I. BACKGROUND

This chapter reviews evidence of a wide-ranging set of topics integral to the conservative management of faecal incontinence. A summary of the findings of the 6th Consultation on Incontinence (ICI6) (1) is provided as background to the current review. Topics without new evidence since ICI6 are not included. The chapter provides an updated review of evidence from studies about the initial clinical assessment of faecal incontinence, initial and secondary conservative management interventions, and specialized diagnostic testing for secondary and tertiary interventions. The focus is primarily on adults living in the community independently or with minimal, informal care assistance. Conservative management of faecal incontinence in individuals with neurological diseases or conditions is now included here as interventions used are similar. Recognizing the cyclic nature of faecal incontinence and constipation there is appropriate attention given to managing constipation for preventing incontinence. Because quantitative instruments or scales assessing the severity of faecal incontinence symptoms are sometimes used as part of clinical assessment, an evaluation of the common scales is included in this chapter. The impact of faecal incontinence on associated quality of life assessed from qualitative studies is reviewed using an evaluation system designed for those types of studies.

Levels of evidence are evaluated and recommendations for clinical practice that consider the body of available evidence have been developed. Recommendations for future research are offered. An

algorithm organized according to the three levels of intervention for conservative management is provided. Strategies for searching the literature for studies to review in this consultation are summarized at the end of this chapter.

1. SUMMARY OF ICI6 FINDINGS

1.1. Initial Clinical Assessment and Secondary and Tertiary Diagnostic Testing - ICI6

ICI6 (1) showed the reliability of a digital rectal examination to assess anal sphincter strength as part of the initial clinical assessment of faecal incontinence by experienced clinicians. The digital rectal examination scoring system (DRESS) was identified as a useful tool to describe anal sphincter tone. There is a valid and reliable scoring tool for the presence and severity of incontinence associated dermatitis/skin damage named the Incontinence Associated Skin Damage tool (version IASD.D.2) that has been tested using dark and light-toned skin colors. There have been numerous instruments developed for scoring the severity of anal incontinence. Six of the most commonly used scales were evaluated in ICI6. The tools contained differing items involved in scoring of faecal incontinence severity such as frequency of faecal leakage, flatus, urgency, use of pads, and impact on quality of life; none of the tool enabled scoring of faecal incontinence severity only. The tools had varying degrees of psychometric testing.

Regarding secondary and tertiary diagnostic testing, endoanal ultrasound (EAUS) is considered an important test in evaluating faecal incontinence. Use of 3D-EAUS improves outcomes after OASIS repair and some anorectal surgeries. High resolution (vs. usual) anorectal manometry (ARM) provides more detailed information about anal sphincter function. Defaecography is useful in the assessment of rectal intussusception and rectocele. Endocoil magnetic resonance imaging (MRI) is an accurate alternative to EAUS for detecting anal sphincter injuries. MRI can be used for anorectal malformations and external anal sphincter atrophy.

1.2. Lifestyle Modifications - ICI6

There is low health literacy about faecal incontinence and its management in patients with the condition and in family/informal caregivers. Observational studies described the need to educate patients and their caregivers about faecal incontinence but the most effective methods of educating different groups are undetermined. Supporting patient self-management of faecal incontinence in an essential part of its conservative management.

There were additional findings associating being overweight or obese with increased risk for faecal incontinence, primarily in studies of women and those with dual incontinence. Results of the effectiveness of weight loss from diet programs and after bariatric surgery in reducing faecal incontinence continue to be mixed; therefore recommendations for weight loss as a management strategy for faecal incontinence could not be made.

Evidence from two randomized clinical trials showed the effectiveness of supplementation with the dietary fibre psyllium in decreasing faecal incontinence. Low and higher amounts of supplemented fibre can be effective and intolerance symptoms are low suggesting options for incrementally increasing the fibre dose to an optimal amount. Formation of a gel in feces may be a mechanism of the effect of psyllium.

The use of trans-anal irrigation (mainly on a daily basis) by individuals with various causes of faecal incontinence has shown to reduce anal incontinence and defecation frequency and improve quality of life. Different types/brands of irrigation systems were used. Patients require education about how to perform trans-anal irrigation and use the supplies.

1.3. Medication Treatment - ICI6

There was new evidence that taking the anti-motility medication loperamide or a supplement of psyllium fibre decreased faecal incontinence. Other findings showed a reduction in faecal incontinence after a combination therapy of biofeedback, loperamide and dietary fibre supplementation. Medications for treating diarrhoea in inflammatory bowel syndrome with diarrhoea or increasing anal sphincter pressure have shown effects that have potential to reduce faecal incontinence but have not yet been studied for that problem.

1.4. Behavioural Therapies - ICI6

Behavioural therapies continued to be recommended as a secondary intervention for faecal incontinence. Pelvic floor muscle therapy has potential for reducing faecal incontinence but findings of studies remain mixed. A standardized optimal procedure is lacking. Home-based biofeedback using battery operated portable devices can be an effective adjunct to clinic-based therapy in reducing faecal incontinence. Young patients seem to be more responsive to this approach. There is initial evidence that higher frequency electrical stimulation (ES) combined with biofeedback may be more effective in reducing faecal incontinence than low-frequency ES alone or biofeedback alone.

1.5. Quality of Life from Qualitative Research - ICI6

Findings from several qualitative studies were consistent with those of earlier studies showing a negative effect on quality of life. Quality of life domains that are affected include bodily symptoms, self-esteem and body image, time and planning, dietary issues, social relationships, and sexuality. Negative feelings associated with living with faecal incontinence included anger, frustration, injustice, guilt, shame, disappointment, hopelessness, despair and sadness.

New information identified that other chronic illnesses and aging worsened bowel control. The unpredictability of faecal incontinence and urgency are some of the most troubling bodily symptoms. Attempting to have a sense of control over symptoms was a main theme of living with faecal incontinence in women, while some men became resigned to it. Men and women often adapted to faecal incontinence and tried to make the “best of it.” Receiving an explanation for symptoms made them easier to accept. After years of dealing with the symptoms of faecal incontinence, some individuals developed a sense of mastery and self-confidence. The low level of public knowledge of faecal incontinence created feelings of stigma.

II. INTRODUCTION

Faecal incontinence affects adults across age groups and sexes. It is a distressing and embarrassing condition that impairs quality of life and well-being, and interferes with work, social interactions, and intimacy (2-7). Faecal incontinence increases risk of skin damage in the extended perineum (including buttocks and inner thigh areas) from inflammation of epidermal skin layers (8, 9), to pressure injury (10). Conservative management of faecal incontinence is recommended in the absence of acute traumatic anal sphincter rupture or a major defect in the external anal sphincter confirmed by endosonograph in the presence of gross faecal leakage (See algorithm). Patients with these problems should be referred for surgical evaluation.

Conservative management refers to a variety of non-surgical and generally non-invasive interventions that are aimed to improve faecal incontinence or prevent worsening of its severity. In community-living adults, success of conservative management of faecal incontinence relies on patient self-management and self-management support by their clinician. Self-management can be defined as the ability of a person along with family and care from a clinician to manage symptoms, treatments, lifestyle changes, and psycho-social, and cultural consequences of chronic diseases (11). Self-management support is defined as the systematic provision of education and support by health care staff/systems to increase patients' skills and confidence in managing health problems, including goal setting, monitoring progress, and problem-solving (12). Conservative management with support of a patient's ongoing self-management is recommended as the initial approach of treatment in the vast majority of patients before considering surgical treatments. These conservative approaches are comparatively inexpensive, have low risk for morbidity or mortality, and outcomes may be satisfactory and sufficient to achieve the treatment goals of many patients.

Initial conservative management begins with a clinical assessment a clinician with knowledge of the condition's presentation and experience with its management. Self-management support is guided by an evidence-based management plan developed by the clinician and patient that considers a patient's goals for treatment (13). Depending on the patient's response, various conservative interventions and lifestyle modifications may be introduced, tried, evaluated, and changed at different times. Clinical experience shows that patients may need to use more than one self-management intervention at a time and that adjustments to their plan may be needed over time. Environmental factors such as toilet availability can promote self-management and continence, activity and socialization in public spaces and improve quality of life whereas environmental barriers are created when these are lacking. If initial conservative management interventions are unsuccessful or unsatisfactory, there are numerous secondary interventions that may be used or added to a patient's management plan. Inclusion of a clinician with expertise in these secondary, specialized interventions in the patient's care team is recommended. For faecal incontinence that is refractory to conservative management, additional specialized diagnostic testing and tertiary level management including possible surgery are indicated. Faecal incontinence can significantly decrease quality of life and assessing the areas it impacts can guide development of goals for therapy and supports a holistic management plan.

1. DEFINITIONS

1.1. Definitions of Types of Bowel Incontinence

This committee uses and recommends the following definitions for types of bowel incontinence (1):

- Anal incontinence (AI) is the involuntary loss of flatus and faeces and/or mucus.
- Faecal incontinence (FI) is the involuntary loss of faeces.
- Flatus (or Flatal) incontinence is the involuntary loss of rectal gas or flatus.
- Mucus incontinence is the involuntary loss of mucus only (without faeces).

The terms and definition of FI and AI are not synonymous. The committee recommends that whichever definition is used in studies and publications, the conceptual and operational definition be made explicit and used in a consistent manner. In particular, scores of symptom severity should allow for quantification of FI severity separately from that of AI to facilitate comparison with findings of studies of FI , describe the contribution of faecal and flatus leakage to guide management, and expand the body of knowledge in this area. Similarly, quantifying the severity of flatus or mucus incontinence separately is optimal. The choice of which definition to use depends on the outcome of interest and scientific and clinical judgement. The prevalence of the different types of bowel incontinence and the percentage of anal incontinence that the different types constitute are not fully known. Use of these definitions in research studies will enable collection of these data. This committee acknowledges that the degree of bothersomeness, embarrassment, or distress associated FI or AI is subjective and may influence a patient's treatment seeking.

1.2. Definitions of Subtypes

Subtypes of FI and AI are leakage that is passive, associated with excessive urgency to defaecate, and due to functional or multimodal limitations. Passive FI is the involuntary leakage of faeces without forewarning. Seepage between the buttocks or on a small pad without the patient's awareness is an example of passive FI.

- Passive FI thought to be related to internal anal sphincter dysfunction; (14-16); it may also occur after normal defaecation, which is can be related to internal anal sphincter dysfunction or poor "snapping shut" (i.e., closure) of the external anal sphincter after defaecation (16, 17). FI associated with defaecation urgency is the inability to defer defaecation once the urge is perceived for long enough to reach a toilet. However, as distances to a toilet, waiting time for a public toilet to become available, and mobility level will vary, urgency is an inconsistent and uncontrolled condition that is difficult to measure and hence assess accurately.
- FI associated with excessive urgency is often associated with external anal sphincter dysfunction (14, 15). Faecal incontinence associated with urgency has also been associated with reduced rectal capacity and with increased rectal sensitivity (18, 19). Preliminary findings from 3D endoanal ultrasound show that patients with urgency had a higher rectal compression ratio during Valsalva compared to those with passive FI suggesting there may be a dynamic anatomic component to urgency (20).
- Functional (disability associated) FI occurs in the context of limitations in such activities as mobility, ability to manipulate clothing, cognitive impairment or delayed assistance with toileting. Functional (disability associated) incontinence when referring to UI is also termed dependent incontinence (21). Fonda and Abrams (21), proposed "contained incontinence" as a term to describe where urine leakage is contained in an absorbent pad or appliance. This definition has some relevance to FI that is managed solely with absorbent products or an appliance such as a peri-anal pouch.
- Multimodal incontinence refers to incontinence due to multiple health and functional comorbidities that reduce toileting ability. Being obese and having shortness of breath due to chronic obstructive pulmonary disease that reduce walking speed to the toilet is one example.

III. INITIAL CLINICAL ASSESSMENT AND DIFFERENTIAL DIAGNOSIS FAECAL INCONTINENCE

1. INTRODUCTION

The initial clinical assessment of FI is critical for successful management. The initial clinical assessment includes a focused history (including symptom assessment), focused physical examination, medication and diet review, and an assessment of impact on quality of life. As FI is maintained by complex mechanisms and relies on several different factors, including stool consistency, anal sphincter function, anorectal sensation, intra-rectal pressure, rectal capacity and compliance, colonic function, and cognitive processes (22, 23), and the aetiology of FI is often multifactorial. Therefore, a detailed history and physical examination, including an anorectal exam, is essential to evaluate these factors for its initial management.

Patient completed bowel diaries can be a useful part of the assessment process (24). A 7-14 day bowel diary can identify the relationship of bowel patterns, rectal urgency and daily routine to FI in women (25). Bowel diaries often include items such as stool frequency, shape, consistency and colour, along with episodes of faecal urgency, incontinence or the need to strain to pass stool. Additional items might be food and fluid intake and medications, particularly laxatives. At present there are no standardized items to include in a bowel diary, but an ICS working group is working towards identifying and making recommendations as to the most useful and clinically relevant items to incorporate.

Initial management may also include referral for proctosigmoidoscopy and/or colonoscopy as needed to assess for specific conditions including haemorrhoids, inflammatory bowel disease or suspected cancer, if history and physical examination suggest these conditions are included in the differential diagnosis.

2. HISTORY

History gathering requires sensitivity, but patients prefer clinicians (physicians, nurse practitioners, continence nurse specialists, physiotherapists, etc.) to ask them directly about FI (26, 27). More than two thirds of women with FI do not seek care voluntarily (28), while men take longer than women before asking for treatment (29). The aims of history taking and examination are to identify conditions that are amenable to management and to characterize symptoms so that they might be reduced.

In taking a history, assessing the impact of FI on quality of life (See Section XII-Qualitative Research on the Experience of Faecal Incontinence and Quality of Life), the patient's goals of treatment (30), and symptom severity (31), are important in planning care and to engage the patient in the plan. Questionnaires to assess symptom severity of AI such as the Fecal Incontinence Severity Index (FISI) (32), Fecal Incontinence Symptom Severity Score (FISS) (18, 33), or St. Mark's/Vaizey Score (34), should be used in the symptom assessment (See below). Use of valid and reliable measures is recommended for clinical practice and essential in research. In clinical practice, short, simple, and easy to use questionnaires are preferable for all patients.

A history should include:

- Daily bowel habits, the nature of the incontinence, past surgical & obstetric history, co-morbidities and current medication, including laxatives. Daily bowel habits include bowel frequency and stool consistency. Stool consistency can be quantified with Bristol stool form scale (35), **(Level of Evidence 3)** or a simpler and shorter stool consistency classification developed by Bliss and colleagues (18, 34) **(Level of Evidence 2)**.
- Ask about symptom onset and duration, and the nature of the incontinence by subtype (e.g., passive), frequency, amount, consistency of the leakage and the presence of urgency (23, 36) **(Level of Evidence 4)**. Timing of faecal incontinence (e.g. post-defaecation, during the night, any time) is important as faecal incontinence is not always associated with a bowel movement. Leakage can occur immediately before or in between bowel movements (37) **(Level of Evidence 3)**. Nocturnal faecal incontinence is uncommon, most frequently encountered in patients with neurogenic disorders, faecal impaction, low anterior resection syndrome, post-restorative proctocolectomy, diabetes mellitus and scleroderma (23) **(Level of Evidence 4)**.
- Differentiate the type (anal, faecal or mucus) as well as subtype of FI (passive, urge, and functional faecal incontinence) may help identify aetiology (31) (See Section I in this chapter about subtypes of FI).

2.1. Assessing Risk factors

The clinician must identify risk factors potentially associated with aetiology of FI. This is a part of constructing a comprehensive list of potential items in a differential diagnosis that need to be evaluated through the process of clinical reasoning to identify the most likely diagnosis and contributing factors to the FI. (See Chapter 1 for more detailed information regarding FI risk factors). Assessment of risk factors includes inquiring about:

- Diet – including intake of caffeine **(Level of Evidence 4)** and poorly absorbed carbohydrates (e.g. fructose, high fructose corn syrups and sorbitol) sorbitol (Level of Evidence = 3) as they may stimulate GI transit or diarrhoea (38-41). Medication - overdose or abuse of laxatives could cause chronic diarrhoea leading to faecal incontinence, particularly in older persons (42) **(Level of Evidence 4)**.
- Anti-anginal and antihypertensive medications (e.g., calcium channel blockers and adrenergic alpha-1 receptor antagonists) may reduce internal anal sphincter tone (43), magnesium containing antacids (40, 44) and metformin (45). Menopausal hormone therapy may increase risk for FI in postmenopausal women (46), as can obesity **(Level of Evidence 3).**
- Co-morbidities – risk factors for FI include older age, diabetes mellitus, irritable bowel syndrome, inflammatory bowel disease, constipation (faecal impaction with overflow), benign anal disease (haemorrhoids, fistula, anal warts), and scleroderma. Low activity level in older women is also a risk factor (46) **(Level of Evidence 4).**
- Neurological disease and disorders - brain (e.g., Parkinson's disease, stroke and dementia), spinal cord (e.g., spinal cord injury, tumour, multiple sclerosis) and peripheral nerve (e.g., diabetes mellitus) disorders increase the risk for developing FI (22, 23, 47-49) **(Level of Evidence 4).**
- Obstetric history - Obstetric anal sphincter injury (OASIS) (sphincter disruption, tear or pudendal neuropathy) risk factors following vaginal delivery include: primiparous delivery, forceps or ventouse (vacuum) use, birth weight > 4 kg, occipital-poste-

rior position at delivery, and prolonged second stage of labour (50-53) **(Level of Evidence 3).**
- Anal intercourse has been identified as a risk factor for FI in both women and men **(Level of Evidence = 3)** (54).
- Surgeries - including anal fissure surgery (sphincterotomy or anal stretch), haemorrhoidectomy, fistula surgery and low anterior resection (55-57) (Level of Evidence = 3). Cholecystectomy could cause post-cholecystectomy diarrhoea, leading to FI (57) **(Level of Evidence = 3)**.
- Pelvic radiation - risk of radiation prostatitis causing decreased rectal compliance and internal anal sphincter damage (58). Radiation dose may increase risk of late FI (59) **(Level of Evidence = 4)**.
- Symptoms of other pelvic floor problems (urinary incontinence and pelvic organ prolapse), which have similar risk factors (57, 60, 61) **(Level of Evidence = 3)**.

3. INSPECTION AND PHYSICAL EXAMINATION

3.1. General and Perianal Examination

Although there is a lack of well conducted studies in clinical examination comparing subtypes of FI (62), it remains a key component of evaluation. Examination is focused on the detection of evidence of FI and identifying its causes, if possible. True FI must be differentiated from conditions that cause discharge or seepage of mucus such as prolapsing external haemorrhoids, fistulae, and low rectal or anal tumours as well as from poor perineal hygiene. Physical examination should include inspection of underclothing for soiling and staining by stool, pus, or mucus. Perianal skin should be examined for signs of irritation such as erythema, rash, and excoriation (63). The Incontinence-Associated Skin Damage and Severity Instrument, version D.2 for use with light to dark toned skin (IASD.D.2), is a validated and useful tool to assess inflammatory damage of the upper skin layers resulting from FI (64, 65).

Perianal inspection should also include attempts to identify a patulous anus or one which gapes on gentle traction of the anal verge and/or a “keyhole” deformity of the anal canal which suggests a persisting sphincter defect. Inspection may reveal scars from previous episiotomies, or obstetric tears. Abnormalities at the anal verge from previous surgery or a gaping anus suggestive of marked loss of function may be present. Perianal inspection should identify the following (22, 23) **(Level of Evidence = 4)**:
- Scars from previous surgery or obstetric injury
- Perianal disease - prolapsing haemorrhoids, fistula, anal warts
- Presence of sensory deficits – numbness on the perianal skin
- Absence of perineal body - suggestive of obstetric trauma; at its worst this may manifest as a cloacal deformity

3.2. Vaginal Examination

For women, a vaginal exam using a Simms speculum may show a rectocele, cystocele and/or uterine prolapse, all of which may contribute to developing FI (66, 67) (Level of Evidence = 4). Physiological and complementary radiological tests are used to confirm clinical suspicion and provide objective data on the function of the anorectum. Pelvic floor dysfunction is a complex problem and multiple tests may be needed based on initial findings and complexity of the planned intervention.

3.3. Digital Rectal Examination

A digital rectal examination should be undertaken to assess the following (22, 23, 68, 69) **(Level of Evidence = 4)**. Assess for:
- Rectal contents - if faecal impaction is present, this could explain incontinence
- Rectal tumour or mass – if palpable, colonoscopy is required.
- Resting tone - indicative of internal anal sphincter function.
- Voluntary and reflex squeeze pressure – indicative of external anal sphincter function and potential function, respectively. The latter is elicited most commonly by asking the patient to cough while assessing sphincter tone - a cough causes a reflex near-maximal external sphincter contraction.
- Function of the puborectalis muscle (palpable at the anorectal junction) - assessed by asking the patient to squeeze the sphincter at which time the puborectalis should push the examiner’s finger anteriorly.
- Regional sphincter defects - detected as asymmetry.
- Paradoxical puborectalis contraction - this may be valuable in assessing constipated patients to identify paradoxical contraction as a cause of retained stool, and hence overflow incontinence (70).

