techniques for urinary diversion with continent stoma (Mainz pouch, Indiana pouch, Kock pouch) are covered in the chapter on urinary diversion in adults (46-48).

Currently, augmentation cystoplasty is the standard treatment for low capacity and/or low compliance bladders secondary to neurogenic, congenital and inflammatory disorders. Whilst other techniques have been discussed and experimental work continues to develop alternatives (eg. through tissue engineering) none have yet become part of routine clinical practice (49-54).

Conclusion: ileal and colonic bladder augmentation are effective in the treatment of neurogenic bladder with therapy resistant overactivity of the detrusor, small capacity, and poor compliance (LoE 2)

Recommendation: bladder augmentation with ileum or colon is recommended in neurogenic bladder with therapy resistant overactivity of the detrusor, small capacity and poor compliance GR: B)

4.3.5. Auto-augmentation

The principle of auto-augmentation of the bladder involves excision of a great portion of the detrusor while leaving the urothelium intact. This creates a large diverticulum for the storage of urine at lower pressures. Urine drainage would normally require intermittent catheterisation. The theoretical advantages of this procedure are the low complication rates of surgery, shorter hospital stay, absence of metabolic anomalies, the absence of mucus production and no increased risk of cancer. Although good results have been reported (55-58), these have not been clinically reproducible (59). Long-term results are disappointing: in a series of 17 patients, with neurogenic bladder, MacNeily et al. reported that 71% were clinical failures and 14 out of 15 were urodynamic failures following auto-augmentation hypocompliance or low bladder volume. All patients had failed to respond to conservative medical and pharmacological treatments. Median patient age at surgery was 10.2 years (range 2.2 to 13.2(60). Similar findings have been reported by others (61,62). The reasons for poor long-term outcomes have been suggested as the regeneration of nerve fibres and ischaemic atrophy of the mucosa – this may result in a reduction in intraluminal pressure but no increase in bladder volume. Thus the procedure has fallen out of favour.

Although there are many potential advantages to this approach to a small poorly compliant bladder the inconsistency of success make it a less favourable option. It is generally felt that pressures can be lowered but that capacity remains unchanged.

More recently there have been attempts to revive the technique with a laparoscopic or robotic approach – to date published data have not demonstrated long-term superiority over historical techniques. Whilst there is little to substantiate the technique of auto-augmentation by any means, there are a number of centres who are developing a range of robotic techniques for urological reconstruction. Data are still early and bigger series will doubtless be forthcoming, but the technology is developing and it appears that with developing experience and technique these technologies may offer comparable results with cystoplasty, ureteric reconstruction and some outlet procedures (63,64).

Conclusion: robotic techniques for urological reconstruction are effective (LoE:4)

Recommendation: robotic techniques for urological reconstruction are recommended for bladder augmentation, ureteric reconstruction and bladder outlet procedures (GR:C)

4.3.6. Seromuscular patch

To overcome enteric mucus formation, techniques have been developed to use intestinal segments free of mucosa. The first attempts resulted in viable seromuscular segments covered with urothelial mucosa (65,66). The intense inflammatory response and shrinkage observed in the intestinal segment prevented its use in humans (67). Further attempts consisted of using the association between demucosalised intestinal segments and auto-augmentation. In a sheep model the procedure was poorly tolerated and resulted in inflamed, haemorrhagic colonic segments at one month following operation. Colonic mucosa regrowth occurred in one third of the animals (68). Later studies using a canine model, suggested shrinkage of the intestinal patch in seromuscular enterocystoplasty was avoided with preservation of both the bladder urothelium and lamina propria, together with the submucosa and muscularis mucosa of the intestinal patch (69,70). This form of bladder augmentation did seem to prevent absorption of toxic substances like ammonium chloride (71). Other authors using the same technique to line de-epithelialised gastric patches in the mini-pig model found it useless due to the fibrotic changes and decreased surface area of the patch (72).