The evaluation by the digital rectal examinations is reasonably correlated with anal canal manometry for resting pressure (68, 71-73), squeeze pressure (68, 71, 73, 74) **(Level of Evidence = 3)**, although there are some conflicting data (75), and more experience examiners have better correlation with manometry than beginners. The digital rectal examination scoring system (DRESS) describes anal sphincter tone on digital rectal examination (68), using a scale of 0 to 5 for both resting and squeeze pressures, ranging from 0 = no discernible pressure to 5 = extremely tight and 3 = normal. The DRESS correlates very well with anal manometry pressures for both resting and squeeze pressure **(Level of Evidence = 3)**. Experienced clinicians can reliably use the digital rectal examination to assess the anal sphincter strength, although anal inspection and digital rectal examination is not accurate enough to identify small to moderate external anal sphincter defects, which require further diagnostic work-up such as endoanal ultrasonography in select patients (73, 76) **(Level of Evidence = 3)**. For persons with known or suspected neurological disease, perineal sensations over the sacral dermatomes examined by using the pinprick method (69), and assessing the bulbocavernosus reflex may be relevant **(Level of Evidence = 4)**.

If rectal prolapse is suspected by history of mass prolapse per anus or perianal discomfort on straining or walking, but cannot be confirmed by Valsalva manoeuvre on a couch, the patient should be asked to sit on a commode and attempt defaecation and the perineum should then be inspected for evidence of a rectal mucosal or full thickness prolapse on straining.

3.4. Laboratory (Blood) Tests

There is no set panel of laboratory tests for FI. The clinician should be directed by the history and physical exam findings, and refer to practice guidelines for suspected conditions for guidance on laboratory testing.

3.5. Assessments for Condition-Specific Management

Referral for proctosigmoidoscopy and/or colonoscopy may be made at the time of initial assessment to assess for evaluation of specific conditions. Anoscopy and proctoscopy with a rigid instrument or flexible sigmoidoscopy are examinations of value in excluding potentially treatable causes of FI: anorectal tumours or polyps, inflammatory bowel diseases and haemorrhoids (22, 77), and solitary rectal ulcer syndrome, a functional disorder of evacuation

in which repeated straining at stool and or rectal self-digitalisation may result in an ulcerated area of the anterior rectal wall (77) **(Level of Evidence = 4)**.

3.6. Referral for Other Condition-Specific Problems

Based on the history and physical examination findings, referrals to appropriate providers should be made. For example, if a rectal mass is identified during the digital rectal examination, referral should be made for further assessment and investigation (e.g. rigid proctoscopy, biopsy) by a colorectal surgeon (78).

3.7. Referrals for Secondary Interventions

Based on the initial assessment, referrals to incontinence specialists including a specialist continence nurse or physical therapist, with assessment for potential surgery to a urogynecologist or gynaecologist, for secondary interventions may be made. Pelvic organ prolapse of the posterior compartment of the vagina could be improved with conservative management such as lifestyle interventions and physical therapies or reconstructive surgery (79). Referrals might also be for pelvic floor muscle therapy or incontinence products. The clinician conducting the assessment for FI should be knowledgeable about referral resources and clinical in their local area.

New Evidence about Clinical Assessment

There is further evidence that clinicians experienced with digital rectal examination can reliably use the procedure to assess the anal sphincter strength for both resting and squeeze pressure, and that more experienced examiners have better correlation with manometry than beginners (80).

An electronic diary (e-diary) designed to be used on a mobile phone was developed and data collection about FI, urgency, and continent bowel movements from the e-diary was compared to that on a paper diary in a randomized, crossover trial (81). Sixty of 67 women (87%) with refractory FI completed up to three consecutive 14-day diaries in two sequences. Study participants were required to report about each FI episode or bowel movement on both a paper diary and the e-diary. Paper and e-diaries were moderately or highly correlated for number of FI episodes per week (r = .66) and number of FI associated with urgency per week (r = .72). Test-retest reliability of the e-diary was good (ICC =.74 for number of FI episodes per week, and .62 for number of urgency FI episodes per week). Similar findings were reported for bowel movements. Usability of the e-diary, measured by the System Usability Score, was high (score = 82.3 ± 17.5). Approximately three-quarters of the users (75.9%) preferred the e-diary over a paper one.

Recommendations for Practice Related to Clinical Assessment

- Perform a baseline assessment including a focused medical history, a general physical examination, and an anorectal examination with inspection of perineal skin (Grade of Recommendation = C).
- The history should include risk factors and comorbid conditions, neurological and non-neurological, that could contribute to FI (Grade of Recommendation = C).
- Use of a validated questionnaire can assist in assessing symptoms in clinical practice (Grade of Recommendation = C).
- Try to differentiate the type of FI (passive and/or urge, or functional), which can help identify its aetiology (Grade of Recommendation = C).
- Several conditions should be specifically assessed for in the history and physical examination, as they may be amenable to definitive treatment, including anorectal tumour, rectal prolapse, haemorrhoids, faecal loading, potentially treatable causes of diarrhoea (e.g., inflammatory bowel disease, infection and irritable bowel syndrome), acute anal sphincter injury, and neurological disease (e.g., spinal cord injury and cauda equina syndrome) as they may be amenable to definitive treatment, including (Grade of Recommendation = C).
- Conduct a digital rectal examination to assess the strength of the internal and external anal sphincter as well as puborectal muscle (Grade of Recommendation = B).
- Clinicians trained in anoscopy and proctoscopy with access to equipment can undertake these examinations as part of initial assessment to exclude potentially treatable causes of FI (e.g., anorectal tumours, haemorrhoids, inflammatory bowel disease) (Grade of Recommendation = C).
- Further diagnostic work-up such as anorectal manometry, endoanal ultrasonography and defaecography are required, when the initial management fails to improve symptoms sufficiently (Grade of Recommendation = C).
- Assess and manage skin damage associated with FI (Grade of Recommendation = C).

Recommendations for Research on Clinical Assessment

- Establish Identify optimal approaches the best way for clinicians to ask patients directly about FI.
- Characterise the FI in men, who are remain less studied. This is inspite of although according to the epidemiological studies reporting both sexes are equally affected.

4. SYMPTOM SEVERITY SCALES FOR FAECAL (AND ANAL) INCONTINENCE

4.1. Description Of Scales

There are over 20 scales for rating the severity of FI or AI. Many scales were developed prior to 1992, are rarely used and have been reviewed elsewhere (82); these are not included in this review. Subsequently, six other scales; the instrument developed by Pescatori and Wexner (44, 82), which is also known as the Cleveland Clinic incontinence score, the Vaizey or St. Marks incontinence score (34), the Fecal Incontinence Severity Index Modified Manchester Health Questionnaire (83, 84), and the Fecal Incontinence and Constipation Assessment (FICA) symptom severity instrument (18, 33, 84, 85), now referred to as the Fecal Incontinence Symptom Severity Scale (FISS) have been developed and used in clinical studies to rate the severity of FI or AI. More recent instruments, the Bowel version of the International Consultation on Incontinence modular questionnaire (ICIQ-B), (86, 87), the ICIQ-IBD, which is tailored for patients with inflammatory bowel disease (88), and the Revised Fecal Incontinence Scale (89), have been developed and validated but not been widely used in clinical studies. The scales are summarised in Table 16-1.

In addition to the severity of FI, these scales also score the severity of flatus leakage and/or the impact of FI or AI on quality of life/lifestyle. However, none of the currently available scales provide a score for the severity of faecal leakage only, separately from anal/flatus incontinence, urgency, or quality of life. Use of these instruments typically relies on patient recall as they are not part of a daily diary.

All of these instruments contain an assessment of frequency of different types of rectal leakage suggesting that frequency is considered one of the most important dimensions of incontinence severity. Some scales assess additional issues related to incontinence, such as rectal urgency, amount or volume of leakage, or use of perineal protective products (e.g., pads). Five scales, Vaizey, FICA (FISS), ICIQ-B, ICIQ-IBD, Rapid Assessment FI Score (90), and the Accidental Bowel Leakage Evaluation instrument (91) include a measure of rectal/ defaecation urgency (18, 33, 34, 87, 88). The Vaizey scale (34), evaluates urgency with a question that asks about the "lack of ability to defer defaecation for 15 minutes" for which two response options are provided; weekly or daily. However, clinical observations suggest that this question may not accurately discriminate between people who have and do not have urgency because most people with severe urgency have a few, perhaps 5 minutes, at most to reach the toilet.

Population-based studies from the Rochester Epidemiology Project defined urgency as the need to "rush to the toilet" often (>25% of time) or usually (>75% of time) because of an "urgent need to empty the bowels" (18). Through an initial survey followed by a case-control study that included a two-week daily bowel diary, this study observed that bowel disturbances are the most important factors associated with FI and for incontinent bowel movements in women with FI (18, 25, 33, 57, 92). Rectal/defaecation urgency was an independent and the strongest factor associated with FI even after adjusting for other bowel disturbances.

Urgency is a distressing symptom (93). Patients with more severe urge FI report greater use of pads (94). Urgency is associated with loose stools, increased rectal sensitivity (18, 94), and reduced rectal capacity (i.e., a smaller reservoir) (18). Nonetheless, the time required for measuring the inability to reach a toilet before leakage occurs is not standardised and patients' estimates and sense of being rushed may vary greatly.

A state of the science summary emanating from a workshop organized by the U.S. National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health (31), emphasised the importance of considering the amount/volume of leakage when characterizing the severity of FI. When the amount of leakage was greater, the impact on quality of life was worse (92). Only one scale, the FISS, incorporates the amount of leakage into the assessment of AI severity, with a question that categorises the "usual leakage" as staining, a moderate amount (i.e., requiring change of underwear), and a large bowel movement (i.e., requiring change of all clothes) (18, 25, 33, 57, 92). Conceivably, a matrix defined by amount*frequency, which assesses the amount of leakage for each consistency of faeces leaked (e.g., solid or liquid) may more comprehensively characterise the severity of FI. This type of matrix scoring of FI severity was used by Bliss et al. (37), in summarizing data from a stool diary in a clinical trial of fibre supplementation for the treatment of FI. Using this assessment for AI would comprise four options for type of leakage (i.e., solid and liquid faeces, flatus, and mucus) and three for amount/volume (e.g., small, moderate, and large) requiring 12 items. The challenge is to develop measures that are comprehensive and useful for clinical practice and research but are not overly burdensome. One FI severity instrument also inquires about the bother related to leakage, predictability of leakage, lack of control over leakage, and bowel symptoms (91).

The current AI severity scoring systems assume that leakage of solid and liquid stools is equivalent. However, the FISI study observed that patients and physicians have different perspectives of severity; loss of liquid and solid stool was the worst for patients and physicians respectively (32). Patients with FI are able to reliably distinguish solid from loose/liquid stools (36, 37). Some measures (e.g., Wexner (44) and Vaizey (34) scales) consider the use of pads when characterising severity. However, use of these measures may conceivably reflect not only the severity of AI but also fastidiousness regarding one's sense of hygiene. Finally, the relationship between symptom severity and anorectal functions (e.g., anal resting and squeeze pressures) has not been established.

4.2. Assessing Clinically Important Differences in Symptom Severity

Most contemporary clinical trials have considered a 50% or greater reduction in the number of days or episodes of FI recorded with bowel diaries as the primary endpoint (95, 96). However, in an internet based survey, some patients, especially women aged 65 years and older, reported that they would not consider a 50% reduction in the frequency of FI to be sufficient; on average they considered a 77% reduction as sufficient (97). In accepting this assumption, it is necessary to ascertain whether a statistically significant change in the frequency of FI is also clinically significant (98). One way to accomplish this is to assess the minimum clinically important difference (MCID), which is the smallest change detected by an instrument that is associated with a clinically meaningful change (99). The MCID can be identified with distribution-based (½ of standard deviation of the population mean at baseline (100), and the effect size (mean change /standard deviation at baseline or an anchor based approach (98). These anchor-and distribution-based approaches (99), have been used to estimate the MCID for the FISI, FISS, Modified Manchester Health Questionnaire, and the Accidental Bowel Leakage Evaluation instrument (91, 101, 102). For example, based on the 0.5 SD threshold, the improvement in FISS exceeded the MCID in 75% and 83% of patients in whom the FI frequency declined by 50– 74% and ≥75% respectively (102).

A few practical issues pertaining to assessment of the MCID deserve emphasis. First, the distribution-based MCID (e.g., 0.5*SD, effect size) can be readily calculated. The SD is not a universal value but is unique for each study. The anchor-based methods require additional data to be collected at all follow-up assessments. This may be as simple as adding one additional item to the "post" measurement (for e.g., a global rating of better/worse for the time period between baseline and post measurement.) While MCID represents a step in the right direction and current methods have demonstrated a utility relative to identify meaningful 'day-to-day' life changes for a person with FI, we have to be more cautious if considering them "Clinically Important." None of the methods rely on a clinical gold standard to determine the amount of change that is clinically significant as defined by a gold standard. These methods rely on either distributional properties (1/2 standard deviation, MCID) or other self-reported assessments (anchor based) to identify meaningful change, not clinical indicators. These two questions may be considered as the anchor for assessing the MCID:

Over the past <period of time> please rate whether or not the frequency of bowel accidents has become: Much Less Frequent, Moderately Less Frequent, Somewhat Less Frequent, Somewhat More Frequent, Moderately More Frequent, Much More Frequent. Thinking about the bowel accidents you have had over the past <period of time> do you think that you are getting: Much Better, Moderately Better, Somewhat Better, Somewhat Worse, Moderately Worse, Much Worse.

4.3. Blending Symptom Severity and Quality of Life Scales

FI and AI can have a devastating impact on quality of life (QOL), which can be evaluated by generic or disease-specific instruments

(103). Some symptom severity scales also include typically one (34, 44, 89), sometimes more (87), questions related to impact of FI on lifestyle and QOL. The alternative approach is to use dedicated instruments with more questions that provide a more refined assessment of the impact of FI or AI on QOL (e.g., Fecal Incontinence Quality of Life Scale and modified Manchester Health Questionnaire, and FICA QOL scale) (33, 83, 104). There is a significant correlation between symptom severity and QOL in FI and AI (33, 104, 105).(See Qualitative Research section below). The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire - IUGA Revised is validated in women with FI, allowing for measurement of sexual function with a condition-specific measure (106).

Bowel diaries are widely used to record bowel habits and track the severity of FI or AI. Bowel diaries are less prone to recall bias than questionnaires. They not only quantify FI or AI but also the relationship of episodes of incontinence to bowel habits, e.g., whether episodes of FI or AI are related to liquid or formed stools or preceded by urgency (25). These features are useful for guiding therapy. However, maintaining daily bowel diaries entails more work for patients and more analysis. With advancements in digital technology, mobile “apps”, internet, and telephone-based daily reporting of symptoms will likely be increasingly used in future.

New Evidence about Symptom Severity Scales

As detailed above and in the Table 15-1, there are two new scales for characterizing the severity of FI (90, 91). Of these instruments, the Accidental Bowel Leakage Evaluation instrument characterizes the frequency (and bother related to) leakage of solid faeces, liquid feces and flatus; urgency; awareness of leakage; sense of complete evacuation; predictability of leakage; control over leakage; and ancillary bowel symptoms. While treatment success is generally defined as a 50% reduction in the frequency of FI, a new study suggests that some, especially older, women consider this threshold to be higher (i.e., 77% reduction) (97).

Summary of Symptom Severity Scales

- The severity of FI or AI is based on symptoms evaluated by a self-report questionnaires. Questionnaires should be standardised and possess validity and reliability, but existing questionnaires vary in these quality properties.
- A scale that scores the severity of FI separately from AI that includes flatus incontinence is lacking and development is needed.
- The assessment of AI severity is currently comprised of the following domains: frequency, consistency, amount, subtype of leakage (e.g., urgency, passive leakage). Not all AI questionnaires incorporate all domains.
- At present, a 50% or greater reduction in the number of days or episodes of FI is a primary outcome measure in therapeutic trials. In one study, this outcome measure reflects a clinically important difference as measured by the minimal clinically important difference in 75% of patients.

Recommendations for Practice Related to Symptom Severity Scales

- The severity of FI should be assessed using standardized, quality instruments that incorporate score/grade its symptoms (Grade of Recommendation C).
- The severity of FI is correlated with its impact of the quality of life (Grade of Recommendation B).

Recommendations for Research on Symptom Severity Scales

- Develop and test an instrument offering a severity score for FI only, separate from that of AI and from quality of life measures.
- Evaluate the addition of weighting the scoring of the consistency of leaked faeces (e.g., liquid vs. solid) in FI or AI severity scales.
- Further studies are necessary to ascertain whether use, size, or number of pads is an indication of FI or AI severity, hygiene preference, affordability, or a coping mechanism that mediates the relationship between severity and QoL.
- Evaluate the role of behavioural and coping factors (e.g., staying near a toilet, ability to respond to urgency) in FI or AI severity. Develop measures for including the effects of these factors in FI severity scales if they have a significant impact.
- If rectal/defaecation urgency is to be used as an item in FI or AI severity scales, a way to standardize and measure urgency is necessary.

Table 15-1. Instruments for Rating Severity of Faecal or Anal Incontinence and Their Quality

Scale Name Reference	Content included in score and Type of Score (AI, FI or Blended with Impact on QOL)	Inclusion of Urgency or Amount/Volume of Faecal Leakage*	Construct Validity	Criterion Validity	Internal Consistency†	Test-Retest Reliability	Responsiveness
Pescatori (82)	Frequency of leakage of solid and liquid faeces, flatus, and flatus AI score	Urgency - Amount/Volume -	A (19)	B	B	A (19)	B
Wexner (44)	Frequency of leakage of solid and liquid faeces, flatus, pad use and lifestyle restriction AI QOL impact score	Urgency - Amount/Volume -	A (19,(107)	A (216)	A (107)	A (19)	A (217)
St Mark's Incontinence Score (34)	Frequency of leakage of solid and liquid faeces, flatus, and altered lifestyle Presence of urgency (inability to delay defaecation), needing to wear a pad or anal plug, or use of constipating medication AI score	Amount/Volume -	A (107)	A (218)	A (107)	A**	A (218)
FISI (32)	Frequency of leakage of solid faeces, liquid faeces, flatus, and mucus AI score	Urgency - Amount/Volume -	B	A	B	A (21)	A (206)
FICA (FISS) (18, 33, 84, 85, 102)	Frequency of incontinence, type/amount of leakage (flatus only, small or large amount of faeces), number of pads changed, presence of urgency AI score		A	A	A	A	A (219)
Modified Manchester Health Questionnaire (83, 84)	Frequency of: urgency, leaking faeces in various conditions (e.g., coughing and sneezing, walking), leaking solid or liquid faeces, flatus, not wiping clean, and effects on various activities (physical activity, sexual relations, etc) AI QOL impact score	Urgency + Amount/Volume -	A (21)	A (21)	A (21)	A (21)	A (21
ICIQ-B (86, 87)	In the Bowel Control section: Frequency of: ability to control solid faeces, liquid faeces, mucus, and flatus, frequency of needing to wear a pad, frequency of leakage in between bowel movements, frequency of unpredictability of incontinence In other sections: frequency of urgency, and using medication to stop leakage along with usual bowel pattern and impact on lifestyle AI QOL impact score	Amount/Volume -	A	A	A	A	B

Scale Name Reference	Content included in score and Type of Score (AI, FI or Blended with Impact on QOL)	Inclusion of Urgency or Amount/Volume of Faecal Leakage*	Construct Validity	Criterion Validity	Internal Consistency†	Test-Retest Reliability	Responsiveness
Revised FI Scale (89)	Frequency of leakage of solid faeces, liquid feces, urgency, needing to change underwear and needing to alter lifestyle FI QOL impact score	Urgency - Amount/Volume -	A	B	A	B	A
ICIQ-IBD (88)	ICIQ instrument adapted for patients with inflammatory bowel disease (IBD).		A	B	B	A	B
Rapid Assessment FI Score (90)	Frequency of stool leakage – does not discriminate between solid or liquid FI. Flatus leakage (yes-no response, not frequency). Few questions on perception related to FI. No questions on QOL.	Urgency + Amount/volume –	A	A	A	A	B
Accidental Bowel Leakage Evaluation instrument (91)	Frequency (and bother related to) leakage of solid faeces, liquid feces and flatus; urgency; awareness of leakage; sense of complete evacuation; predictability of leakage; control over leakage; ancillary bowel symptoms	Amount/volume +	A	A	A	A	A

QOL refers to Quality of Life.
"A" refers to attributes that have been partly or adequately validated. "B" refers to attributes that have not been validated.
**** Items which are not incorporated in the instrument are indicated by a - sign; those items included have a + sign***
†Internal consistency has been evaluated with Cronbach's α coefficient, which may not provide the most appropriate assessment of this characteristic
*****For cells with an "A" rating that do not include a citation, the citation is provided in the row heading.***

IV. INITIAL CONSERVATIVE MANAGEMENT OF FI

The initial management of FI involves patient and/or caregiver education, setting of patient goals for treatment outcomes, and conservative therapies including support of patients' self-management efforts by clinicians.

1. PATIENT AND CAREGIVER EDUCATION AND SELF-MANAGEMENT SUPPORT

Knowledge and awareness about FI in the general population is low (4). Moreover, many patients with FI and their informal caregivers who assist them with self-management lack knowledge and understanding about how the bowel functions normally, how it may be altered in some disease processes, the influence of lifestyle practices that might influence defaecation and FI, and available therapies (4, 108-110). Therefore, educating patients and caregivers about these topics is an important part of the initial management of FI (13). Managing FI is also influenced by stigma, taboo attitudes, negative emotional reactions, and change in family roles (4, 109, 111-114). Numerous qualitative studies reviewed later in this chapter reveal the tremendous negative impact of FI. The impact on emotional distress and personal relationships is greater for younger versus older (>65 years) women (115, 116). Providing counselling and emotional support is integral in supporting self-management.

Past and recent studies show that individuals with FI living in the community have insufficient knowledge about the name of their health problem, its risk factors, therapies, and self-management strategies (4, 27, 110, 117). In a recent survey about self-management of FI (termed accidental bowel leakage, ABL), nearly half of 161 female respondents (47%) "did not know anything" before visiting a clinician, and only 4% "knew a lot" (117). The vast majority (89%), of respondents thought that it was important to have ongoing guidance and support for self-managing ABL regardless of the level of knowledge about ABL self- management and effectiveness of one's own self-management efforts. For example, 91%, of participants who had "no knowledge" about ABL self-management and 67% of those who had "a lot" of knowledge thought that receiving support or guidance was "very important". Nurse-led education and advice about conservative FI management alone was as effective in reducing FI as a combined intervention that added exercises and/or biofeedback to nurse-led education and advice (118). Nurse-led education and advice addressed diet modification, medication titration, and bowel retraining. Education about FI is integral to support of patient's self-management. Qualitative research, summarized later in this chapter, shows that women and men differ in their experiences managing FI and gender-specific educational strategies may be beneficial. (5, 6, 119).

Informal caregivers assisting family members living at home in managing incontinence also have numerous incontinence literacy needs. Bliss *et al.* (27), was one of the first to describe the health literacy needs of informal caregivers assisting in managing incontinence and associated skin problems in their care recipients with cognitive problems (Alzheimer's disease or dementia) who were living in the community. Results can guide the selection of educational topics for patients with FI and their caregivers. From focus groups and interviews of 48 family and friend caregivers with culturally diverse backgrounds, three main areas of incontinence literacy needs were identified: knowledge, skills, and attitudes. For example, caregivers wanted information about the risk of and reasons for incontinence in dementia, therapies other than using absorbent products, selecting absorbent products and over-the-counter skin care products, and trustworthy resources. Caregivers were interested in improving their skills for managing incontinence, cleansing soiling and preventing skin problems, and lessening resistance of care recipients. Most caregivers expressed a desire for incontinence to be framed as a health versus behavioural problem and saw a need for greater public awareness and empathy so the stigma associated with incontinence would be less (27). These results were supported and had further insights added by recent preliminary findings of Murphy *et al.* and Talley *et al.*

Caregiving for a person with dementia and incontinence presented unique concerns and challenges depending on the type of informal caregiver (spouse versus children versus extended family member or friend) (109). For example, husbands often had limited physical caregiving experience and skills, children needed to manage reversal of caregiving roles, while showing respect for parents, and extended family members often felt excluded from visits and consultations with clinicians.

1.1. Resources

A series of educational and supportive materials for clinicians to provide to patients and informal caregivers is available free via the webpage of the Nursing Committee of the International Continence Society (ICS) (120), or the first author of the study (27). A continence product advisor website (121), to assist in selecting absorbent products has also been developed from a collaboration of ICS, International Consultation on Incontinence, University College of London and University of Southampton.

The most effective approaches for educating patients about FI and its management have yet to be identified. Teaching approaches may be in-person, online or internet-based, or use telehealth, or video/remote or mobile applications. In teaching women about FI management (122), patients were randomized to a standard counselling group or counselling and use of a mnemonic to assist them to recall the types of lifestyle therapies that they were to perform. The mnemonic was RELIEF: routine lifestyle and routine bowel habits, exercise, live, Imodium, effort, and fibre and food diary. At two months following counselling, there was no difference in recall of FI treatments between groups. The group using the mnemonic had higher (better) scores on the Manchester Health Questionnaire however.

Mobile health applications for managing urinary incontinence (UI) show positive outcomes. (123, 124). Women seen in a urogynaecology clinic for FI were surveyed about interest in a mobile application to support their self-management plan (117). Half (50%) of the 161 participants had "a lot of" interest in and 30% had "some" interest. A mobile health app for supporting self-management of FI is currently under development (1R21NR019676-01, NINR, NIH).

1.2. Goal Setting

Cure of FI and amelioration of all symptoms is the ultimate goal of treatment but may not always be possible. Reduction of symptom severity, resumption of self-restricted activities, and improvement of quality of life are goals of therapy for many individuals when complete cure is not attainable (125). Manthey *et al.* (125), surveyed 176 men and women with FI revealing five themes of patient-identified goal statements related to improving their FI severity, lessening the impact on lifestyle and desire for a more normal life, emotional responses such as wanting more confidence and better control of

their symptoms, and reducing adverse effects of FIand need for self-care practices such as wearing pads. The top investigator identified goals were having fewer and less liquid consistency of leakage and feelings of greater control.

1.3. Environment Resources: Information about Public Toilet Availability

The lack of availability or information of public toilets are factors that can contribute to episodes of FI in public and lower quality of life of those with the condition due to deterring activity and socialization in public areas. Qualitative studies have shown that a common and effective self-management strategy of individuals with FI is to make note of the locations of toilets in public areas (6). Australia offers a free online interactive map of toilet locations throughout the country that serves as an outstanding example of such a resource for supporting self-management (126). The map can be portable with mobile applications on Google Play and Apple Store. The United Kingdom (UK) has also created an interactive map of its public toilets that has a "find a toilet" function and a filter to search on features of a toilet such as accessibility and having a baby changing station (127).

New Evidence about Patient and Caregiver Education, Goal Setting, and Environmental Resources

There were new studies identified for this review:One study investigated the effectiveness of patient education for reducing FI as an arm of a randomized trial (107), two studies examined use of social media for obtaining information about FI management (128, 129), one study reassessed patient goals for FI treatment (130), one study identified outcomes of therapy in research studies of interest to patients (97), and two studies identified locations of public toilet in the environment (131, 132).

Regarding patient education, the CAPABLe trial used a 2x2 factorial design and randomly assigned 300 women with FI in a 0.5:1:1:1 allocation to one of four treatment groups: (1) oral placebo and an educational pamphlet about FI management, (2) placebo and biofeedback exercises assisted by anorectal manometry (ARM), (3) loperamide and an educational pamphlet, and (4) loperamide and ARM-assisted biofeedback exercises (107) Women with hard or liquid stools, previous abdominal or pelvic floor radiation, or positive colon cancer screening were excluded. The primary outcome was the change from baseline to 24 weeks in the St Mark's (Vaizey) FI severity scale, calculated from reports on a 7-day bowel diary. At 24 weeks, there was no significant difference among the treatment groups and all groups had some improvement in the St. Mark's score. Limitations of the study are inclusion of only women and those with normal stool consistency, no reporting of results for FI only separately from AI, and lack of monitoring adherence to exercise in subjects not randomized to the ARM-assisted biofeedback group. These results support those reported earlier by Norton *et al.*(118), that patient education about conservative management of FI is an important component of supporting self-management and in reducing symptom severity.

Internet and social media (Facebook and Twitter) sites have been evaluated for information about FI. Using the DISCERN quality analysis tool and JAMA benchmark criteria, Kadam-Halani *et al*. (128), concluded that the quality of information varied by the search term used, with FI (versus ABL , for example) having the highest quality. Leo *et al.* (129), identified that Twitter was used more than Facebook to exchange information about FI between health care providers and patients, possibly due to its anonymity. Sources of tweets were mainly a few dominant hospitals and physicians rather more broad perspectives. Website search engines also yielded product advertisements, and scientific journal information. The abundance of information posed difficulties to sort through and identify appropriate, quality information. The COVID-19 pandemic resulted in emergent changes to the use of telehealth, video conferencing, and online resources for continence care and education. These approaches extend access to care and some may remain after the crisis is resolved but will need evaluation.

In reassessing patient goals for FI treatment, Halder *et al*. (130), conducted a retrospective chart review of 100 women with FI who were asked to identify up to three goals for treatment prior to their initial visit with a health care provider. Identified themeswere, compete elimination or control of faecal leakage, improvement of symptoms, and prevention of worsening of their condition. Women emphasized the importance of working toward feasible/realistic outcomes. Findings supported previously identified goals of wanting greater control and confidence in managing symptoms and decreases in frequency of leakage (30). Goals that were added were reducing the need for self-care such as performing incontinence-associated hygiene and having pelvic health in general. In seeking to identify outcomes for research studies, Heymen *et al.* (97) quantified patients' acceptance of FI improvement when cure was not possible using an online focus group (n=28 individuals) and an online survey (n=186 individuals). Satisfaction with treatment outcomes ranged from 50% to 80% reduction in symptoms.

There were two studies that identified and mapped the location of public toilet facilities in parks/recreation area and open spaces in major international cities and in the United States using geographic information systems (131, 132). Also, toilet density by population and residential area (mi^2 or km^2) was calculated, and toilet distribution was visualized using Choropleth maps. Results showed differences among the cities in availability (i.e., distribution and density) of these public toilets in their park and recreation areas. For example, considering city population and area, availability of public toilets in parklands or open spaces is generally high in Paris, Seoul, Minneapolis, Philadelphia, and Sydney and low in Berlin and Brussels. Sydney has the highest toilet density in open spaces per km^2 even though they have the lowest population density. There is a relatively even distribution of public toilets in parkland areas per km^2 in Minneapolis and Toronto. Limitations of these early investigations is the unavailability of a single score for toilet availability, use of freely available public databases whose information may not keep up with recent changes, and lack of these databases in some cities.

Summary of Patient and Caregiver Education, Self-Management Support, and Environment

- Patients with FI and their informal caregivers have low incontinence literacy (Level of Evidence 3).
- The internet contains a variety of information related to FI that can pose difficulties to patients to identify accurate, quality information. Women across age groups have interest in a mobile application to support self-management of FI (Level of Evidence 3).
- Patients have goals for outcomes of conservative therapies when cure is not possible including feelings of greater control, reduced symptom severity and hygiene needs/products, participation in social and public activities, and improved quality of life (Level of Evidence 2).
- Publicly available maps of the location, distribution and density (per population and area) of public toilets in urban and park/recreation areas are helpful resources to support self-management of FI and for community planning (Level of Evidence 2).

Recommendations for Practice Related to Patient and Caregiver Education, Self-Management Support, and Environment

- Educate patients (and their informal caregivers if appropriate) about bowel function, FI, and conservative therapies and self-management practices (Grade of Recommendation B).
- Advocate for developing and communicating freely accessible information about the location and availability of public toilets (Grade of Recommendation C).
- Support patients' self-management of FI by providing a variety of educational resources including those on the internet (Grade of Recommendation C).

Recommendations for Research on Patient/Caregiver Education, Self-Management Support, and Environment

- Identify effective teaching strategies that are gender-specific and culturally appropriate
- Develop mobile applications to support self-management with conservative therapies for FI

2. LIFESTYLE CHANGES

Lifestyle modifications are part of the initial conservative management of many chronic health conditions including FI. For some lifestyle modifications for managing FI where there is insufficient research-based evidence and low/few risks of harm to patients, expert opinion or experience can be encouraged and their effectiveness evaluated on an individual basis.

3. DIET, FLUIDS, AND DIETARY FIBRE

3.1. Diet and Fluid Modification

Individuals with FI modify their dietary intake as a self-management strategy to reduce severity of symptoms and improve quality of life. Evidence comes mainly from observational and qualitative studies (reviewed later in this chapter) initially reported in studies by the team of Peden-McAlpine and Bliss (6, 133), and more recently supported by Andy *et al.* (134). Dietary modifications include avoiding certain foods or fluids worsening FI severity periodically or permanently and restricting the amount of those foods consumed. Foods identified as worsening FI from several studies and samples include certain vegetables especially those increasing flatus (such as cabbage, broccoli, onions, and garlic), fruits (such as strawberries and apricots), fatty or greasy foods, spicy foods (spare ribs, ethnic foods), foods and fluids containing caffeine (such as coffee and chocolate), and dairy products (ice cream, cream, cheese) (135, 136). Younger adults are more likely to report that fatty foods worsened their FI than older adults (135). There are differences in use of diet modification by age and sex. More women than men avoid foods as a self-management strategy for FI (133, 135). Some women with FI modify their diet based on suggestions for managing other gastrointestinal problems (e.g., lactose intolerance and IBS) that they find in the professional or lay literature (6, 136).

Some foods and fluids reported as aggravating FI by some patients have physiological effects on gastrointestinal function but there are few studies about this association. Caffeine, of which coffee is a popular source, can increase rectosigmoid motility and induce a desire to defecate in normal individuals (137-139). Caffeine has also been observed to stimulate defaecation urgency in some patients with FI (140). However, regular consumption of coffee was not associated with prevalent or incident FI in elderly men and women (140). There remains no study on caffeine restriction to improve FI.

Chronic consumption of alcohol has been associated with accelerated gastric emptying and small bowel transit in animal studies whereas a single large dose has an inhibitory effect (125, 141, 142). Excessive alcohol consumption leads to damage to the duodenal and upper jejunal mucosa and inhibition of sodium and water absorption. There is an increased prevalence of bacterial overgrowth in the small intestine of alcoholics, which may contribute to loose stools, diarrhoea, incontinence, and other GI symptoms (125). More younger versus older adults reported that alcohol worsened their FI but the amount of alcohol consumed associated with this effect was not known (135). No studies were found in which alcohol restriction was reported to reduce FI.

In addition to modifying dietary intake, individuals with FI change their eating patterns, eating schedules, and food preparation/recipes to reduce their symptoms (134, 136). They skip meals before going out into public, eat small amounts or avoid eating while at a social event, and eat at home rather than at restaurants. They may eat at the same times of day in an attempt to achieve regular bowel movement pattern or avoid going into public after they have eaten a desired food that worsens FI symptoms. Recipes are adjusted to reduce spiciness or omit some spices altogether, and baked rather than fried foods are preferred.

Concerns about dietary manipulation and skipping meals are nutritional deficiencies and subsequent poor health, especially in those at higher risk for malnutrition. Bliss *et al.* (38), found few significant differences in the nutritional composition of a usual western diet of those with FI compared to the usual diets of age and sex matched controls with normal bowel function. Those with FI had a greater intake of carbohydrates, manganese, and vitamin B1.

3.2. Prebiotics, Probiotics, Synbiotics, and FODMAP Diets

Prebiotics, probiotics, or synbiotics are used as complementary or alternative therapies for gastrointestinal problems. A prebiotic is a general term describing a food ingredient that is not digested in the human small intestine and thus stimulates the growth and/or activity of one or more types of bacteria in the colon that have the potential to improve the health of the host. Fructo-oligosaccharides and galacto-oligosaccharides are popular prebiotics. Dietary fibre can also be considered a prebiotic. A probiotic is a food supplement containing live non-pathogenic and non-toxic microbes that have the potential to affect the balance of colonic microbes and thereby improve the host's health. Bifidobacteria and lactobaccilli are the most commonly used probiotics, and yogurt which has active microbial cultures can be considered a probiotic. A synbiotic refers to a product that combines a prebiotic and probiotic. FODMAPs are foods that include different types of short-chain carbohydrates including fructans (fructo-oligosaccharides) and galacto- oligosaccharides, polyols (sugar alcohols) of which a common one in the diet is sorbitol, fructose and lactose (143). FODMAPs can be can be poorly digested or absorbed by certain people & can increase volume of liquid and gas in the intestines.

3.3. Dietary Fibre

Dietary fibre is the non-starch, polysaccharide component of plant cell walls and lignin that resists digestion by human intestinal enzymes (144). Dietary fibres have various physiological effects depending on their structure and properties, amount ingested, extent of their degradation and fermentation in the colon, and health of

colonic cells. Dietary fibre that is not completely degraded and fermented by colonic bacteria increases bulk, water-holding, and gel-formation in faeces while those that are metabolized to short chain fatty acids (SCFAs) promote water absorption and serve as an energy substrate for colon cells (37, 145). Thus supplementation with dietary fibre might lessen FI by increasing rectal distension and sensory awareness of the need to defecate, promoting more complete elimination of faeces and leaving less in the rectum to leak, or normalizing the consistency and reducing the liquidity of faeces making it easier to control (37, 146).

Low dietary fibre intake from food has been associated with FI in women. In a study about weight loss for reducing urinary incontinence, women with urinary and FI were 2.5 times as likely to have a low dietary fibre intake (≤ 10 g/d) than those without FI (147). Randomized controlled clinical trials (RCTs) (37, 146, 148), provide **Level 1 evidence** that a supplement of moderately fermentable, soluble dietary fibre (i.e., psyllium) significantly reduced the frequency and severity of FI in community-living men and women (Table 15-2). Significant reductions in FI resulted from lower (3.4 g/d) (148), and higher doses (16 g total fibre/d) (37), of psyllium. Stool analyses showing the formation of a gel in subjects' stools during psyllium supplementation are consistent with other observations of psyllium's effects (149), suggesting this as a mechanism in FI (37).

Dietary fibre has also been used in combination with other therapies and as part of staged management. Results of these studies are mixed. In one non-experimental study, faecal soiling resolved in 24% of patients after psyllium supplementation alone, in 48% who added transanal irrigation to psyllium supplementation, and in 2% in those who added cholestyramine to psyllium supplementation and transanal irrigation (150). An RCT investigated two combination treatments for AI; one treatment included loperamide, a diet advice sheet describing a high vs. low fibre diet, and a low-dose psyllium fibre supplement, and the other treatment used loperamide and a placebo supplement of a food thickener and some locust bean gum fibre (151). There was no difference found between the groups, suggesting no additional reduction of AI from a dietary fibre supplement and diet advice sheet over antimotility medication. In a staged intervention with a non-experimental design, 46% of women taking a supplement of methylcellulose alone (n=19) or with the antimotility medication loperamide (n=40) resolved their FI compared to no one in the control group who declined study treatment (n=10) (152).

Adverse gastrointestinal (GI) symptoms are a potential problem mediating tolerance of dietary fibre. In community living adults with FI, supplementation with 16 g/d of psyllium, gum arabic, or carboxy-methyl-cellulose fibre was associated with minimal adverse symptoms (153). A greater feeling of fullness in the psyllium group was the only symptom that differed compared to the placebo group. However, subjects with greater symptom severity were more likely to request a reduction in fibre amount or discontinue supplementation (153). Lesser amounts of psyllium supplementation have few symptoms (146).

New Evidence about Diet, Fluids, and Dietary Fibre

There were five new studies about diet modifications, dietary fibre, and fluid intake and FI. One study compared the types of foods ingested by women with FI and a national sample of women in Japan (154). A cohort study examined the association of long-term dietary fibre intake and fecal incontinence in female nurses (155). There was a retrospective chart review reporting effects of eating a diet low in fermentable oligo- di- and mono-saccharides and polyols (FODMAP) on FI (156). One study tested an intervention that was comprised of methylcellulose fiber and dietary advice (157). A retrospective study examined the relationship between fluid intake and bowel symptoms in women with and without FI (158).

In an observational study, data about the dietary intake of 100 women with FI symptoms were compared to that of 3,332 women from Tokyo who had completed a national health and nutrition survey (154). The dietary intake of the samples was calculated differently. Women with FI completed a one-week food diary from which a one-day mean of foods consumed was calculated. For woman completing the national survey, a one-day mean of foods consumed during one month was calculated. The age of both samples ranged from 20 to 70^{+} years but the percentages in the age groups differed between the samples; therefore, a weighted mean of diet intake per day was calculated for every year over 20 years based on the national survey data.

Differences in food intake were observed. There were significantly higher intakes of wheat products, fruits, and snacks containing dietary fibre and a significantly lower intake of rice by women with FI compared to those from Tokyo completing the national survey. Study limitations include the limited types of food in the analysis, lack of adjustment of diet intake for body weight, and differences in calculating dietary intake between the groups. Generalizations to other populations are limited by potential national/cultural and regional differences in diets and exclusion of men.

In a longitudinal cohort study, FI incidence and dietary fibre intake of 58,330 older female nurses (average age = 73 years) was obtained using a mailed survey and a food frequency questionnaire, respectively (155). Dietary fibre intake was reported at 7 time points at two to four year intervals from 1984-2006. Development of FI was surveyed three times at two-year intervals from 2008-2012. There were 7,056 incident cases of FI (12%) overall. A multivariate analysis adjusting for several FI risk factors such as BMI, parity, smoking, etc. showed that women with dietary fibre intake in the highest quintile (25 g/d) had a significant decrease in risk of FI of 18% compared that in the lowest quintile (13.5 g/d) (HR=0.82, 95% CI (0.76-0.89)). The decrease in risk (31%) was greatest for liquid FI (HR=0.69, 95% CI (0.62-0.75). Risk was not associated with fibre source (e.g., fresh fruit, vegetables, cereal, whole grains, etc.).

The effectiveness of a low a low fermentable oligo- di- and mono-saccharides and polyols (FODMAP) diet in reducing FI was examined in a retrospective review of health records of 65 patients (87% female, mean (sd) age = 62 (14) years) who had some loose/liquid stools (156). Occurrence of FI was self-reported. The low FODAP diet was associated with a reduction in FI symptoms in 64.6% (42/65) of patients; 88% of patients reported a reduction of 50% in FI episodes and 35.7% had no FI episodes while on the diet. Limitations of the study are the absence of a randomized control group and statistical testing of differences, use of non-validated tools for evaluating FI, and lack of control of concurrent therapies such as anti-diarrhoeal medications, antibiotics, and physiotherapy.