The initial experience in treating humans with colocystoplasty lined with urothelium were reported by Gonzales and Lima who independently developed a slightly different technique (73,74). Bladder capacity increased significantly while bladder pressures decreased. Later biopsies demonstrated urothelium covering the augmented portion of the bladder in the majority of cases. Longer term follow-up is now available and although the results have been encouraging, they seem to be highly operator dependent and the way in which the mucosa is removed seems to be crucial. Lima et al. no longer preserve the bladder urothelium and use a silicone balloon to prevent the augmented segment from contracting (they remove the balloon after 2 weeks: urine is diverted using ureteral stents): in 123 patients, no ruptures were found and only 10% were regarded as failures (75).

Gonzalez et al. reported seromuscular colocystoplasty in combination with an artificial urinary sphincter showing 89% success in their patients; with continence and no upper tract deterioration, they published this as their preferred method of augmentation when adverse bladder changes occur following implantation of an AUS six females(76).

More authors have now reported results of this procedure, it remains a more complex technique for bladder augmentation and has not achieved a place in widespread clinical practice. It is carried out in some designated centres (77-80). Comparison of long-term results with conventional enterocystoplasty has indicated no improvement in outcome.

Conclusion: seromuscular colocystoplasty is an effective bladder augmentation technique overcoming mucus formation (LoE:3)

Recommendation: seromuscular colocystoplasty is recommended as a bladder augmentation technique that overcomes mucus formation (Gr: C)

4.3.7. Ureteric bladder augmentation

Redundant ureteric segments have been used to improve bladder capacity and/or compliance. Megaureters associated with poorly or non-functioning kidneys provide good augmentation material with urothelium and sero-muscular backing, avoiding metabolic disturbance and mucus production (81-82).

In patients with ureteric dilation and good ipsilateral renal function, a combination of transureteroureterostomy with ureterocystoplasty is possible (83) – anecdotally, the long term risk of this is that a problem at the uretero-ureteral anastomosis or distally will risk damage to both kidneys. An additional option in patients with bilateral dilated ureters with preserved renal function is bilateral reimplantation and the use of the distal ends for detubularised bladder augmentation (84).

Bladder augmentation with ureter may be effective for a small group of patients with ureteric dilatation and poor bladder capacity. Overall, long-term results are good and remain so over a longer period (85-90).

Recent evaluation of long-term functional outcomes of ureterocystoplasty showed good functional, urodynamic improvement, however, some patients (4 out of 17 in this series) eventually needed a standard intestinal cystoplasty (91).

This type of augmentation can also be employed in children who require a renal transplant (92-94).

Conclusion: ureter can be used effectively for bladder augmentation (LoE:3)

Recommendation: in cases of a dilated ureter, bladder augmentation with ureter can be recommended (Gr:B)

4.3.8. Experimental Methods

Experimental work to generate a bladder replacement continues – but there has been nothing that merits widespread clinical application. One possible route may be tissue-engineered autologous urothelium and bladder muscle cells. These cells may be grown or seeded on biodegradable scaffolds, both naturally derived and synthetic, for the temporary support of the growing tissue until it is sufficient to become a surgical substrate that can be implanted to augment or replace the bladder. Several synthetic materials and natural matrices have been used in experimental and clinical settings. Techniques of cell harvest, culture, and expansion as well as polymer design continue to develop.

There have been a few ideas that have developed as far as preclinical trials with hope of future clinical application. The mantra that clinical trials may not be far away (95-108) has been stated for many years and continues. Thus, whilst this field of research may become the future of bladder reconstructive surgery, as yet it remains still some way from the front line. We strongly encourage further research in this field.

5. BLADDER OUTLET SURGERY

5.1. Urethral enhancement

In children with sphincteric incompetence as the primary cause of incontinence, procedures to enhance outlet resistance are important. In cases where the bladder has reduced capacity or compliance, bladder outlet surgery may be performed in combination with

other procedures to achieve a continent, low pressure reservoir with sufficient volume.

5.2. Bulking agents

Injection of a peri-urethral or bladder neck bulking agent in children first dates back to at least 1985. Initial concerns about distant migration of the injected substance and risk of granuloma formation prevented widespread acceptance (109,110).