Ribas & Munoz-Duyos (157), studied the effects of a supplement of methylcellulose fibre (500 mg every 8 hrs for 6 weeks) and dietary advice (foods recommended to eat and foods to avoid) on several AI outcomes in a one-group study using a non-experimental design. Of the 83 patients enrolled, 61 (73%) completed the study. Subjects completed the Fecal Incontinence Quality of Life scale (FIQL), a three-week bowel diary from which St. Mark's AI score was calculated, stool form using the Bristol Stool Form scale, and defaecation deferment time (using a four-point scale) before and at the end of six weeks of fibre supplementation. Of those who completed the study, 11 (18%) did not report any AI during the baseline period,

explaining they did not leave their house. After the methlycellulose and dietary advice period, St. Mark's score significantly decreased (mean 8.6 (6) (sd)) compared to baseline (14 (4.4)). There was no significant difference among the categories of defaecation deferment time. Although 33% subjects reported improvement of overall deferment time, no statistical testing was done. The Bristol Stool Form score improved in 38/61 (62%) of subjects. Approximately half (n=37) of the subjects completed the FIQL and there were significant improvements in lifestyle and coping/behaviour subscales. As secondary outcomes, the number of urge AI episodes/week but not passive AI episodes/week significantly decreased after treatment compared to baseline. Study limitations are absence of a randomized control group, inclusion of subjects without AI during the baseline period, and a lack of monitoring if subjects consumed the fibre supplement as they were required to buy the methylcellulose on their own.

In a retrospective study, records of fluid intake and bowel symptoms of 924 women presenting to a urogynaecology clinic for evaluation of pelvic floor disorders were analyzed. Forty-one percent (379), of the women -reported that they had FI. Data on bowel symptoms were collected using the Colorectal-Anal Distress Inventory short form (CRADI-8). Data about fluid intake was collected using the Questionnaire- based Voiding Diary, which is based on food frequency questionnaires. A greater percentage of women with FI consumed lesser amounts of water (p=.009) and greater amounts of carbonated beverage than those without FI (p=.009). Median water intake of women with FI = 1065 mL (IQR, 518–1774 mL) and without FI = 1420 mL (IQR, 710–2129 mL). Median carbonate beverage intake of women with FI = 0 mL (IQR, 0–710 mL) and without FI = 0 mL (IQR, 0–311 mL). There were no significant differences in caffeine, alcohol, juice, or milk intake between those with and without FI. Limitations of the study are the inability to assess a causal relationship between FI and fluid intake.

Summary of Diet, Fluids, and Dietary Fibre

- Patients consider diet a factor affecting the severity of their FI symptoms (Level of Evidence 3).
- Many patients can identify foods and fluids that worsen the severity of their faecal incontinence and they modify dietary intake, cooking practices, and eating patterns as a self-management strategy (Level of Evidence 3).
- Consumption of higher amounts of dietary fibre, i.e., near the recommended daily amount, is associated with lesser severity of FI (Level of Evidence 2).
- Supplementation with psyllium dietary fibre appears to be a safe and tolerable intervention that can reduce the frequency and severity FI (Level of Evidence = 1).
- The severity of adverse symptoms of supplementation with some dietary fibres up to 16 g total fibre/day are small on average but tolerance may be more individual (Level of Evidence 1).
- Gel formation in faeces may be a mechanism by which psyllium dietary fibre exerts its effect in FI (Level of Evidence 1).
- A supplement of a low amount of psyllium fibre (3.4 g/day) was as effective as a low dose of loperamide (2 mg/day) in reducing FI (Level of Evidence 1), but may not lower FI more when taken in addition to loperamide (Level of Evidence 2).
- Studies of effectiveness of supplementation with other dietary fibres such as methylcellulose have differing results, possibly due to differences in the composition and properties of the fibres, amounts given, and methods and quality of studies (Level of Evidence 2/3).
- Use of diets low in fermentable oligo- di- and monosaccharides and polyols may reduce AI or urgency in some patients with liquid stools (Level of Evidence 3).
- Dietary fibre as an adjuvant to trans-anal irrigation can reduce FI (Level of Evidence 3).
- Regular consumption of coffee is not associated with FI in older men and women (238) (Level of Evidence 3).
- Alcohol intake may worsen faecal incontinence symptoms in some individuals, more so in younger patients (Level of Evidence 3).

Recommendations for Practice Related to Diet, Fluids, and Dietary Fibre

- Patients should identify and reduce/eliminate intake of foods and fluids associated with worse FI symptoms as a self-management strategy for reducing symptom severity (Grade of Recommendation C).
- Modifications of eating patterns and food preparation have been reported as a useful, temporary self-management strategies. Dietarymodifications should be evaluated by clinicians for their nutritional impact and effectiveness (Grade of Recommendation C).
- Consuming the recommended daily amount of dietary fibre from dietary supplements and/or foods should be encouraged to reduce FI (Grade of Recommendation C).
- Psyllium dietary fibre supplementation is recommended for the management of FI. Starting with a lower fibre amount (3.4 g/d) then increasing to a higher amount as needed is suggested (Grade of Recommendation A).
- Psyllium dietary fibre should be recommended as part of a combination therapy involving rectal irrigation (Grade of Recommendation B).
- Supplementation with stool bulking dietary fibre such as methycellulose at small amounts or using a low FODAP diet for patients with liquid stools may be tried in managing FI (Grade of Recommendation C).

Recommendations for Research on Diet, Fluids, and Dietary Fibre

- Further studies on the effect of dietary fibre and other diet modifications on FI are required to build a greater body of evidence.
- Determine the optimal type and amount of dietary fibres to reduce FI since dietary fibres differ in their chemical composition and properties.
- Evaluate the effect of modifying usual diet and eating patterns as a management strategy for FI.
- Determine the extent to which dietary/fibre interventions can augment other behavioural and pharmacological interventions and the optimal sequence of initiating and changing interventions.
- Controlled studies on the effectiveness of low FODMAP diets.

Table 15-2. Intervention Studies Using Dietary Fibre for Managing FI

Study and Country	Design and Sample	Intervention and Outcome Measures	Findings	Strengths	Limitations
Ribas & Munoz-Duyos 2018 (157) Spain	One-group pilot study 61 of 83 patients with FI and/or faecal urgency associated with loose stools or diarrhoea completed the study	The intervention was dietary advice and intake of methylcellulose 500 mg every 8 h for 6 weeks. All assessments were carried out at baseline and 6 weeks after the intervention. Data collection tools were the Bristol Stool Scale, a 3-week bowel diary, the St. Mark's score, the FI Quality of Life scale (FIQL) and defaecation deferment time (using a four-point scale).	Bowel diaries showed a statistically significant reduction in the number of bowel movements, urge episodes, urge FI episodes and soiling per week. The St Mark's score improved after methylcellulose (mean 8.6 (6) (sd) compared to baseline (14 (4.4)). Bristol Stool Form score improved in 38/61 (62%) of subjects FIQL significantly improved in the 2 subscales of lifestyle, coping/behaviour but only half of subjects provided these data.	Independent pharmacists dispensed the treatment	Absence of a randomized control group, Inclusion of subjects without FI during the baseline period and lack of monitoring if subjects actually consumed the fibre supplement. Inability to distinguish faecal from AI as an outcome. Use of data collection tools without validity and reliability, and some data were not reported by all subjects.
Markland et al. 2015 (148) USA	Double-blind, randomised, cross-over design 80 veterans with FI or liquid or solid stool at least weekly for 3 months	Random assignment to loperamide (2 mg/day) first then a supplement of psyllium fibre (3.4 g/day) or psyllium first then loperamide for 4 weeks each with a 2 week washout and a 2 week non-equivalent baseline period FI frequency was reported daily on a diary for 7 days during each period	No significant difference in FI between treatment groups. Within each treatment group, FI frequency significantly decreased from baseline during the first treatment period for both treatments, but did not significantly change after the crossover to the other treatment.	Double-blind, and used a longitudinal analysis	Use of a stool diary untested for validity and reliability, potential error due to subjects needing to prepare part of the supplement, possible unmeasured cross-over effects, non-equivalent baseline period, and attrition during the washout.
Bliss et al. 2014 (37) USA	Single-blind, randomised, placebo controlled, parallel groups 206 community-living adults with at least 2 episodes of FI of loose/liquid stools in 2 weeks	One of 3 dietary fibre supplements, carboxy-methylcellulose, psyllium, or gum arabic, (16 g total fibre/day) or placebo for 32 days each FI frequency was reported daily on a diary for 14 days at the end of each period	Both the intent-to-treat and per protocol analyses showed that FI frequency significantly decreased after supplementation with psyllium fibre compared to placebo. The percent change of FI in the psyllium group was 51%	Blinding of subjects, pre-prepared supplements with a known amount of fibre, monitoring dietary intake with a food diary and adherence with appearance of a dye in faeces, and a longitudinal analysis that adjusted for baseline values	Use of a diary and FI severity index whose parts had not all been tested for validity and reliability; not double blinded; lab measures only on a subsample

Study and Country	Design and Sample	Intervention and Outcome Measures	Findings	Strengths	Limitations
van der Hagen et al. 2011 (150) Netherlands	One non-experimental study 50 consecutive patients (41 men) who had faecal soiling and normal sphincter function were recruited	For two months, patients consumed 3.25 g psyllium fibre per day and a fibre rich diet. Patients with persistent faecal soiling added rectal irrigation using 500 ml of tap water daily for two months. Patients whose faecal soiling continued added 4 g of cholestyramine daily.	Faecal soiling resolved completely in most patients. In some, soiling resolved after psyllium supplementation alone.	Abnormalities were excluded prior to the study (such as rectal tumours, prolapses, etc.) A conservative treatment algorithm	Absence of a randomized control group, lack of monitoring if subjects actually consumed the fibre rich diet
Sze & Hobbs 2009 (152) USA	Staged intervention with a non-experimental design 69 women with FI	If the incontinence persisted after taking the maximum dose of methylcellulose for two weeks, loperamide, one capsule twice a day was added, which was increased to two capsules three times a day as needed. If both fecal urgency and incontinence resolved, the therapy was continued for a three□month treatment period.	59 subjects were treated with methylcellulose, (1-2 tsp/day) 40 also required loperamide (1-2 capsules/day). 10 women who declined study treatment served as controls. 46% Women treated with methylcellulose and/or loperamide resolved FI vs 0% in the control group.	The use of a control group Regulation of fluid intake	Nonrandomized study, possible changes in diet
Lauti et al. 2008 (151) Australia	Double-blind, randomised, cross-over design using blocks of 10 63 adults with incontinence of mucus, or liquid or formed stools. started study, and 47 subjects (91% female) completed the study Treatment A n= 31 and treatment B n= 32 49 crossed-over Treatment A = 27 and B = 22	Treatment A: self-titrated dose of loperamide (starting at 2 mg twice/day), 1 tsp of a food thickener containing starch, maltodextrin, and locust bean gum twice/day, and a diet advice sheet about a low-fibre residue diet. Treatment B: same self-titrated dose of loperamide, 1 tsp of psyllium fibre in water twice/day, and a diet advice sheet about a high and low fiber residue diet. Treatments were for 6 weeks each Primary measure was self-reported AI for the last 4 weeks of each treatment using the FISI. Secondary clinical measures were FIQL and SF-36, a measure of general health.	67% of treatment A fibre and 73% of treatment B fibre were taken. The mean difference in the FISI score between treatments was not statistically significant.	A power analysis was used for sample size calculation. Independent pharmacists dispensed the treatments. The interval for data collection during both treatments was the same. 75% of subjects completed the study protocol and reasons for attrition were reported.	Possible carry-over effects between treatments; Period and treatment effects were not assessed; Attrition resulted in low statistical power; Possible confounding from fibre in the placebo; Subjects mixed their own fibre supplements and intake was not controlled; Doses of the anti-motility medication and suppositories for constipation were uncontrolled.

Study and Country	Design and Sample	Intervention and Outcome Measures	Findings	Strengths	Limitations
Bliss et al. 2001 (159) USA	Randomised, parallel-group, placebo-controlled, single blind trial Subjects, statistician, lab technician, and subjects' clinicians were blinded. 39 adults (79% female) with FI of loose or liquid stool at least weekly. A block scheme resulted in equal numbers (n=13) in each group. Groups' characteristics were comparable at baseline.	Intervention: soluble dietary fibre supplements mixed into fruit juices: 7.1 g of psyllium/day, 21.5 g of gum arabic/day, or placebo (0.2 g pectin/day). Supplements taken for 31 days in addition to usual diet FI reported daily on a stool diary for 8 days in baseline and supplement periods Primary measure was the proportion of incontinent stools. Secondary clinical measures were stool consistency and frequency, and flatulence reported daily al Secondary lab measures were stool wet and dry weights, % of water, pH, total fibre content, water-holding capacity of stool solids, and faecal short chain fatty acids.	Proportion of incontinent stools in psyllium or gum arabic groups was significantly lower than placebo. Percent of loose or liquid stools in psyllium and gum arabic groups was significantly lower than placebo. The water-holding capacity of stool solids was highest for the psyllium group. No significant differences among the groups in other measures.	Sample size was based on a power analysis. Data collection period was equal during baseline and supplement periods. Control of concomitant treatments. Supplements were premixed and ready-to-take. 95% of subjects completed the study and reasons for attrition were reported.	Details of the procedures for random assignment and allocation concealment were not provided. Although adequately powered, small group sizes reduce generalizability of findings.

4. COMPLEMENTARY AND ALTERNATIVE THERAPIES

Complementary and alternative therapies are those that are not part of standard, conventional medical therapies. Complementary therapies are performed alongside conventional medicine to help patients feel better, improve quality of life, and cope with symptoms while alternative therapies are used instead of conventional medicine (160). There are a numerous complementary and alternative therapies including acupuncture, aromatherapy, herbal medicine, imagery, relaxation, and yoga. These therapies are sometimes administered along with prebiotics or probiotics for managing FI.

A survey of patients using a biofeedback service revealed that a variety of complementary or alternative therapies were used for bowel problems (161).The most common therapies for bowel problems were the use of herbal medicines or acidophilus/ probiotics. Other therapies included acupuncture, massage, homeopathy, kinesiology, relaxation therapy, reflexology, and traditional Chinese medicine. Of the 93 survey respondents, 31% were being treated for FI, but use of complementary therapies for FI was not specified. Users considered complementary or alternative therapies safe, natural, and providing them with some control over their health feeling that conventional treatment had failed them or was unavailable.

Case reports of complementary or alternative therapies reveal mixed results. For example, use of a herbal preparation considered antimicrobial and a probiotic followed by different herbal mixture and a bioceutical product was reported to cure FI in a woman with multiple sclerosis (162). In another case report of a woman with multiple sclerosis, trigger-point acupuncture for pain triggered the development of FI (163).

New Evidence about Complementary and Alternative Therapies

Acupuncture is a form of traditional Chinese medicine that aims to strengthen the relationship and regain a balance of power between energies in the body through the application of needles, seeds, beads, suckers etc. (164). In one study, 18 adults with FI (2 men, 16 women; age range = 28-76 years) underwent acupuncture using 22 traditional acupuncture needles in 10 weekly sessions. Patients reported the severity of FI using a visual analogue scale (VAS) and completed the FIQL scale for assessing FI related quality of before and after acupuncture treatment. After acupuncture, FI severity improved in all patients and all domains of the FIQL scores ($p<.05$) improved. Seven of 18 patients reported they no longer had FI after acupuncture. Study limitations were the absence of a control group and random assignment, lack of a valid and reliable measure of FI severity, and reporting data about FI by individual patients without any summary values or analyses.

Summary of Complementary or Alternative Therapies

- Patients may use complementary or alternative therapies to manage FI (Level of Evidence 3), Studies of their effectiveness are few and lacking in quality

Recommendations for Practice Related to Complementary or Alternative Therapies

- Clinicians should inquire about use of complementary or alternative therapies and evaluate their safety and effects (Grade of Recommendation 3).
- Complementary or alternative therapies are not recommended for the management of FI (Grade of Recommendation 4)

Recommendations for Research on Complementary/ Alternative Therapies

- Randomized clinical trials, or at minimum pragmatic clinical trials, of effects of complementary or alternative therapies for reducing FI are required

5. WEIGHT LOSS AND PHYSICAL ACTIVITY

Of the lifestyle modifications for FI, weight loss for obesity has been a frequent topic of investigation.Many of these studies are in women only (Table 15-3). Weight loss has been proposed as a lifestyle modification to reduce FI based on improvements in urinary incontinence after weight loss (165), but associations between obesity and FI are mixed (166-170). For example, in one study, overweight or obesity was associated with an increased risk of anal and FI in women with a BMI over 30 compared to women with a normal BMI (i.e. <25) (56). The odds ratio for obese women was 2.5 for loose stool incontinence, 1.3 for solid stool incontinence and 1.8 for flatus incontinence. Conflicting results were reported in two studies of U.S. women. (171, 172). Being overweight (BMI 25-29) or obese (BMI >29 or 30) was not predictive of FI in a study of identical twin sisters (171) or in a large population-based survey of women (172). When examining the severity of FI in both men and women, being overweight was marginally associated with leaking a greater amount of faeces (OR 1.4) (95% CI 1.002-2) (173). Risk factors for FI from anorectal manometry testing in women who were obese were higher baseline anal resting tone and squeeze pressures compared to normal or overweight women, suggesting a lower threshold to leakage with pressure increases in one study (174).

Results from past studies examining decreases in FI after weight loss resulting from diet programmes or bariatric surgery have been inconclusive. In two secondary subgroup analyses of obese women with dual (faecal and urinary) incontinence on a non-surgical dietary weight loss programme, AI was not significantly different from that of the control group receiving education (147, 165). In one subgroup analysis of 80 women (147), there was no significant difference in the FI Severity Index (FISI) or FI consistency between the weight loss programme and control groups. The 6-month intervention focusing on dietary intake was not correlated with a decrease in AI. On the other hand, women who showed improvement in AI had a lower weight at baseline (89 kg) than those with no improvement in AI or no AI (97 kg).

A subgroup analysis of of 338 obese women with dual incontinence showed an overall decrease in AI in 13% of women when combining data from 6, 12, and 18 months of the study, but the change was not significantly different from that of the control group (165). In comparing women with and without improvement of AI (using the FISI), those who showed a decrease in AI had a lower weight and BMI at baseline. A decrease in lower urinary tract symptoms (LUTS) was associated with lesser AI severity in all women. Limitations of this study included use of an untested modification of the FISI score and the lack of adjustment for baseline AI severity in the analysis.

Studies of decreases in FI after weight loss following bariatric surgery for morbid obesity have had conflicting results with some studies showing increases in FI ; study comparisons are confounded by different outcome measures (i.e., AI versus FI) (168, 175, 176).

There are few studies about the relationship of exercise or physical activity and anal/ FI or if increasing activity lessens the risk or severity of these problems. Available studies of the association of exercise and anal or FI show mixed results. In a cross-sectional study of more than 60,000 middle to older aged female nurses, the odds of developing FI increased with decreasing physical activity (56). An internet survey of 311 female triathletes showed that 28% reported having AI (177). A quasi-experimental pilot study published in abstract form reported that a general exercise program improved symptoms of AI measured by the ICIQ-B questionnaire in 30 women after treatment for gynaecological cancer (178). Vitton *et al.* (179), reported that the prevalence of AI was higher (14.8%) in younger female athletes (18-40 years) who engaged in intensive sports than those who performed non-intensive sports (4.9%). For the majority, the reported incontinence was categorized as flatus incontinence. In a recent review of studies about effect of general exercise on the pelvic floor (180), no studies were found on AI in weight/power lifters and none reporting that women exercising have less AI.

New Evidence about Weight Loss and Physical Activity

There are 10 studies about obesity or weight loss and FI or AI included in this review. There was one observational study about the risk of obesity for FI in women (49), and one study examining anorectal manometry values and clinical characteristics in obese versus non-obese patients with FI . (181). A secondary analysis of data from a randomized trial of nonsurgical therapies in women with FI described baseline characteristics associated with significant treatment responses (182). There were three observational studies (183, 184), about the association of obesity and FI/AI in patients awaiting bariatric surgery. There were two observational studies (185, 186), and two systematic reviews (187, 188), about the effects of bariatric surgery and accompanying weight loss on FI/AI. Regarding physical activity and FI, there were two observational studies. One prospective cohort study analysed the association of different levels of physical activity and risk of FI in women (49). Using a retrospective cohort design, Vitton *et al.* (189), examined the associations of wearing high-heeled shoes with severity of FI and with anorectal manometry values.

In a large cohort study, the development of FI and association of body mass index (BMI) and FI at two time points two years apart was examined in 51,708 middle to older aged female nurses who were free of FI at the starting time of the analysis (49). Data were collected using a mailed questionnaire. FI was defined as ≥ 1 FI episode of liquid or solid stool in the past year in each follow-up years. Being overweight was defined as BMI = 25-29 kg/m^2 and obesity as BMI = 30$^+$ kg/m^2. There were 5,954 incident cases of FI (11.5%) and no significant association between BMI and FI. Limitations of the study were its observational design, the age of the data (2008-2012), and limiting the definition of FI to liquid and solid faeces only.

In a 1:2 case-matched study, a total of 201 obese (n=67) and non-obese (n=134) patients with AI (87% women 13% men; mean (sd) age = 61.9 (12.1) years) were evaluated using anorectal manometry and endosonography (181). Obese patients with AI had significantly better anorectal function than non-obese patients with I with regard to a longer anal canal length and higher resting pressures at the lower and upper part of the anal canal. The obese patients had higher abdominal pressures and higher anal resting pressures than the non-obese patients, which was thought to reflect a decreased threshold to leakage. With regard to the clinical characteristics, obese patients had a comparable severity of FI to that of non- obese patients. Obese patients were more likely to have liquid stools and diarrhoea-predominant inflammatory bowel syndrome (21/67 (31.3%) than non-obese patients (20/134 (14.9%); p=.0065).

A secondary analysis of baseline clinical and demographic characteristics of 296 women participating in an intervention trial for FI identified that being overweight, defined by body mass index (BMI), was associated with response to treatment (182). The parent study (107), used a 2x2 factorial design in which women with FI were randomly assigned in a 0.5:1:1:1 allocation to one of 4 groups: (1) oral placebo and an educational pamphlet, (2) placebo and biofeedback exercises assisted by anorectal manometry (ARM), (3) loperamide and an educational pamphlet, and (4) loperamide and ARM-assisted biofeedback exercises, respectively. Women with hard or liquid stools were excluded. Results showed no significant difference in FI severity, measured by changes in St. Mark's scores from baseline to 24 weeks. In the secondary analysis, treatment response was defined in 3 ways from baseline to 24 weeks: minimal clinically important difference (MID) of -5 points in St. Mark's score, ≥50% reduction in FI episodes, and combined St. Mark's MID and ≥50% reduction of FI episodes. Being overweight versus normal/underweight was a significant as a factor associated with a positive treatment response using the one outcome of St. Mark's MID (adjusted odds ratio=2.15, 95% CI 1.07–4.34). Results were unable to explain why being overweight was associated with treatment success, and authors suggested that other factors such a lower dietary fibre intake, which was 2.5 times more likely to in overweight and obese women with FI symptoms, may be influential in outcomes (84). Limitations of the study are discussed in the section of this chapter about Patient and Caregiver Education and Self-Management Support.

Two studies with case-matched designs showed that more obese patients before bariatric surgery had FI/AI than non-obese patients (183, 184). Seventy-five obese women awaiting bariatric surgery (BMI=41.7 (8.6) kg/m^2 mean (sd)) were age and parity-matched with 91 non-obese (BMI=24.9 (2.9) kg/m^2) controls (183). FI was reported in 21% of obese vs 7.7% of non-obese women, reported with the Pelvic Floor Distress Inventory/ Colo-Rectal-Anal Distress Inventory-8. (p=.01) There was no significant difference in scores for loss (FI) of well-formed or not well-formed stools between the obese BMI≥30 kg/m^2 and non-obese (<30 kg/m^2) groups (p=.818 and .539 respectively). The score for loss of gas however was significantly greater in the obese (3.1) versus non-obese group (1.9, p=.031). Study limitations were unequal group sizes and lack of adjustment for other risks of FI between groups.

In the second study, 20 men and six nulliparous women awaiting bariatric surgery (BMI = 48.8 (8.5) kg/m^2 (mean (sd)) were matched by age and sex with 26 non-obese controls (BMI = 25.1 (2.8)) (184). AI was reported using the Cleveland Clinic Florida Incontinence score. A higher percentage of obese patients (65.4%) had AI than non-obese controls (0%). Anorectal manometry (ARM) was also performed on both groups. Contraction/squeeze pressure (mean (sd)) was significantly lower in the obese group (155.6 (64.1) mmHg compared to the non-obese group (210.1 (75.9) p=.004)) but no other ARM measure was significantly different, including resting pressure. Limitations of the study were the absence of reporting the Cleveland Clinic AI scores and lack of multivariate analyses controlling for other risk factors of AI.

Two studies showed no effect of weight loss after bariatric surgery on AI. A retrospective cohort study reviewing medical records of 116 patients (83 women and 33 men, age = 47.6 (11.9) (mean (sd)) years) showed no significant difference in AI severity or prevalence before or one year after surgery (185). One of two surgeries were performed, gastric bypass or laparoscopic sleeve gastrectomy. Weight loss was significant; overall mean BMI was 43.6 (6.9) kg/m^2 preoperatively and 30.7 (6.5) kg/m^2 one year after bariatric surgery

(p=.0001). AI was reported before and after surgery using the Wexner scale. The Wexner score was 0.1 (0.6) before bariatric surgery and 0.1 (.6) one year after surgery (p= .57). The rate of AI before bariatric surgery was 5.2% (4.8% in women and 6.1% in men) and did not significantly change after surgery and weight loss. Limitations of the study include its retrospective design and not reporting the specific prevalence rate of FI postoperatively.

In a second study, using a prospective design, 86 of 117 obese patients (age=45 years (IQR 34–54 years), 84.6% women) receiving bariatric surgery (sleeve gastrectomy) were evaluated before and after surgery for AI (186). The median time of postoperative follow-up was 15 months (IQR 12.5–17.3 months). AI was defined as a Vaizey score above 4. The FIQL scale assessed quality of life.

There was no significant change in the prevalence of AI preoperatively (12.8%) vs postoperatively (24.4%), p = 0.06). The median Vaizey score for AI was 4 (IQR 4–4)) before and after surgery (p = 0.1). No patient developed new AI, but 10 patients had worsening of AI symptoms postoperatively. Patients lost weight postoperatively. The median BMI was 41.2 kg/m2 (IQR 38.3–44.5 kg/m2) at baseline (n = 117) and 31.6 kg/m2 (IQR 27.7–32.4 kg/m2) at the end of the study (n = 98). No patient had a percent excess BMI loss (%EBMIL) < 50%, which defined success of the surgery. The prevalence of AI (AI) nearly doubled after surgery from (12.8% preoperatively to 24.4% postoperatively, p = 0.06) but was not statistically significant.

An FIQL total score was calculated and did not significantly change before and after surgery. FIQL scores for subscales of Lifestyle and Depression did not significantly improve. Coping behaviour improved postoperatively from 1.8 (1.7–2.0) to 2.0 (2.0–2.1) p< 0.0002. There were too few responses to score the Embarrassment scale. Limitations included an absence of a control or comparison group of non-surgical patients, an inability to differentiate between anal and FI as an outcome, and 26.5% of participants were lost to follow up. The FIQL scale does not have a total score, but one was calculated in this study.

Lian *et al.*(187), conducted a meta-analysis of 11 cohort studies published between 2009-2016, reporting outcomes of pelvic floor disorders in obese women before and after bariatric surgery. The total number of subjects in the 11 studies was 784 and the follow up period ranged from 6 months to 3.1 years. Pooled results of nine studies showed a significant decrease in BMI after bariatric surgery (standardized mean difference (SMD) = 1.8, 95% CI (1.3, 2.3). FI was reported using the Pelvic Floor Distress Inventory/ Colo-Rectal-Anal Distress Inventory-8 in five studies. Bariatric surgery was not associated with significant improvements in FI (SMD=0.15, 95% CI (-0.15, 0.45).

Montenegro *et al.* (188), conducted a meta-analysis of English and non-English language studies from 2007-2017 about the effect of bariatric surgery on FI. FI was analysed in nine studies and reported using the Pelvic Floor Distress Inventory/ Colo-Rectal-Anal Distress Inventory-8. The mean reduction in BMI (12.90 kg/m^2) was significant, p < 0.001 There was a 22% decrease in FI after bariatric surgery which was not statistically significant (OR=0.80, 95% CI (0.53, 1.21, p =.29). Limitations included the high heterogeneity among the studies examining FI.

In the cohort study of female nurses by Staller *et al.* (49) the risk of FI was compared among four categorical levels of physical activity determined by assigning a value for a metabolic equivalent task over a week. In an age-adjusted analysis, the there was a modest reduction (25%) in the risk of FI with increasing physical activity. In the group with the lowest level of physical activity, the hazard ratio (95% CI) for FI was 0.86 (0.80-0.93) and in the group with the lowest level of physical activity it was 0.75 (0.70-0.81).

Because wearing high heels may adversely influence musculoskeletal health, resulting in foot and ankle problems and increasing lumbar lordosis, it may also affect the activity of pelvic floor muscles. Vitton *et al.* (189), examined the severity of anal incontinence and results of 3D high resolution anorectal manometry in 338 women with anal incontinence who wore shoes with high-heels ≥3cm at least four times a week for 4 consecutive hours for at least 1 year and or no high heels. Data in the health records of the women from two years were analysed. Anal incontinence was measured using the Wexner scale. There was no significant difference in the anal incontinence score between the women who wore high-heeled shoes (mean (sd) = 12 (6)) and those who did not (11 (5)), p=NS. There was no significant difference in mean anal resting pressure, voluntary contraction, high pressure zone or sphincter defects between those who wore high-heels or not. Study limitations were the retrospective design and absence of a control group without FI.

Summary of Weight Loss and Physical Activity

- Observational studies suggest an association between FI being overweight or obese. Many studies are of women (Level of Evidence 3).
- Anorectal manometry testing and observational studies indicate there are risk factors for FI in obese or overweight individuals; most studies are of women (Level of Evidence 3).
- There is conflicting evidence about the improvement of FI symptoms after weight loss from diet programmes or after bariatric surgery for morbid obesity. Current studies of weight loss after bariatric surgery show no significant improvement in FI (Level of Evidence 3).
- FI can limit physical activity.
- Low to moderate physical activity has no association with FI (Level of Evidence 3).
- High levels of physical activity may be associated with a modest decrease in risk of FI in older women but may increase risk younger athletic women (Level of Evidence 3).
- Wearing high heels was not associated with changes in anorectal function or FI (Level of Evidence = 3).

Recommendations for Practice Related to Weight Loss and Physical Activity

- No recommendation regarding physical activity can be made for lowering FI (Grade of Recommendation C)

Recommendations for Research on Weight Loss and Physical Activity

- Additional RCTs of the effect of weight loss to reduce FI in obese men and women are needed.

Table 15-3. Studies of Weight Loss Interventions for Managing FI

Study and Country	Design and Sample	Intervention and Outcome Measures	Findings	Strengths	Limitations
Pelletier et al. 2020 (186) France	Prospective cohort/observational 86 of 117 obese patients receiving bariatric surgery completed the study. Their age = 45 years (IQR 34–54 years), and 84.6% were women.	Patients were evaluated before and after surgery (sleeve gastrectomy). The median follow-up period after surgery among the 86 patients who completed follow-up Was 15 months (IQR 12.5–17.3 months). AI was measured using the Vaizey score. The Fecal Incontinence Quality of Life scale (FIQL) assessed quality of life.	The prevalence of AI nearly doubled after surgery from (12.8% preoperatively to 24.4% postoperatively, p = 0.06) but was not statistically significant. No patient developed new AI but 10 patients had worsening of AI symptoms postop. The median Vaizey score for AI was 4 (IQR 4–4) both before and after SG (p = 0.1). The median BMI was 41.2 kg/m2 (IQR 38.3–44.5 kg/m2) at baseline (n = 117) and 31.6 kg/m2 (IQR 27.7–32.4 kg/m2) at the end of the study (n = 98). The percent excess BMI loss (%EBMIL) was 67.5 (7.4) (mean (sd). No patient had a %EBMIL < 50%, which defined success of the surgery. An FIQL total score was calculated and did not significantly change before and after surgery. FIQL scores for subscales of Lifestyle and Depression did not significantly improve. Coping behavior improved postop 1.8 from (1.7–2.0) to 2.0 (2.0–2.1) p< 0.0002. There were too few responses to score the Embarrassment scale.	Median length of followup was adequate. Preoperative AI was measured and compared to postoperative AI.	No control (or comparison group), i.e., patients without surgery. Sample attrition was 26.5% and some measures were of small numbers of participants. Inability to differentiate between anal and FI as an outcome FIQL does not have a total score but one was calculated.

Study and Country	Design and Sample	Intervention and Outcome Measures	Findings	Strengths	Limitations
Ait Said et al. 2017 (185) USA	Retrospective cohort/observational design Medical records of 116 obese patients who underwent bariatric surgery between 2013-2014 were analysed. Patients were 83 women and 33 men. Average age of sample = 47.6 (11.9) years.	One of two surgeries was completed on patients: gastric bypass or laparoscopic sleeve gastrectomy. All participants had completed 2 questionnaires about urinary incontinence (UI) and 2 about AI the day before bariatric surgery and 1 year postoperatively. AI was reported using the Wexner score.	Preoperatively, the rate of AI in the sample was 5.2%. BMI after bariatric surgery decreased from 43.9 kg/m² to 30.7 kg/m² ($p<0.0001$). The Wexner score was 0.1 (.6) (mean (sd)) before and after bariatric surgery ($p=.5660$). There was no significant change in AI prevalence or Wexner score after weight loss after bariatric surgery.	One year followup; sample had both men and women Used validated data collection tools	Retrospective design; Prevalence values of AI after bariatric surgery was not reported; Convenience sample; Unable to differentiate between FI and AI with flatus
Scozzari et al. 2013 (168) USA	Observational 32 consecutive obese women completed questionnaires and had anorectal manometry measured before and after bariatric surgery. 71 age-matched healthy non-obese women with the same inclusion criteria completed the same questionnaires whose scores were used as a control in a multivariate analysis.	The bariatric procedure was laparoscopic Roux-en-Y gastric bypass in 18 cases, laparoscopic vertical banded gastroplasty in ten, laparoscopic gastric banding in two, and laparoscopic sleeve gastrectomy in two. The questionnaires used were the Pelvic Floor Distress Inventory Short Form 20 (PFDI-20) and the Pelvic Floor Impact Questionnaire—Short Form 7 (PFIQ-7). The selected PFDI-20 and PFIQ-7 cut-off scores were 18.2 and 2.4, respectively, AI was reported using the Wexner score before and after surgery.	Median PFDI-20 total score did not show a significant change from preop 24.2 to postop 26.6, (p=ns (not statistically significant)) in obese patients. Although median total score of PFIQ-7 in obese women showed a significant improvement in the (from 4.8 to 0.0, p= 0.044) as did their urinary score, the colorecto-anal scores did not change significantly. Mean Incontinence Wexner Score was 1.1 preop and 1.0 post-op (p=ns). AI increased from 28.1 % before surgery to 40.6 % after surgery but was not not significant. There was an increase in the rate of flatus AI from 19% before surgery to 37.5 % after surgery (p=ns).	Used validated data collection tools	Unable to differentiate between FI and AI with flatus Women only; convenience sample; No comparison treatment
Markland et al. 2011 (165) USA	Secondary analysis of 338 overweight and obese females with urinary incontinence in an RCT of a weight loss program vs control group receiving education	The modified FI Severity Index (FISI) was administered at 6, 12, and 18 months in 338 women. Repeated measures analyses identified factors associated with improved FISI scores among women with baseline scores >0	No significant difference in FISI score/AI between control vs treatment groups Women who showed a decrease in AI had a lower weight and BMI at baseline		Untested modification of the FISI score Lack of adjusting for baseline AI severity in the analysis

Study and Country	Design and Sample	Intervention and Outcome Measures	Findings	Strengths	Limitations
Roberson et al. 2010 (176) USA	Observational survey Questionnaire was mailed to 404 adults who underwent bariatric surgery at one hospital during July 2002 to May 2006. 48% (n=193) of questionnaires were completed and returned of which 33 were from men. Time of followup was >700 days after surgery for both men and women.	Gastric bypass or gastric banding surgery was performed. 83% of women and 75% of men underwent a gastric bypass. The severity of self-reported AI was determined after surgery only using the Vaizey score Patients were asked about perceived changes in AI after surgery using 4 categories, much worse' worse, better' and ''much better. In the analysis, the categories of ''much worse'' and ''worse'' into one category were combined, as were ''better'' and ''much better.''	AI was worse two years after gastric bypass or gastric banding surgery than before surgery despite an average 48 kg weight loss in more than half of the patients. The mean Vaizey FI score for women was 8.4 (sd= 2.8) and for men it was mean 8.5 (sd=2.5) Worsened AI was attributed to postoperative diarrhoea.	High response rate to mailed questionnaire	Vaizey score of AI was not obtained preoperatively Change in AI was determined using non-validated questions and not a bowel diary
Burgio et al. 2007 (175) USA	Prospective cohort study 101 women, aged 20-25, with a BMI of 40 or more	Women underwent laparoscopic Roux-en-Y gastric bypass AI was assessed by asking participants 2 questions: Do you have any uncontrolled anal leakage? and If yes, specify gas, liquid, solid or a combination before and at 6 and 12 months after surgery Change in AI from before the bypass surgery to 12 mo. after was analysed	Mean BMI decreased from 48.9 (7.2) mean (sd) before surgery to 35.3 (6.5) at 6 months and 30.2 (5.7) at 12 months after surgery Prevalence of FI (solid or liquid stool) decreased from 19.4% to 9.1% at 6 months and 8.6% at 12 months (p=.018)	Follow-up was for 1 year	Absence of control group and validated questionnaire of AI Unable to differentiate between FI and AI with flatus

AI refers to anal incontinence; BMI means body mass index; FI refers to faecal incontinence; IQR refers to interquartile range; ns means not statistically significant; sd means standard deviation

6. SMOKING CESSATION

Smoking cessation is considered a possible lifestyle modification to manage FI. In healthy individuals, nicotine can cause a dose-dependent, significant decrease of total colonic transit time, accelerate recto-sigmoid transit time, reduce colonic compliance, and induce propagated colonic contractions while relaxing the descending colon (190, 191). This colonic effect is associated with a sense of defaecation urgency and prompting initiation of defaecation. However, observational studies have shown no association between cigarette smoking and FI (56, 171, 192). In a longitudinal observational study of community-living elderly men and women, smoking was not predictive of prevalent or incident FI (140). No new studies of the association of smoking or effects of smoking cessation on FI were found.

Summary of Smoking Cessation

- There is no association between cigarette smoking and FI (Level of Evidence 3). There are no studies of the effects of smoking cessation on FI

7. RECOMMENDATIONS FOR PRACTICE RELATED TO SMOKING CESSATION

- No recommendation can be made for smoking cessation in the management of FI due to a lack of evidence.

Recommendations for Research on Smoking Cessation

- Studies of the effects of smoking cessation on reducing FI are required

8. BOWEL HABIT MANAGEMENT, TRANS-ANAL IRRIGATION, AND BOWEL TRAINING FOR URGENCY

8.1. Bowel Habit Management

Conservative management for FI includes advice for attempting to establish a regular pattern of bowel elimination, and most bowel management programmes typically involve patient teaching, modifying diet/fibre and fluid intake, encouragement for adhering to a meal-time and defaecation routine, and physical activity (193-195); toileting programmes, usually for those in long-term care settings, may be added. Because peristaltic contractions of the colon that are associated with defaecation increase in frequency following awakening from sleep and meals (196, 197), the period after breakfast is considered the best time for attempting scheduled defaecation. Bowel management programmes with or without or a toileting component has been tested for their effectiveness for FI mainly in adults with neurogenic FI or in those in rehabilitation centres or long-term care institutions (nursing homes) (195). Managing FI in community-living adults with normal cognitive function through bowel habit training is understudied.

8.2. Rectal Emptying and Trans-Anal Irrigation

Emptying the rectum of faeces in between bowel movements can be part of a bowel management programme or a strategy for reducing FI. The aim is to ensure that the rectum remains empty most of the time reducing the chance of faecal leakage. Trans-anal (retrograde) irrigation systems, small enemas, suppositories, laxatives. Digital rectal stimulation and manual evacuation are techniques used to empty the rectum. Trans-anal irrigation has been studied the most and is often recommended for those with passive FI, incomplete evacuation of the rectum, and neurogenic FI (spinal cord damage, spina bifida, multiple sclerosis, stroke etc.) but it is also used by patients with FI due to other causes. The development of small irrigation systems and addition of pumps for instilling the irrigation fluid has increased the convenience of trans-anal irrigation. A typical procedure is that the patient sits on the toilet and instills water into the rectum through the anus using one of the systems, after which they defaecate or expel the fluid into the toilet.

Several observational and quasi-experimental studies, most with small sample sizes, have shown that trans-anal irrigation can reduce the number of FI episodes in about 40-60% of users, decrease the total number of daily or nightly defaecations in some cases, and improve quality of life (150, 198-200). Patients perform trans-anal irrigation daily or less than daily. Trans-anal irrigation has been used in combination with dietary fibre supplementation (150). Adverse symptoms or reasons for discontinuation include minor rectal bleeding, transient abdominal pain after irrigation, time required for the procedures, or difficulties with the procedure (150, 198-200). Group sessions for teaching and supporting patients using transanal irrigation were a cost-effective means to providing psychosocial support and improving patients' skills in the procedure.

8.3. Bowel Training for Urgency

Sensing an urge to defaecate is part of the normal process of defaecation, but some patients experience an overly strong sensation. Bowel training programmes aim to manage the response to this urge and prolong the time to defaecate while maintaining continence. However, in an RCT that compared patients who received education, including urgency resistance techniques and dietary advice, to patients who received the same education plus anal sphincter exercises with or without home or clinic biofeedback, there was no significant difference in outcomes (118).