Cross-linked bovine collagen has been trialled, and an initial 20-50% reported improvement was not sustained. The theoretical increase in urethral resistance did not consistently yield the dryness that was aimed for; continued incontinence or short-lived effect meaning this is no longer recommended (111-115).

The following substances remain available and have been tested in children with incontinence: dextranomer / hyaluronic acid copolymer (a nontoxic, nonimmunogenic, non-migrant synthetic substance) and polydimethylsiloxane.

The technique is endoscopic injection at the bladder neck area: more than one procedure may be necessary. On average 2.8 – 3.9 ml is injected. More than 50% of patients need more than one injection. Initial success of 75% has been reported, but after 7 years there is a gradual decrease and only 40% remained dry (113,116,117). Others have reported success rates of 0 - 70% (118-125). Despite limited success bulking agents remain an option for all patients who are poor surgical candidates and those who want to avoid extensive bladder neck reconstruction. An alternative route may be the injection around the urethra using laparoscopy (126).

Conclusion: bulking agents are effective to increase bladder outlet resistance (LoE:3)

Recommendation: bulking agents are recommended to increase bladder outlet resistance (GR:C)

5.3. Artificial urinary sphincter (AUS)

Since the AUS was first introduced in 1973, it has undergone several iterations. Currently, the most frequently used device (for around 30 years) is the AMS 800 (127). It is a 3-part device with an inflatable cuff, a pressure regulating balloon and a control pump. The inflatable cuff needs to be implanted around the bladder neck in females and pre-pubertal males. In post-pubertal males, bulbar urethral placement is possible but not recommended for patients in a wheelchair (128). For those who have had extensive urethral surgery (eg. exstrophy and epispadias) placement may be extremely difficult but possible at the bladder neck (129).

AUS implantation is specialist procedure, as technical difficulties may be encountered in dissection around the bladder neck in obese, post-pubertal males or those with a history of previous bladder neck procedures. In principle, a 61-70 cm H2O pressure balloon is used when the cuff is around the bladder neck and a lower pressure balloon with bulbar cuff placement. The AUS remains the most effective means of increasing urethral resistance, whilst preserving the potential to void spontaneously. The ideal candidate for an AUS implantation has isolated sphincter incompetence with spontaneous voiding, good bladder capacity and compliance. Unfortunately, only a small proportion meet these criteria. The AUS may be used in those dependent on clean intermittent catheterisation. The combination of AUS placement and enterocystoplasty with subsequent intermittent catheterisation is well documented (130-132).

Spontaneous or strain voiding may be possible following AUS implantation. Spontaneous voiding was reported in 25 % of children with AUS, the majority (in this series) having neurogenic incontinence (133). If an AUS is implanted before puberty, the ability to void spontaneously may deteriorate after puberty. 40 to 50% of neurogenic patients require their AUS to be combined with augmentation cystoplasty either simultaneously or subsequently to initial implantation (134-137). Reported rates of continence range between 63 and 97% (138-144). Herndon et al. reported success in 86% (n=134): 22% voided, 11% needed post-void CIC, 48% emptied exclusively with urethral CIC, 16% performed CIC through a continent channel and 3% had urinary diversion 142 patients underwent implantation of an artificial urinary sphincter, of whom 93 males and 41 females with a median age of 10 years (range 3 to 39(145). 28% required a secondary bladder augmentation. Mechanical device problems occurred in 30% with an AMS 800 (versus 64% in the old model). Revisions (16%) were significantly less with the AMS 800. Erosion occurred in both groups (16%). Perforation of the augmented bladder occurred in 10 patients.

In some children (and adults) with an AUS, the device is deactivated or no longer functions but they remain dry: others have reported continence following placing the cuff only (146,147).

Children who have had an AUS require life-long follow up. Data relating to device failure vary widely – some reporting a mean device survival of 4.7 years (148) others report (in an adult population) 10 year device survival of 66 % (149). In all (but especially those with a neuropathic bladder) long-term bladder behaviour may change – decreased compliance and raised end-fill pressure risk obstructive uropathy and nephropathy. Long-term monitoring with renal ultrasound is essential – where changes are seen renal scintigraphy and/or urodynamics are likely to be needed.