New Evidence about Bowel Habit Management, Trans-Anal Irrigation, and Bowel Training for Urgency

One clinical study focused on bowel management (201), and three clinical studies (202-204), focused on trans-anal irrigation for FI were identified and analysed in this review. One study about trans-anal irrigation described reductions in FI after TAI was used over time (202), one study examined predictive factors for TAI adherence (203), and one study described patient preferences regarding potential outcomes of trans-anal irrigation and standard bowel management (204). Regarding bowel training, there was one expert consensus paper about bowel training to lessen urgency (205) , and one quasi-experimental study reporting that dietary fibre supplementation and diet advice decreased defaecation urgency (157).

The effectiveness of a combination bowel management intervention that offered education and skills training to perform self-management strategies for urinary incontinence (the primary outcome) and bowel incontinence for women aged 50+ years was investigated by Brown *et al.* (201). The intervention was named "Mind Over Matter; Healthy Bowels, Healthy Bladder" and was investigated using a randomized controlled design with a wait-list control group. The bowel management part of the intervention addressed pelvic floor muscle exercises (relaxation, contraction, endurance, and coordination components), dietary changes for optimization of stool consistency, and information about defaecatory position over three

sessions of two hours each. It was facilitated by a community member (neither an investigator nor a clinician) who received a two-day training session.

Of the 121 women who participated, 60% (n=73) had both urinary and bowel incontinence, and 1% had only FI; 95% completed the 4-month self-assessment of incontinence (201). More women in the treatment group (55%) than in the control group (27%) reported that their bowel incontinence improved on a modified Patient Global Impression of Improvement tool (p<.005). However, differences between the treatment and control groups in the colorectal subscale of the Pelvic Floor Distress Inventory Short Form-20 were not statistically significant (mean (SD) reduction 6.12 (15.72) vs 0.92 (14.33) points, p=0.07). The quality of life and self-efficacy scores of the treated group improved statistically significantly more than the control group. Limitations of the study were inadequate power for outcomes of FI, a non-concurrent control/comparison group, lack of monitoring fidelity of the intervention, and use of only self-report measures. The homogenous, motivated sample limits generalizability of the findings.

In a prospective cohort study, AI of patients with anal/FI and/or constipation who failed conservative therapy was examined before (baseline) and after 12 months of using trans-anal irrigation (TAI) (202). Patients were instructed in the use the trans-anal irrigation (TAI) using a catheter system with a cone shaped tip and irrigation fluid driven by gravity (Coloplast irrigation bag/Colotip®, Coloplast A/S, Humlebæk, Denmark). Of the 507 patients (83% female, median age = 56 (range 19–86) years) receiving TAI at study start, 216 (43%) patients were using it at the one year follow up. Among those who used TAI, the Wexner incontinence score decreased from 12.4 at baseline to 10.2 at the 12-month follow-up (p < 0.001) and the St. Marks incontinence score decreased from 14.9 to 12.7 (p<0.001). Quality of life and general satisfaction with bowel function, measured on an 11- point Likert-type scale developed for the study, also significantly increased over the duration of the study (202).

The main reason for not continuing TAI was an unsatisfactory outcome, which was reported by 86 (49.4%) of those who discontinued its use. Undesirable symptoms during the TAI procedure were abdominal pain (the predominant complaint) in 50 patients (23.1%), anorectal pain in 32 patients (14.9%), sweating in 28 patients (13.0%), nausea in 23 patients (10.6%), and each of the following, chills/shivering, dizziness, headache, facial flushing, and general discomfort in less than 22 (10%) of the patients.

Strengths of this study (202), were its prospective design, length of follow up, use of common scoring tools measuring bowel function and FI. Limitations included the lack of a control group and the high percentage of patients who did not use or continue TAI (>50%). The incontinence scores were unable to distinguish anal from FI, and some scoring tools lacked validity and reliability testing.

The adherence to TAI of 108 patients (87 women and 21 men; median age 55 years (range 18-83)) with constipation or FI over a four-year period was retrospectively assessed using a mailed questionnaire (203). Of these patients, 57 (53%) had FI. Patients were classified as adopters if they continued using TAI for at least one year or as non-adopters if they stopped. Overall, 48 of the 108 (43%) patients continued to use TAI at one year after training, and 70% of those performed the irrigation at least 2 to 3 times per week. The patients with FI had the best results, with 54.5% continuing the therapy. The majority of patients (41%) discontinued TAI because of its lack of efficacy. Other reasons were technical problems such as catheter expulsion, rectal balloon bursting, instilled water leakage, pain during irrigation, anal bleeding, and anal fissure in 36% of the patients. Twenty-three percent of patients thought there were too many constraints, mainly related to the time spent performing the irrigation.

There was no significant difference between the individual characteristics of the patients who discontinued TAI versus the adopters (203). The only factor predictive of discontinuation of TAI was having a first TAI training session complicated by technical problems (expulsion of catheter, fluid leakage, or no evacuation of stools during irrigation) (p = 0.02). Limitations of the study were its retrospective design, a sample with heterogeneous neurological conditions, and not presenting results about reasons for discontinuing TAI separately for those with FI.

The aim of the third study (204), was to describe the preferences of adult patients with neurogenic bowel dysfunction regarding potential outcomes or attributes of TAI and other standard approaches to bowel management. Participants (n=143) were recruited through a panel of patients in the UK who have used TAI products of one manufacturer (Coloplast; Humlebaek, Denmark). The study used a discrete choice exercise in which participants were surveyed about the amount that they were willing to pay out of pocket for a treatment benefit or attribute. The survey combined 7 device/treatment attributes and levels of benefit into 17 choice sets. Each choice question presented two TAI devices (device A or B) and a third choice that represented a standard or conventional approach to bowel management that did not include anal irrigation, which remained constant in each question. The conventional approaches were use of suppositories, laxatives, antidiarrhoeals, active monitoring of diet and fluid intake, use of incontinence pads, and use of digital evacuation to empty the bowel. Regression models were used to analyze the influence of each of the study attributes on participants' choices. Results showed that the most highly valued attributes were the reduction in risk of FI (OR =5.18) and frequency of use (OR = 4.69) (204). For example, participants were five times more likely to prefer a device that was associated with no episodes of FI compared with one that was likely to leave three episodes of FI per month and four times as likely to prefer a device that led to going to the toilet once in every 2 days rather than three times a day. Other preferences were complete avoidance of a UTI, minimizing the amount of time spent on the toilet, and using a manual pump for TAI vs an automatic one or none. Limitations were inclusion of patients who used only one manufacturer's device and exclusion of 14 patients' responses. The majority of the included patients was independent in care, limiting generalizability of results.

A consensus document about bladder and bowel training for urgency was developed by a group of clinical and research expert nurses in the International Continence Society (205). The consensus document addresses a gap of evidence to support clinicians providing this therapy. The document provides comprehensive expert advice, based on available evidence, about the steps of assessment, planning, intervention and evaluation in bowel training programmes. The document advises on how to conduct a bowel training programme to assist an individual to make lifestyle, behavioural and sometimes environmental changes to regain a controlled response to urgency and a satisfactory pattern of defaecation. A bowel training programme provides education, increases skill in progressively increasing intervals between defaecations, using urgency suppression and relaxation techniques, and performing pelvic floor muscle exercise routines, and offers positive reinforcement.

In a non-experimental pilot study by Ribas & Munoz-Duyos (157), reviewed in the previous section, about dietary fibre for FI, defaeca-

tion and FI urgency was measured in patients before and after they consumed a supplement of 500 mg of methylcellulose fibre every 8 hrs for 6 weeks and received dietary advice. Of the 61 subjects who completed the study, 50 reported urgency incontinence episodes at baseline on a bowel diary. After treatment, 37 subjects had 50% or greater reduction in defaecatory urgency and/or urge FI episodes. The number of urge FI episodes/week decreased from 3.8 (range= 0–42) at baseline to 1.7 (0–35), $p < 0.001$ after treatment.

No new studies examining the use of laxatives or suppositories to treat FI in adults with non-neurogenic FI were found.

Summary of Bowel Management, Rectal Emptying or Trans-Anal Irrigation, and Bowel Training

- A bowel management programme focused on education and skills training to perform self-management strategies including pelvic floor muscle exercises (relaxation, contraction, endurance, and coordination components), dietary changes for optimization of stool consistency, and defaecatory position reduced FI and improved quality of life and self-efficacy in women (Level of Evidence 3).
- Trans-anal irrigation reduced FI for up to one year of its use in some patients and improved quality of life (Level of Evidence 2).
- Reasons for discontinuing TAI were an unsatisfactory outcome, a variety of adverse symptoms, or difficulties with the procedure during training (Level of Evidence 2).
- Patients prefer to use a TAI system that eliminates all episodes of FI, avoids a UTI, requires less frequency of going to the toilet, lessens the amount of time spent on the toilet, and uses a manual pump (Level of Evidence 2).
- A methylcellulose fibre supplement (500 mg every 8 hrs) and dietary advice reduced the number of urge FI episodes (Level of Evidence 2).
- There is a consensus statement to guide clinicians in bowel training for managing urge FI (Level of Evidence 3).

Recommendations for Practice Related to Bowel Management, Rectal Emptying or Trans-Anal Irrigation, and Bowel Training

- Advise the patient to attempt to establish a bowel habit routine (Grade of Recommendation B/C).
- Transanal irrigation should be recommended for patients with passive FI, incomplete rectal evacuation, or FI with defaecation difficulty; it may be tried by patients with FI of other types/causes who do not respond to other initial conservative therapies and to improve self-management (Grade of Recommendation B).
- Group sessions should be considered as a way of teaching and supporting patients performing trans-anal irrigation (Grade of Recommendation C/D).
- Evacuation of the rectum using a suppository or enema in patients with passive FI or incomplete rectal evacuation is useful (Grade of Recommendation C/D).
- Bowel training for resisting defaceation urgency that includes dietary fibre supplementation and dietary advice may be useful for patients with FI associated with urgency (Grade of Recommendation C).

Recommendations for Research on Bowel Management, Rectal Emptying or Trans-Anal Irrigation, and Bowel Training

- Randomised clinical trials of the effectiveness of trans-anal irrigation compared to other bowel emptying approaches, or to usual care and other conservative therapies are needed.
- Research on bowel management approaches and effectiveness of bowel training programmes are needed.

9. MEDICATIONS

Medication treatment of FI should be allocated according to symptom profile and patient lifestyle. The goals of this section are to identify the medications that have been used to treat FI and to evaluate the evidence regarding their efficacy (Table 15-4). Medications are part of the initial conservative management of FI, and have focused on three mechanisms

1. Reduction of diarrhoea. Diarrhoea is consistently found to be a strong risk factor for and exacerbating symptom of FI.
2. Increasing resting anal canal pressure. Low resting anal canal pressure is a risk factor for passive FI, and is commonly seen following some types of anorectal surgery (e.g., ileal pouch procedures, sphincterotomy, abdomino-perineal pull-through for imperforate anus).
3. Treatment or prevention of constipation. Constipation with overflow of liquid faeces around a faecal mass or a subsequent large bowel movement when constipation resolves is frequently found to be a risk factor for FI, especially in older persons or those with neurogenic FI (206).This treatment is addressed in the section on neurological causes of FI.

9.1. Treatment of Diarrhoea-Associated FI with Antidiarrhoeal Drugs

Loperamide (synthetic opioid with μ-agonist activity) is the most studied drug specifically for diarrhoea-associated FI. The mechanism of action is slowing of gut transit, increasing fluid reabsorption and reducing secretion, as well as directly increasing resting anal pressure. Loperamide is effective in decreasing stool frequency and improving stool consistency and reducing FI to some degree. Constipation can be a side effect. In earlier work, loperamide improved continence by reducing diarrhoea in a manner equivalent to codeine and superior to diphenoxylate, a natural opioid (207). Results of a double-blind placebo- controlled cross-over trial of loperamide in 10 obese subjects taking orlistat with resulting FI, showed loperamide significantly decreased soiling and FI (208).

Studies have compared the effects of taking loperamide along with a fibre supplement and/or using biofeedback on FI. In a study of 63 patients, taking loperamide and a psyllium fibre supplement or loperamide and a placebo supplement both improved FI (151). Results suggested taking psyllium fibre in addition to loperamide did not increase the benefit of loperamine (151). Sze and Hobbs (152), showed that 46% of women treated with methylcellulose fibre (n=19) or methylcellulose plus loperamide (n=40) resolved their FI compared to 10 control women who declined study treatment.

Another study administered loperamide supplemented with methycellulose fibre for 2-4 months or biofeedback therapy for 4-6 months then a combination of the treatments to 57 women in a cross-over design (209). Results showed the combination treatment was superior in improving FI compared to both single treatments. There was no significant difference between single or combined treatments at any time point. Markland *et al.* (148), conducted a randomised, dou-

ble-blind, placebo-controlled cross-over trial comparing loperamide (followed by psyllium) and psyllium (followed by loperamide). Both treatments reduced FI. Loperamide was associated with greater frequency of constipation. The considerable variation in comparators and study design has prevented meta- analysis of studies of loperamide for FI.

Other drugs have been investigated for FI associated with diarrhoea. Cholestyramine and biofeedback therapy versus biofeedback alone were compared in 42 patients, 21 in each group, (210). FI improved only in the group adding cholestryramine to biofeedback. Sucralfate, a formulation of aluminium hydroxide used primarily for the treatment of peptic ulcers, has been shown to reduce diarrhoea, which worsens FI, in patients with radiation proctitis. Randomised controlled trials have shown no significant benefit of sucralfate for diarrhoea (211), and a worsening of FI (212), in patients with radiotherapy-induced symptoms.

9.2. Treatment to increase resting anal canal pressure

A few small studies, have examined a variety of drugs for FI from the premise of increasing resting anal canal pressure. Table 15-4 lists studies of oral and transdermal clonidine (213), (214), as well as amitriptyline (215).There was no difference in FI or anorectal function between treatment and control groups using oral clonidine (n=44) (213). An uncontrolled study (n=12 women) of the clonidine patch reported reduced stool frequency and FI with no significant changes in anorectal manometry measurements or rectal capacitance (214). Santoro *et al.* (215), carried out an uncontrolled study of oral amitriptyline (20 mg) at bedtime in 18 patients with FI, reporting that the treatment reduced the amplitude and frequency of rectal contractions and improved sphincter pressure. Phenylephrine gel, an alpha-1 adrenergic agonist, has been investigated for the treatment of passive FI. Two studies failed to show any benefit (216, 217), but three others (217-219), suggested a modest benefit. The clinical utility of phenylephrine gel seems limited, and the topical preparation was associated with local discomfort. L-erythro methoxamine gel, an alpha-1 adrenoreceptor agonist like phenylephrine, was shown to increase internal anal sphincter resting pressure (220, 221).

New Evidence about Medication Treatment

There are three new reports of a trial of loperamide with four groups (education vs oral placebo and education vs oral placebo and anal manometry assisted biofeedback vs loperamide and biofeedback) (107, 182, 222), two trials of eluxadoline (223, 224), one trial of oxymetazoline (225), and one trial of clonidine (226). A cohort study describing use of various pharmaceutical agents including loperamide and bile acid sequestrants was also included (227).

Anti-Diarrhoeal Medications

Some new studies have been more focused on specific population groups rather than mixed groups of individuals with FI found in earlier studies. For women with FI and normal stool consistency, three analyses of data from a trial comparing loperamide with other first line treatments including education and biofeedback have been reported. Jelovsek *et al.* (107), reported that in women with normal stool consistency and FI bothersome enough to seek treatment, loperamide was no different to placebo, anal exercises using manometry-assisted biofeedback were equivalent to an educational pamphlet, loperamide and biofeedback together were equivalent to oral placebo and biofeedback or loperamide plus an educational pamphlet. The authors concluded that combining loperamide, anal manometry-assisted biofeedback, and a standard educational pamphlet resulted in negligible improvement over individual therapies.

Andy *et al. (222)*, conducted a secondary analysis of the same study data to assess changes in constipation symptoms between groups. There was no difference in constipation symptoms between treatment groups, and the authors concluded that loperamide reduced the FI but did not worsen constipation.

Improvements in defaecatory symptoms were greater in those reporting improvement in FI. Richter *et al.* (182), focused on participants in the CAPABLe trial with clinically important responses to treatment. This was defined as either a minimal clinically important difference (MID) of −5 points in St. Mark's score, a ≥50% reduction in FI episodes (as reported on a bowel diary), or a combined St. Mark's MID of -5 points and ≥50% reduction in FI episodes. Those women with higher baseline severity, adherence to drug therapy, and those who were overweight were more likely to meet the minimal clinical important difference in the St. Mark's scale score.

Two trials of eluxadoline, the mu-opioid receptor agonist to treat symptoms of irritable bowel syndrome with diarrhoea (IBS-D), report on FI. However, the primary outcomes for these studies tended to be abdominal pain and stool consistency rather than FI which was reported as a secondary outcome. In pooled data from two large randomized controlled Phase 3 studies comparing two doses of eluxadoline to placebo, Lembo *et al* (223), reported no significant decrease in FI episodes, referring to data in a supplementary data table. Brenner *et al.* (224), conducted a large randomized controlled trial comparing eluxadoline to placebo and included recording of FI episode in a diary along with other symptoms including stool consistency and abdominal pain, the primary outcome measures. FI in the two groups was only reported at baseline.

Other Medications

Barak *et al.* (225), reported a double blind crossover trial of topical oxymetazoline, an alpha-agonist that increases anal resting pressure, versus placebo in a sample of 19 spinal cord injured patients with FI. Results favoured oxymetazoline over placebo in the number of incontinence episodes 12 hours after application. However, this small study was under powered, and most participants were male, which limits generalizability.

In a two-part study, Sharma *et al.* (226), evaluated rectal compliance and sensation in response to saline or atropine (muscarinic antagonist) in 44 women with urge predominant FI compared to 16 healthy controls. Women with FI were then randomized to oral placebo versus clonidine for 4 weeks in a double blinded trial. The authors suggested the acute response to atropine provided a pharmacological challenge that may predict the long-term effects of clonidine. Results revealed a subset of FI patients with reduced rectal distensibility and increased rectal sensation, which were reversible in some patients. Larger trials are needed to confirm these findings and evaluate the efficacy of clonidine in treatment of women with urge dominant FI.

There was one descriptive cohort study (227), of people referred for treatment of chronic bowel symptoms (frequent bowel movements, loose stools, faecal urgency and FI) after having colon or pelvic cancer. Treatments were variable involving medication (bile acid sequestrants, antibiotics, loperamide) and dietary interventions. Due to the heterogeneity of the sample characteristics and interventions, specific recommendations were not possible.

Table 15-4. Effectiveness of Medication Treatment for FI

Citation	Sample	Study Design	Major Findings	Adverse Events	Comments
Antidiarreals					
Jelovsek et al. 2019 (107)	300 women with at least monthly FI over preceding 3 months and normal stool consistency were recruited from 8 clinical sites. Randomized to 4 groups: • Oral placebo and education only (n=42), • Loperamide and education (n=88), • Oral placebo and anorectal manometry assisted biofeedback (n=84), • Loperamide plus biofeedback (n=86). • Intention to treat analysis included 274 women at 12 weeks and 266 women at 24 weeks.	Randomized controlled trial (CAPABLe). Electronic randomization and stratification. Researchers, interviewers and outcome evaluators blinded to biofeedback assignment. Instruments: St Mark's (Vaizey) FI severity Scale, a 7-day bowel diary (leakage episodes and pad use), Colorectal-Anal subscales of the Pelvic Floor Distress Inventory Short Form, Colorectal-Anal subscale of the Pelvic Floor Impact Questionnaire (CRAIQ), Modified Manchester Health Questionnaire severity Subscale, Modified Patient Global Impression of Improvement (PGI-I) scale for bowel function, anal sphincter tone on physical examination using the Digital Rectal Examination Scoring System and anal manometry measures. A Fruits/Vegetables/ Fibre Screener questionnaire for dietary fibre intake. Adherence: pill counts, provider-reported adherence question and modified Medication Adherence Self-Report Inventory. Other not reported listed in study publication.	Primary outcome: changes in St. Mark's scores from baseline to 24 weeks. Results: No significant differences between groups at 24 weeks on St Mark's score. Bowel diary outcomes improved in all groups. No evidence against the null hypotheses that loperamide is equivalent to placebo, that anal exercises with biofeedback is equivalent to an educational pamphlet, and that loperamide and biofeedback together are equivalent to oral placebo and biofeedback or loperamide plus an educational pamphlet	Constipation in 2 participants in each of the loperamide groups. Only one serious side effect identified as potentially related to treatment was small bowel obstruction in the placebo and biofeedback group.	Study met sample size analysis requirements, adequately powered to detect a statistically significant difference between groups base on a minimally important difference (MID) of −5 points for the change from baseline in St. Mark's score Similar rates of post-randomization withdrawals at 24 weeks among groups are reported. Four participants were ineligible after randomization
Andy et al. 2020 (222)	296 women with at least monthly FI over preceding 3 months and normal stool consistency recruited from 8 clinical sites.	Secondary analysis of CAPABLe trial data Defaecatory symptoms measured by the Patient Assessment of Constipation Symptoms (PACSYM) at baseline, 12, and 24 weeks. Response to FI treatment: a clinically important improvement of ≥ 5 points on the St. Mark's (Vaizey) scale between baseline and 24 weeks.	Primary aim: Changes constipation symptoms between groups. No difference in constipation symptoms between treatment groups. Secondary aim: changes in constipation in responders and non-responders to FI treatment. Responders (n=137) had greater improvement in constipation compared to non-responders n=129) (-0.4; 95% CI -0.5, -0.3 vs. -0.2; 95% CI -0.3, -0.0), p<0.01, mean difference = 0.2, 95% CI 0.1, 0.4	None reported	

Citation	Sample	Study Design	Major Findings	Adverse Events	Comments
Richter et al. (2020) (182)	296 women with at least monthly FI over preceding 3 months and normal stool consistency recruited from 8 clinical sites. 266 had outcome data.	Secondary analysis of CAPABLe trial data P Minimal clinically important difference as −5 points in St. Mark's score, a ≥50% reduction in FI episodes (bowel diary), and combined St. Mark's MID and ≥50% reduction in FI episodes.	Primary aim was to identify participants with clinically important responses to treatment. Women with higher baseline severity, adherence to drug therapy, and those who were overweight (vs normal/ underweight) were more likely to meet the minimal clinical important difference in St. Mark's scale score.	None reported	Predominantly white participants (79%) who were menopausal (mean age 63.7 years). The authors identify this may limit generalizability.
Lembo et al. 2016 (223)	2427 adults with IBS with diarrhoea aged 18-80 years. Data was from Phase 3 two trials (IBS-3001 and IBS-3002). Intention to treat sample was 2425.	Randomized controlled trial. Participants randomly assigned to eluxadoline (75 mg or 100 mg) or placebo twice daily for 26 weeks or 52 weeks. Instruments were the Bristol Stool Form Scale and IBS-D global symptom score. Participants also recorded number of bowel movements and whether these were associated with urgency or FI in a diary.	Primary end point was decrease in abdominal pain and improvement in stool consistency on the same day for at least 50% of the days from weeks 1 through 12 and from weeks 1 through 26. Both doses of eluxadoline were significantly superior to placebo with respect to the end points of adequate relief of IBS symptoms, scores for global symptoms, and scores on the IBS-QOL questionnaire No significant reduction in FI was found (reported in published supplemental data.	Five patients had pancreatitis, eight cases of abdominal pain with elevated hepatic enzyme levels consistent with spasm of the sphincter of Oddi.	FI was not a primary endpoint. No link to supplementary data table.
Brenner et al. 2019 (224)	346 adults with irritable bowel syndrome with diarrhoea and self- reported inadequate symptom control with loperamide	Randomized controlled trial. Double blinded, Phase 4 study. Participants randomly assigned to placebo or eluxadoline 100mg twice daily for 12 weeks. Instruments were the Bristol Stool Scale and the Worst Abdominal Pain (WAP) scale. Participants also recorded number of bowel movements, faecal urgency and FI in a diary.	Primary efficacy endpoint was the proportion of composite responders (daily WAP score improvement and BSS score less than 5 [or absence of bowel movement accompanied by greater WAP improvement compared to baseline for at least 50% of treatment days. Weekly average FI reported as part of baseline characteristics (1.1 for placebo, 1.2 for eluxadoline group.	Three patients in the placebo group (1.7%) and 1 patient in the eluxadoline group (0.6%) experienced serious treatment emergent adverse events.	No outcome data for FI reported.

Citation	Sample	Study Design	Major Findings	Adverse Events	Comments
Markland et al. 2015 (148)	Double-blind, randomised, cross-over design 80 veterans with FI or liquid or solid stool at least weekly for 3 months	Random assignment to Loperamide (2 mg) first then a supplement of psyllium fibre (3.4 mg) or psyllium first then loperamide for 4 weeks each with a 2 week washout and a 2 week non-equivalent baseline period FI frequency was reported daily on a diary for 7 days during each period	No significant difference in FI between treatment groups. Within each treatment group, FI frequency significantly decreased from baseline during the first treatment period for both treatments, but did not significantly change after the crossover to the other treatment.	Loperamide group had one adverse event, constipation and none in psyllium group	Use of a stool diary untested for validity and reliability, potential error due to subjects needing to prepare part of the supplement, possible unmeasured cross-over effects, non-equivalent baseline period, and attrition during the washout
Sze & Hobbs 2009 (152)	59 patients and 10 controls (latter recruited if declined active treatment). Outcomes: overall improvement and Pescatori score at 8 weeks	Prospective unblinded controlled study of methyl-cellulose (1-2 Tbls/d) with (n=19) or without loperamide (1-2 capsules/d) (n=40) vs. controls (n=10)	FI resolved in 27 patients (46%) using methyl-cellulose with or without loperamide vs. control	Constipation with loperamide relieved by dose alteration.	Power calculation aimed to detect 46% difference in open study.
Lauti et al. 2008 (151)	63 randomised (49 completed both phases of cross-over) consecutive referrals to specialist centre.	Double-blind randomised cross-over trial, each treatment was given to both groups for 6 weeks. Treatment A = low-residue diet sheet, placebo (1 tsp of an infant food thickener containing locust bean gum fibre/d) and loperamide as needed Treatment B = psyllium fibre (1 tsp/d), low and high residue diet sheet and loperamide as needed	FISI scores fell from baseline 31 to 18 for treatment A and 19 for treatment B. No differences between treatments in terms of FISI or FIQL.	Nil major adverse events – palatability of supplements caused 1 patient (3%) to withdraw	Loperamide was taken as needed so dose was variable; there was low fidelity of monitoring the intervention; Possible confounding from placebo that contained dietary fibre Possible carry-over effects from cross-over to other treatment
Other medications					

Citation	Sample	Study Design	Major Findings	Adverse Events	Comments
Barak et al. 2019 (225)	N= 19 spinal cord patients aged 23.7-57.2 years (Mean 42.6) with FI. SCI injury at least 3 months and less than 5 years before randomization with at least 4 incontinence events per week. 16/19 were men. Prior to randomization, patients underwent a 1 day open label anal manometry and pharmacokinetic study.	Double blind crossover trial of topical oxymetazoline 2 arms: Placebo x 4 weeks followed by oxymetazoline x 4 weeks (n=9) OR oxymetazoline x 4 weeks followed by placebo x 4 weeks (n=10). 2 week washout period between each phase	Primary outcome: number of FI episodes at 8 and 12 hours after administration, recorded on daily diaries. Change in mean faecal incontinence episodes per month (12 hours post drug application) favoured treatment over placebo [26.3 (SD ±28.4) versus 36 (SD ±39.8) (p = 0.021)]. Non-gas episodes only: mean number of episodes decreased from 10.1 (+4.3) to 6.3 (±2.1) per month (p = 0.022).	No differences between groups. Abdominal pain mean less than 1.5 on a 1-10 scale. No deaths. Secondary outcome was quality of life(Faecal Incontinence Quality of Life Scale FIQLS).	Authors acknowledge small sample but argue a clinically beneficial effect and favourable safety and tolerability profile. Sample size analysis: 17 per group with a total of 34.
Sharma et al. 2018 (226)	N=16 controls and N= 44 women with urge dominant FI. Controls mean age = 34 years, FI patient mean age = 57 years. FI patients had urge-predominant FI for > 1 year. Exclusion criteria: current or prior organic colonic or anorectal diseases, severe diarrhoea during run in phase, clinically significant cardiovascular or pulmonary disease or EKG abnormalities, symptomatic hypotension, or systolic blood pressure of <100 mm Hg at screening visit, neurological disorders, use of opiate analgesics, and pregnancy or nursing.	Two part study (RCT in Part 2). Part 1: Baseline in controls and FI patients: rectal distensibility and sensation were evaluated by barostat and sinusoidal oscillation. After randomization to IV saline or atropine, these parameters were evaluated again in controls and FI patients Part 2: Randomized double blind placebo controlled trial. FI patients randomized to oral placebo or clonidine for 4 weeks, rectal compliance and sensation re-evaluated. Clonidine treatment stratified by age and BMI. Study personal blind to assignment in each phase until database unlocked.	Baseline, rectal capacity lower mean pressure and elastance greater in FI participants, signifying reduced distensibility, Compared to placebo, atropine increased the heart rate in controls and FI and reduced the variability in rectal pressures during sinusoidal oscillation in controls. Clonidine significantly increased rectal compliance and reduced rectal capacity in FI patients. Atropine and clonidine effects on compliance, capacity pressures during sinusoidal oscillation, pressure and volume sensory thresholds were correlated.	Reported that neither atropine nor clonidine altered rectal elastance or hysteresivity (lag/return to original state) in controls and FI patients.	Controls were younger and with lower BMI than those participants with FI. A subset of FI patients have reduced rectal distensibility and increased rectal sensation which are reversible in some patients. Larger studies are needed to confirm the effect of clinical on urge dominant FI in women, and to confirm potential findings of reversible rectal features in some individuals.

Citation	Sample	Study Design	Major Findings	Adverse Events	Comments
Larsen et al. 2019 (227)	60 patients with chronic bowel symptoms after treatment for colon or pelvic organ cancer referred to the department of gastroenterology over a 2 year period.	Prospective cohort study	Median time from cancer treatment was 5.5 years (range 1-36 years). Symptoms included frequent bowel movements (65%), loose stools (87%), urgency for defaecation (57%), and FI (50%). Specific cause of bowel dysfunction found in 48 (80%) with 21 (35%) having more than one cause. Treatments included bile acid sequestrants (n =36), antibiotics (n= 33), loperamide (n =21), and dietary intervention (n= 20). Major improvement in bowel symptoms was reported by 23 (38%) patients, 27 (45%) reported some improvement.	Not reported	Heterogenous sample that received a variety of treatments based on identified cause of symptoms. No recommendations can be derived other than authors conclusion such patients may benefit from clinical evaluation and targeted treatment.
Bharucha et al. 2014 (213)	Double-blind, randomised, placebo-controlled, parallel-group study 44 women (age 18-75 years) with urge- predominant FI of 1 year or longer duration.	After a 4 week baseline (no drug) period, patients with ≥ 4 FI episodes in 4 weeks were randomly assigned to clonidine (0.1 mg bid) or placebo. Symptoms, anal pressures, rectal compliance and sensation were assessed before and after therapy. Anal sphincter injury was evaluated by endoanal magnetic resonance imaging.	Differences in FI and anorectal functions between treatment groups were not significant. However, clonidine reduced the proportion of loose stools in patients with diarrhoea and also reduced (p=0.08) the proportion of days with FI in patients with diarrhoea.	Adverse events were more common for clonidine (19 patients) than placebo (7 patients).	Of individual side effects, dry mouth was more common after clonidine than placebo.
Bharucha et al. 2010 (214)	12 women with urge-predominant FI and mixture of sphincter integrity. Outcomes: diary data, FI symptom severity score, FIQL, anorectal physiology	Open label, uncontrolled study of 4 weeks clonidine via patch (0.2mg/day)	Clonidine reduced stool frequency and proportion of patients with >50% reduction of FI episodes (9 of 12, 75%) and FI days (8 of 12, 67%). No significant changes in manometry measurements or rectal capacitance with clonidine	6 (50%) had adverse effects. 5 (42%) had skin reaction, 3 (25%) fatigue, 2 (16%) postural hypotension and 2 (16%) dry mouth.	Unclear whether effects most marked in those with baseline looser stool
Remes-Troche et al. 2008 (210)	21 patients with FI treated with cholestyramine plus biofeedback and matched cohort of 21 with FI who underwent biofeedback alone	Prospectively collected data. Median cholestyramine dose was 4 gm/d	Improved stool frequency and consistency and FI in group taking cholestyramine + biofeedback, but not biofeedback only.	Side effects in 7 (33%), constipation 4 (19%), bloating (9%) and headache 1 (5%).	Poor palatability Side effects improved with dose reduction.

Citation	Sample	Study Design	Major Findings	Adverse Events	Comments
Santoro et al. 2000 (215)	18 patients and 24 controls (latter for anal physiology measurements)	Open study of 20 mg amitriptyline for 4 weeks	FI scores reduced from median 16 (maximum 18) pre-treatment to 3. Treatment reduced amplitude and frequency of rectal contractions and improved sphincter pressure.	Dry mouth or drowsiness in 4 patients (22%) Nil withdrew	Effects suggested to be mediated by anti-muscarinic slowing of transit, and improved anorectal coordination

FI refers to FI; QOL refers to quality of life; tsp means teaspoon

Summary of Evidence for Medication Treatment of FI

- Loperimide may be helpful in women with FI and normal stool consistency, but is not superior to education and anal manometry biofeedback. Women who have more severe FI and are obese may have better outcomes (Level of Evidence 1).
- Loperamide is useful for diarrhoea-associated FI (Level of Evidence 2).
- loperamide may be superior to diphenoxylate (Level of Evidence 2).
- Use of loperamide can be similarly effective to supplementation with psyllium fibre in reducing FI (Level of Evidence 1).
- Combining loperamide with biofeedback or a standard educational pamphlet results in negligible improvement over individual therapies (Level of Evidence 1).

Recommendations for Clinical Practice Related to Medication Treatment

- Administer loperamide to women with FI and normal stool consistency. Women should be advised of the potential for constipation (Grade of Recommendation B).
- Loperamide is useful for reducing non-infectious diarrhoea-associated FI (Grade of Recommendation B).
- Loperamide, supplementation with psyllium fibre, biofeedback therapy, or education about FI may be tried for reducing FI (Grade of Evidence B).

Recommendations for Research on Medications for FI

- There is a need for further research on preparations, doses and combination therapies including medications versus single treatments for FI in various patient groups
- Larger trials are needed to confirm and evaluate the efficacy of clonidine in treatment of women with urge dominant FI. Such studies need to carefully report any adverse effects.
- FI data on eluxadoline, an opioid agonist with low bioavailability, needs to be published in studies along with other symptoms of irritable bowel syndrome with diarrhoea.

V. INTERVENTIONS FOR FI IN NEUROLOGICAL DISEASES

1. INTRODUCTION

In neurological diseases, bowel dysfunction is common. This is true in major neurological diseases including degenerative neurologic diseases e.g., Parkinson's disease (PD) and multiple system atrophy (MSA), and diseases affecting the spinal cord, i.e., spinal cord injury (SCI) and multiple sclerosis (MS). There are various approaches prevent and manage constipation, impaction and overflow FI including position during defaecation, abdominal massage, rectal evacuation, and bowel management.

2. POSITION AND MASSAGE

2.1. Defaecation Position

A position in which the knees are elevated to form a 60-degree angle with the trunk or the trunk is bent forward on the toilet or commode is typically recommended to promote defaecation in patients with bowel dysfunction due to neurological disease. There are no randomized, double-blind control studies (RCT) about the effectiveness of defaecation posture. However, studies using objective measures clearly showed that "Eastern" knee-up posture and a resulting widened recto-anal angle lessened the necessary abdominal strain and led to easier defaecation ($p<.05$), which seemed to be more physiological (228-231). This finding is reported in both normal volunteers and patients with idiopathic constipation. Adopting this position is a simple strategy without any reported adverse events. As compared with usual horizontal sitting, the recommended position decreases basal abdominal pressure ($p<.01$), lowers abdominal pressure on defaecation, and enlarges the recto-anal angle ($p<.01$), all of which promote easier defaecation. This effect might be brought about by mechanical release of the tightened recto-anal angle. A recent study by Tashiro (232) showed almost the same results.

2.2. Abdominal Massage

Manual abdominal massage is traditionally performed to facilitate bowel movement. Abdominal massage can be done by patients (at home, daily) or by a nurse (at a clinic or a hospital, not daily). Most studies employed the similar methods. For example, a recent RCT study by Okuyan (233), employed the following method of massage steps:

- When the older adult was in the supine position, a thin cushion was placed beneath the knees to loosen the abdomen and provide slight flexion in the legs
- Participants were told to breathe normally and relax the abdomen as much as possible.
- The abdominal region was then massaged for about 15 min.
- Then massage was applied in the direction of the colon in order to increase the contractions in the intestines by the deep effleurage method.
- With the kneading method, massages with palms and fingers were applied with upward pressure on the ascending colon and downward pressure on the descending colon.
- Later, the massage was continued by vibration (vibration) method in order to stimulate the nervous system and to relax the muscles. This procedure was performed as the 8-week program.

There are 13 RCTs about abdominal massage showing its effectiveness (234-237). There are also studies using objective measures showing that abdominal massage elicits spontaneous rectal contraction (peristalsis) with sensation and following defaecation (238-240). These effects might be brought about by a somato-autonomic reflex as observed in experimental settings (240-242). This somato-autonomic reflex is reported in patients with idiopathic constipation, in older adults, post-colectomy, HTLV1-associated myelopathy/spastic tropical paraparesis, stroke, spinal cord injury, and post-orthopaedic surgery population. Abdominal massage is simple without any reported adverse events.

3. RECTAL EVACUATION

3.1. Transanal enemata

Transanal enemata comprise an injection of fluid into the lower bowel by way of the rectum. The most frequent uses are to relieve constipation and for bowel cleansing before a medical examination or procedure. There are two RCTs showing the effectiveness of transanal enemata ($p<.05$) (243, 244). In one a docusate/sorbitol enema and usual (not specified) enema were superior to oral laxative macrogol (polyethylene glycol, PEG) 3350 ($p<.05$) in children with constipation (244). This result might be brought about by extending the rectal wall and stimulating sensory afferent fibers. Using a transanal enema is a simple intervention without any reported adverse events.

3.2. Trans-anal suppositories

Rectal suppositories are used into the rectum. The "torpedo" shape helps the device to travel internally, increasing its efficacy. There are five RCTs showing the effectiveness of transanal suppositories using sodium bicarbonate ($p<.05$) (245, 246). The effect might be brought about by extending the rectal wall and stimulating sensory afferent fibres which seems to be physiological. Use of trans-anal suppositories is simple and without any reported adverse events.

3.3. Retrograde continence enema (RCE) (also called transanal rectal irrigation (TAI))

A retrograde continence enema (RCE) (also called transanal rectal irrigation (TAI)) provides a large amount of water into the colono-rectal lumen from the anus, which leads to stool softening, distension of the rectal wall, and stimulation of sensory afferent fibres, promoting evacuation of rectal contents. Time is needed to achieve defaecation. RCE/TAI has been studied in adults and children with idiopathic constipation, spinal cord lesion, and spinal bifida; however, there are no RCTs investigating effectiveness. Recent large-scale systematic reviews concluded RCE/TAI as being useful without reported major adverse events (247, 248). In addition, studies using objective measures showed that RCE/TAI hastened colonic transit time (CTT) by scintigraphy, lessened rectal diameter by ultrasound, and brought about easier defaecation ($p<.05$) (248, 249).

3.4. Malone antegrade colonic (continence) enema with appendicostomy surgery (MACE)

Similar to RCE/TAI, Malone antegrade colonic (continence) enema ith (MACE) provides a large amount of water into the intestinal lumen through the ostomy opening in the colon (appendicostomy surgery is needed) but in an antegrade or forward manner, which leads to stool softening, distension of the rectal wall and stimulation of sensory afferent fibres. There is one RCT and one meta analysis/systematic review about MACE showing its effectiveness ($p<.05$) (250, 251). Two studies, using objective measures, also showed that MACE hastened colonic transit time (CTT) by scintigraphy or marker CTT test ($p<.05$) (248, 252).However, MACE needs surgery (appendicostomy), which raised caution particularly in children in some reports (253).

4. LAXATIVES, STOOL SOFTENERS, AND PROKINETIC SUBSTANCES AND DRUGS

The term laxative originates from Middle French laxatif, which itself originates from Latin laxātīvus (literally "relaxing, loosening"), possibly expressing medicines that ameliorate painful abdominal evacuation (relaxation) and hard stools (loosening). In a modern meaning, a laxative has various physiological effects that can be divided into stool softener (mainly by water-adding, which concurrently bulking stools. Softening and bulking also accelerate colonic transit time mildly) and prokinetics (directly promoting colonic transit time mainly by acting on myenteric plexus nerves, formerly called 'stimulating laxatives').

4.1. Stool softeners/ bulking agents

4.1.1. Magnesium oxide

Magnesium oxide is the oxide salt of magnesium with antacid, laxative and vascular smooth muscle relaxant activities. Magnesium combines with water to form magnesium hydroxide which reacts chemically to neutralize or buffer existing quantities of stomach acid; stomach-content and intra-oesophageal pH rise, resulting in a decrease in pepsin activity. This agent's laxative effect is the result, in part, of osmotically mediated water retention (osmotic laxative), which subsequently stimulates peristalsis presumably by distending the rectal wall and stimulating sensory afferent fibres, also with stool softening, that seem to be physiological. Magnesium ions may behave as calcium antagonists in vascular smooth muscle (relaxant), although this effect is not observed clinically. There is one RCT with favourable effects for the use of magnesium oxide. [32] This drug has few reported adverse events, but particularly in older patients, magnesium overdose/intoxication may occur; therefore, it is recommended to measure serum magnesium levels regularly if prescribing a larger dose of a drug than the Drug Formulary. In general, magnesium oxide is recommended for slow-transit and anorectal constipation with secondary overflow FI in patients with various neurological diseases. Magnesium is relatively inexpensive.