Infection or erosion of an AUS is seen in 15-20 % (149). Rates of both are much lower when there has been no previous surgery, when used as a salvage procedure following bladder neck reconstruction, the erosion rate may be higher at 30% 136). Despite the high complication and revision rate, AUS results show that acceptable continence rates can be achieved in the long-term. It is worth considering an AUS as primary treatment in selected cases (146,150).

5.4. Fascial slings.

Fascial slings, harvested from rectus abdominis, were first described to treat incontinence in children, in 1982 (151). The principle is to increase outlet resistance, with elevation and compression of the bladder neck and proximal urethra. In post pubertal females, urethral dissection may be facilitated with a combined vaginal and abdominal approach (152). Although the short-term success rates were encouraging and yet may affect bladder behaviour (153,154), more recent long-term data show 76.7 % of girls were dry with a mean follow-up of 11 years (155). Most authors report a greater success when fascial slings are used in conjunction with bladder augmentation and success seems more likely in females than in males (156). In patients with neurogenic incontinence, postoperative CIC is recommended (155).

In girls a pubovaginal sling, may be placed through the vagina: of 24 girls with spina bifida this was successful in 19, a further 3 became dry with additional injections of a bulking agent around the bladder neck via a suprapubic needle. CIC was possible in all patients. One patient developed a vesicovaginal fistula (157). Complications of sling procedures include difficulties with intermittent transurethral catheterisation and persistent incontinence. The increase in outlet

resistance provided by slings seems less than that provided by the artificial sphincter, however, data show a success rate between 50 and 80% in females. Small series have shown similar outcomes with 'off-the-shelf' alternatives such as small intestinal submucosa. Continence was better in girls than in boys (85 vs 43%) (158-160). There are data looking at tissue engineered solutions in adult women that suggest positive outcome but there is little further in the paediatric population (161,162).

There is no place for midurethral tapes made from mesh or other artificial materials in children.

Published data support the use of an AUS for the most consistent results in boys and for girls, with a history of spontaneous voiding and no previous bladder neck surgery. Bladder neck slings may enhance outlet resistance in neuropathic patients who need augmentation cystoplasty and who are likely to rely on CIC. At present, given the cost and lack of effectiveness of injection procedures, their use does not appear justified in incontinent children. The cost of an AUS may restrict its use in some healthcare environments.

Conclusion: Fascial sling is an effective treatment to treat incontinence in children due to a functional or anatomical deficiency (LoE2)

Recommendation:Fascial sling is recommended to treat incontinence in children due to functional or anatomical defieciency. (Gr:B)

All patients who undergo bladder outlet surgery need long-term follow-up to monitor for complications, changes in bladder and renal function whether they have had bladder augmentation or not (163).

5.5. Bladder neck closure

Bladder neck closure remains an important option however, for most, should be reserved as the option of 'last-resort' and will often follow multiple other procedures. This is a life-long option – long term difficulties include persistent urinary leakage, stomal stenosis, leakage or stone formation (in up to 40%) (164,165). Surgery and provision of good follow-up are vital, and it is also important that patients are compliant with intermittent catheterisation and regular bladder irrigation.

5.6. Bladder outlet reconstruction

Surgical procedures to achieve urinary continence are directed by functional and anatomical deficiencies; with the goal of either continence (with normal voiding) or dryness (dependent on intermittent catheterisation).

Reconstruction of a functional urethra for continence and emptying, usually implies an anatomical defect with no neurogenic component (eg epispadias / exstrophy) and includes bladder neck reconstruction and urethroplasty with urethral lengthening (166-168). Continence rates (for instance in exstrophy/epispadias) vary widely (22-80%)the management of bladder exstrophy (BE(169).

Postoperatively, intermittent catheterisation or post voiding catheterisation may be necessary but bladder emptying by voiding is possible for some.

Urethral reconstruction for dryness will require intermittent catheterisation. The goal in surgery is to stop incontinence and create a urethra suited to catheterisation. The most dependable procedures for dryness utilise a flap valve or tunnel to achieve urethral integrity, additionally urethral slings, wraps and injections have also been used (170-172).

Conclusion: urethral reconstruction is effective to treat urinary incontinence due to functional or anatomical deficiencies (LoE:3)

Recommendation: urethral reconstruction is recommended to treat urinary incontinence due to functional or anatomical deficiencies (GR:C)

Urethral reconstruction for continence is based on the physical principle that reduction of urethral calibre will support the sphincter mechanism at the bladder neck and proximal urethra. Ideally, narrowing should be dynamic, permitting apposition for continence and urethral opening with funnelling during voiding (3,165-174). Young (1922) described a "double sphincter technique" involving excision of a wedge of anterior bladder neck tissue, as well as removal of a wedge of tissue just proximal to the epispadiac meatus (external sphincter). Dees (1949) added the concept of the urethral lengthening to that of narrowing, parallel incisions were made through the region of the bladder neck creating a posterior urethral plate from the bladder trigone. This plate is tubularised to lengthen the proximal urethra. The added length provides increased potential for urethral closure, increases resistance and moves the proximal urethra into the pelvic cavity. Leadbetter (1964) modified the Young-Dees procedure by creating muscular flaps from the area of the bladder neck and proximal urethra which were used to wrap the newly created proximal tube. This procedure was popularised by Jeffs (1983) who applied it to a staged repair in exstrophy. The Hopkins group reported their long-term continence rate with this procedure as greater than 80%, without the need for CIC or augmentation and to help reapproximate the pelvic floor musculature facilitating urinary continence. RESULTS: Primary closure was done within 72 hours of life elsewhere in 41 (60%(175).

Arguably, bladder neck reconstruction represents a gold standard for continent outlet reconstruction, however, modifications of the technique have sought to improve outcomes. Typically, urethral lengthening procedures require ureteric reimplantation and preservation of the posterior urethral plate. The trade-off for use of bladder tissue to lengthen the urethra, is a reduction in bladder capacity – the creation of continence and resultant bladder cycling may mitigate this. A question remains over how the neourethra functions – whether there is genuine apposition and closure or simply a fixed, anatomical resistance. As before, life-long follow up of bladder and upper tract well-being is essential. Long-term outcomes of urethral lengthening procedures show nearly 80% dryness with 4 hour emptying intervals and 90% at 3 hour intervals; however, the need for additional procedures remained high (catheterisable channel: 54%, subsequent augmentation: 47%) (176). Outcomes for all are also dependant on patient compliance with their catheterisation regime.

An alternative technique is the creation of a flap valve, using a full thickness bladder flap to construct a tube, placed in a submucosal tunnel (168,173,174). The disadvantage with an effective flap valve, is that it will not allow leakage with high intravesical pressures; the lack of a 'pop-off' mechanism risks renal damage. Patient compliance is essential for the safety of these procedures – worsening renal function needs investigation and may trigger a discussion about conversion to an alternative reconstruction.

Bladder outlet procedures without augmentation cystoplasty are controversial. Combination with augmentation is generally accepted as the means to avoid nephropathy and/or continued incontinence. In a review of 109 patients who underwent bladder outlet

procedures without augmentation cystoplasty the need for subsequent augmentation cystoplasty was 30% and additional continence procedures 70%. Imaging showed upper tract changes in more than 50% and chronic kidney disease 20% in a cumulative 10-year follow-up (177-179).

In order to achieve the best outcomes, the surgical approach to childhood urinary incontinence needs to be tailored to the individual and multimodal, where necessary.

Recent data support the concept that very early reconstruction in the exstrophy / epispadias group leads to more physiological bladder cycling, which facilitates normal bladder and urethral development. In the long-term this may improve continence without the need for bladder augmentation and bladder neck reconstruction (Level 3) – more data are needed to support these early conclusions.

5.7. Robotic Procedures