4.1.2. Macrogol (polyethylene glycol, PEG) 3350

Macrogol is an osmotically acting inert substance that passes through the gut without being absorbed into the body (254). It relieves constipation because it causes water to be retained in the bowel instead of being absorbed into the body. This agent subsequently stimulates peristalsis presumably by distension of the rectal wall and stimulation of sensory afferent fibres, also with stool softening. There is one RCT and four meta-analyses/ network analysis showing favourable effects for the use of macrogol (polyethylene glycol, PEG) 3350 (255-259). A study using objective measures also showed that macrogol hastened colonic transit time (CTT) by scintigraphy or marker CTT test (p<.05) (256). This drug has few reported adverse events. It is recommended for slow-transit and anorectal constipation with secondary overflow FI in patients with various neurologic diseases. PEG 3350 is relatively inexpensive.

4.1.3. Bisacodyl

Bisacodyl is a contact laxative; it increases fluid and salt secretion. Bisacodyl works by stimulating enteric nerves to cause peristalsis,. The action of bisacodyl on the small intestine is negligible; stimulant laxatives mainly promote evacuation of the colon. This agent subsequently stimulates peristalsis presumably by extending rectal wall and stimulating sensory afferent fibers, also with stool softening. There are three meta-analyses/ network analysis showing favourable effects of bisacodyl (257, 259, 260). Two studies using objective measures also showed that bisacodyl hastened colonic transit time (CTT) by a marker CTT test (p<.05) (261, 262). This drug has few reported adverse events.

4.1.4. Elobixibat

Elobixibat is an inhibitor of the ileal bile acid transporter (IBAT), undergoing development in clinical trials for the treatment of chronic constipation and constipation predominant irritable bowel syndrome (IBS-C). IBAT is the bile acid:sodium symporter responsible for the reuptake of bile acids in the ileum which is the initial step in the enterohepatic circulation. By inhibiting the uptake of bile acids, elobixibat increases the bile acid concentration in the gut, which accelerates intestinal passage and softens the stool. There are two meta-analyses/ network analysis showing favorable effects for the use of elobixibat (259, 260). This drug has few reported adverse events. Elobixibat is recommended for slow-transit and anorectal constipation with secondary overflow FI in patients with various neurological diseases.

4.1.5. Linaclotide

Like the endogenous guanylin and uroguanylin it mimics, linaclotide is an agonist that activates the cell surface receptor of guanylate cyclase 2C (GC-C) (263). This medication binds to the surface of the intestinal epithelial cells. Activation of GC-C increases cyclic guanosine monophosphate (cGMP), which further activates, through protein kinase 2, *cystic fibrosis* transmembrane conductance regulator (*CFTR*) facilitating water movement into the lumen softening stool. Linaclotide also inhibits activation of colonic *sensory* neurons and activating colonic motor function.

There are **3** meta-analyses/ network analyses supporting the use of linaclotide (257, 259, 260). Studies by objective measure also showed that it hastened colonic transit time (CTT) by a marker CTT test (p<.05) (264). This drug has few reported adverse events.

4.1.6. Plecanatide

Plecanatide works as a laxative by drawing water in to the gastrointestinal tract thereby softening stool and encouraging its natural passage. Similar to linaclotide, plecanatide activates guanylate cyclase-C on endothelial cells within the gastrointestinal tract. There is one meta-analysis/ network analysis supporting the use of plecanatide (259). This drug has few reported adverse events. Plecanatide is recommended for slow-transit and anorectal constipation with secondary overflow FI in patients with various neurologic diseases.

4.1.7. Lubiprostone

Lubiprostone is a bicyclic fatty acid derived from prostaglandin E1 that acts by specifically activating ClC-2 chloride channels on the apical aspect of gastrointestinal epithelial cells, producing a chloride-rich fluid secretion (265). There are one RCT and two meta-analyses/ network analyses which support the use of lubiprostone (257, 259). Studies using objective measures also showed that lubiprostone hastened colonic transit time (CTT) by a marker CTT test (p<.05) (266). This drug has few reported adverse events. Lubiprostone is recommended for slow-transit and anorectal constipation with secondary overflow FI in patients with various neurologic diseases.

4.1.8. Polycarbophil

Polycarbophil is a form of *surfactant* with amphiphilic properties. Polycarbophil is a bulk-forming laxative. Increased stool bulk helps to cause movement of the intestines. It also works by increasing the amount of water in the stool, making the stool softer and easier to pass. Calcium polycarbophil is not absorbed from the intes-

tine. There is one RCT showing favourable effects for the use of polycarbophil (267). Three studies using objective measures also showed that polycarbophil hastened colonic transit time (CTT) by a marker CTT test (p<.05) (268, 269). This drug has few reported adverse events. Polycarbophil is recommended for slow-transit and anorectal constipation with secondary overflow FI in patients with neurological diseases.

4.2. Prokinetics

4.2.1. Sodium picosulfate

Sodium picosulfate is a prodrug. It has no significant direct physiological effect on the intestine; however, it is metabolised by gut bacteria into the active compound 4,4'-dihydroxydiphenyl-(2-pyridiyl) methane (DPM, BPHM). This compound is a stimulant laxative for sensory afferent fibers and increases peristalsis in the gut. There are one RCT and three meta-analyses/network analyses supporting use of sodium picosulfate (255, 257, 259, 270). Use of sodium picosulfate is straightforward and without any reported adverse events.

4.2.2. Mosapride

Mosapride is a gastroprokinetic agent that acts as a selective 5HT4 agonist (271, 272). The major active metabolite of mosapride, known as M1, additionally acts as a 5HT3 antagonist, which accelerates gastric emptyingand is used for the treatment of gastritis, gastroesophageal reflux disease, functional dyspepsia and irritable bowel syndrome. In addition to its prokinetic properties, mosapride exerts anti-inflammatory effects on the gastrointestinal tract which may contribute to some of its therapeutic effects. By stimulating 5HT4 and 3 receptors in colonic wall, mosapride stimulates peristalsis (prokinetic effect). There is one RCT supporting the use of mosapride (273). Four studies using objective measures also showed that mosapride hastened colonic transit time (CTT) by a marker CTT test (p<.05) (274-276). Contraction of the longitudinal muscles in the colonic wall via acetylcholine (Ach) is controlled positively by serotonin (mainly 5-HT4) and negatively by dopamine (D2), vasoactive intestinal peptide (VIP) and nitric oxide (NO). This drug has few reported adverse events.

4.2.3. Prucalopride

Prucalopride, a first in class dihydro-benzofuran-carboxamide, is a selective, high affinity serotonin (5-HT4) receptor agonist with enterokinetic activities (also called as prokinetics) (263). Prucalopride alters colonic motility patterns also via selective serotonin 5-HT4 receptor stimulation: it stimulates colonic mass movements, which provide the main propulsive force for defaecation. There are 3 meta-analyses/ network analysis with favorable effects for the use of prucalopride (256, 257, 259, 260). A study using objective measures also showed that prucalopride hastened colonic transit time (CTT) by a marker CTT test (p<.05) (256). This drug has few reported adverse events. Prucalopride is recommended for slow-transit and anorectal constipation with secondary overflow FI in patients with various neurologic diseases.

4.2.4. Velusetra (investigational drug)

Velusetrag is a selective 5-HT4 receptor serotonin agonist, and is a drug candidate for the treatment of gastric neuromuscular disorders including gastroparesis, and lower gastrointestinal motility disorders including chronic idiopathic constipation and irritable bowel syndrome. It is still under investigation and not yet clinically available. There are two meta-analyses/ network analysis showing favourable effects for the use of velusetrag (259, 260), A study using objective measure also showed that velusetrag hastened colonic transit time (CTT) by a marker CTT test (p<.05) (277).

4.2.5. Nizatidine

Nizatidine is a histamine H2 receptor antagonist that inhibits stomach acid production, and is commonly used in the treatment of peptic ulcer disease and gastroesophageal reflux disease. Nizatidine *has also a cholinomimetic property, which acts as a* prokinetic drug. There is no RCT for the use of nizatidine. However, two studies using objective measures showed that nizatidine hastened gastric emptying (p<.05) by a 13C breath test and hastened colonic transit time (p<.05) leading to easier defaecation without serious adverse events (278, 279). Nizatidine can be an option for slow-transit and anorectal constipation with secondary overflow FI in patients with various neurological diseases.

5. DIETARY HERB EXTRACTS

5.1. Dai-Kenchu-To

Recently dietary herb extracts (herbal medicine) including Dai-Kenchu-To (DKT) have attracted attention because of their few adverse events (they are called 'time-tested'). A mixture of natural ingredients may have a role in reducing unwanted effects. This is particularly important to treat older adults with neurological disease. Dai-Kenchu-To is a combination of ginger, ginseng, and zanthoxylum (Sansho, Japanese pepper). Among these, an active component, hydroxy-beta-sanshool (in Sansho), mostly accounts for the lower-gastrointestinal tract contraction induced by DKT, which stimulates serotonergic 5HT3 receptors in the bowel. DKT has few reported adverse events.

There is one RCT supporting the use of DKT (280). Three studies using objective measures also showed that DKT statistically significantly hastened total colonic transit time (CTT) from 92 hours to 65.6 hours (upper normal limit, 39 hours) by a marker CTT test (p<.05) (281). A videomanometry study showed an increase in rectal contractions on defaecation after administration of DKT (p<.05) (281). DKT is recommended for slow-transit and anorectal constipation with secondary overflow FI in patients with various neurological diseases.

5.2. Rikkunshi-To

Rikkunshi-To (RKT) (also called Xiang-Sha-Liu-Jun-Zi tang (XSLJZT)**)** is a combination of eight natural materials: *Atractylodis lanceae, Poria cocos*, ginseng, *Pinellia ternata*, ginger, orange peel, *Ziziphus jujuba*, and glycyrrhiza. Among these, an active component, 10-gingerol (in ginger), mostly accounts for the gastrointestinal tract contraction induced by RKT. 10-gingerol inhibits the 5-HT2 (and 3) receptors in the myenteric plexus and induces ghrelin secretion. There is one RCT supporting the use of RKT (282), two studies using objective measures also showed that RKT hastened total colonic transit time (CTT) by a marker CTT test significantly (p<.05) (283, 284). RKT has few reported adverse events.

Summary of FI in Neurologic Diseases

- The knees-up position is recommended as the position for defaecation for anorectal constipation with secondary overflow FI in patients with various neurologic diseases if they can achieve this posture (Level of Evidence 3).
- Abdominal massage can be tried for slow transit and anorectal constipation with secondary overflow FI in patients with various neurological diseases (Level of Evidence 3).
- Transanal enemas are effective for rectal evacuation and managing anorectal constipation with secondary overflow FI in pa-

tients with various neurological diseases if patients themselves or their caregivers perform the manoeuvre (Level of Evidence 2).
- Transanal suppositories are effective for rectal evacuation and managing anorectal constipation with secondary overflow FI in patients with neurological diseases if patients or their caregivers can perform this intervention (Level of Evidence 1).
- Retrograde continence enema (RCE) (also called transanal irrigation (TAI)) is effective and managing anorectal constipation with secondary overflow FI in patients with neurological diseases if patients and /or their caregivers are able to do it (Level of Evidence 1).
- Malone antegrade colonic (continence) enema with appendicostomy surgery (MACE) is effective for managing severe slow-transit and anorectal constipation with secondary overflow FI that is resistant to other manoeuvres and drugs, and in patients with neurological disease (particularly spinal cord diseases, spinal bifida, and other diseases that cause severe bowel disorder) (Level of Evidence 1).
- The following stool softeners and bulking agents are effective in managing constipation in patients with neurogenic diseases; however, their effect on FI needs further clarification: magnesium oxide (Level of Evidence 2), macrogol (polyethylene glycol, peg) (Level of Evidence 1), bisacodyl (Level of Evidence 1), elobixibat (Level of Evidence 1), linaclotide (Level of Evidence 1), plecanatide (Level of Evidence 1), lubiprostone (Level of Evidence 1), and polycarbophil (Level of Evidence 2).
- velusetra (investigational drug) is potentially effective for constipation (Level of Evidence 4).

Recommendations for Practice Related to FI in Neurological Diseases
- Advise patients with anorectal constipation with secondary overflow FI to assume a knees up position during defaecation (Grade of Recommendation C).
- Abdominal massage should be suggested for slow transit and anorectal constipation with secondary overflow FI in patients if patients themselves or their caregivers can perform if (Grade of Recommendation C).
- Transanal enemas are recommended for rectal evacuation for anorectal constipation with secondary overflow FI if patients themselves or their caregivers are able to perform this manoeuvre (Grade of Recommendation B).
- Transanal suppositories are recommended to aid rectal evacuation in anorectal constipation with secondary overflow FI if patients or their caregivers are able to perform this manoeuvre (Grade of Recommendation A).
- Retrograde continence enema (RCE) (or transanal irrigation (TAI)) is recommended for anorectal constipation with secondary overflow FI if patients and/or their caregivers are able to do it (Grade of Recommendation B).
- The Malone antegrade colonic (continence) enema with appendicostomy surgery (MACE) is recommended only for severe slow-transit and anorectal constipation with secondary overflow FI that is resistant to other manoeuvres and drugs, and in patients with neurological diseases (particularly spinal cord disease, spinal bifida, and other diseases that cause severe bowel disorder) if patients and/or their caregivers are happy to use this procedure despite its high surgical burden (Grade of Recommendation A).
- Stool softeners and bulking agents should be considered to lessen FI in patients with neurological disease and mild slow-transit and anorectal constipation with secondary overflow FI (Grade of Recommendation C).
- Velusetra (investigational drug) may be tried when other medications fail (Grade of Recommendation C).

Recommendations for Future Research on FI in Neurological Diseases
- RCTs are needed to determine the effectiveness of the knees-up position for promoting defaecation in patients with neurological diseases.
- Because most medications have been studied for managing or preventing constipation, they need to be investigated for their effectiveness in managing or preventing FI as an outcome. Studies with RCT designs are recommended.

VI. SECONDARY INTERVENTIONS

1. BEHAVIOURAL THERAPIES: PELVIC FLOOR MUSCLE TRAINING, BIOFEEDBACK, AND ELECTRICAL STIMULATION

Pelvic floor muscle training (PFMT), biofeedback (BF), electrical stimulation of the anal mucosa (ES), and tibial nerve electrical stimulation (TNS) are secondary interventions for FI. Each is a distinctly different therapeutic technique for treating FI, and is described below. However, these three techniques are discussed together because many studies compare them to each other while other studies test combinations of these techniques (e.g., BF combined with ES) (Table 15-5).

1.1. Pelvic Floor Muscle Exercise Training

The patient is instructed to contract the pelvic floor muscles (usually maximally) including the external anal sphincter and puborectalis while keeping abdominal wall muscles relaxed and to do this multiple times each day with the goal of strengthening pelvic floor muscles. In a typical protocol the patient may be instructed to squeeze for 10 seconds while continuing to breathe deeply so that the abdominal wall muscles do not also contract. Ten to 20 such 10-sec squeezes are separated by 20 second periods of pelvic floor relaxation. Often patients are instructed to squeeze 10-20 times in a block and to repeat this block of exercises 3-5 times a day. The patient may be taught how to perform this exercise using only verbal or written instructions (285), or they may be given verbal feedback on their performance by the therapist during a digital rectal examination (286, 287). However, electronic or mechanical devices are not used to amplify the sensory information available to the patient to make them more aware of how well they are performing the exercises; this distinguishes PFMT alone from PFMT with BF.

1.2. Biofeedback

Biofeedback is distinguished from PFMT alone using electronic or mechanical devices to augment the intrinsic sensory information available to the patient on how well they are contracting and relaxing their pelvic floor muscles. The purpose of this type of training is to ensure that patients learn the appropriate way to selectively contract and relax the pelvic floor muscles while keeping abdominal wall muscles relaxed.

Another feature of many biofeedback training protocols is sensory training (rectal balloon training) or coordination training (288). Because of neurological injuries, many patients lose the ability to recognize sensations associated with the movement of stool into the rectum and may fail to contract the pelvic floor muscles to avoid stool leakage.

In sensory training, a balloon-tipped catheter is introduced into the rectum and distended with varying volumes of air or water to help the patient learn to recognize weaker distensions. Coordination training is a variant of sensory training and refers to having the patient practice contracting pelvic floor muscles in response to any sensation of rectal distention until this becomes a well-practiced habit (289).

A third type of BF training for FI (in addition to strength training and sensory training) is referred to as urgency resistance training (288). This is intended for patients who experience intense sensations of urgency to defecate prior to stool leakage. These sensations may be associated with prolonged smooth muscle contractions of the rectum leading to reflex inhibition of the external anal sphincter and puborectalis muscles and rectal evacuation (290). These smooth muscle contractions may be triggered by stress or anxiety (291), or by food ingestion (292). Urgency resistance training has the goal of desensitizing the patient to the sensation of rectal fullness or rectal contraction. This is accomplished byteaching the patient to use deep breathing or another relaxation technique to counteract anxiety and progressively inflating a balloon in the rectum to desensitize the patient to the sensation of rectal filling (293).

1.3. Electrical Stimulation

Electrical stimulation from probes placed in the anal canal as far up as the puborectalis muscle or from electrodes on the perineum adjacent to the anus has also been used to treat FI. In typical applications, stimulation is performed daily at home using a battery operated electrical pulse generator connected to the anal electrodes (287).

Different theories have been advanced to account for how this might facilitate continence (287). In the earliest applications, ES was used at intensities that triggered a contraction of the pelvic floor muscles, and patients were encouraged to try to augment the contractions produced by ES or to try to reproduce these contractions without electrical stimulation. Others have suggested that the stimulation of afferent nerves by lower intensities of ES may help by increasing the sprouting of synapses peripherally or the size of the receptive fields for these nerves in the brain (294). ES is sometimes combined with BF (295).

1.3.1. Tibial Nerve Stimulation

Tibial nerve stimulation is a form of ES in which surface electrode is placed on the skin over the tibial nerve on one ankle and referenced to another electrode on the ipsilateral foot (transcutaneous, TTNS) or a needle inserted beneath the skin close to the tibial nerve on one side and is referenced to an electrode on the ipsilateral foot (percutaneous, PTNS) (296). Typical TTNS stimulation parameters are 200 microsecond pulses at a frequency of 10 Hz and current of up to 30 mA. Typical PTNS stimulation parameters are 200 microsecond pulses at a frequency of 10-20 Hz and up to 9 mA. In the 6th ICI, Chapter 16, the Committee “Assessment and conservative management of FI and quality of life in adults” reviewed the evidence for tibial nerve stimulation available at that time and concluded: “Percutaneous tibial nerve stimulation remains an investigational treatment protocol which cannot currently be recommended for clinical practice”(1).

2. NEW EVIDENCE ABOUT PELVIC FLOOR MUSCLE TRAINING, BIOFEEDBACK, AND ELECTRICAL STIMULATION

PFMT Studies

In a RCT of 98 adults with FI Ussing *et al.* (297), provided support for a superior effect of supervised PFMT in combination with conservative treatment compared with attention-control massage treatment, which consisted of six 30 minutes sessions of massage of the neck and back over 16 weeks and conservative treatment. The primary outcome was rating of symptom changes, after 16 weeks, based on scores from the Patient Global Impression of Improvement scale.

Secondary outcomes were changes in the Vaizey incontinence score (Vaizey Score), Fecal Incontinence Severity Index, and Fecal Incontinence Quality of Life Scale.They found that participants who received supervised PFMT had 5-fold higher odds of reporting improvements in FI symptoms and had a larger mean reduction of incontinence severity based on the Vaizey score compared with attention control massage treatment.This RCT provides support for a superior effect of supervised PFMT in combination with conservative treatment compared with attention control massage treatment and conservative treatment.

Johannessen *et al.* (298), evaluated the effect of PFMT in 109 post-partum women with AI. They stratified women in a parallel two-armed RCT obstetric anal sphincter injury with primary sphincter repair and hospital affinity. The intervention group received 6 months of individual physiotherapy-led PFMT and the control group written information on PFMT. Primary outcome measures were changes in St. Mark’s scores and predictors of post-intervention AI. Secondary outcome measures were manometrymeasures of anal sphincter length and strength, endoanal ultrasound (EAUS) defect score and voluntary pelvic floor muscle contraction. There was a significant difference in the reduction of St. Mark’s scores from baseline to post-intervention in favour of the PFMT . No differences in secondary outcome measures were found between groups. The authors concluded that individually adapted PFMT reduces postpartum AI symptoms.

Biofeedback in combination with Surgery Compared to only Surgery

In an RCT including 27 women with a complaint of FI because of delivery trauma, Ghahramani *et al.* (299), evaluated the efficacy of biofeedback therapy in combination with surgery to manage FI. The patients underwent sphincteroplasty and levatorplasty via the same method by 2 colorectal surgeons. In Group I, BF was performed 3 months before and 6 months after the surgery; in Group II, BF was applied only 6 months after the surgery; and in Group III, only surgical management was performed.

The results revealed a significant difference between the preoperative and postoperative Wexner scores of incontinence in all the 3 groups. Additionally, the difference between the preoperative and postoperative scores was significant only in Group I and Group III, but not in Group II. The reduction in the Wexner score was significantly less in Group III. However, no significant difference was observed between the 3 groups concerning the mean difference of preoperative and postoperative manometry. The present study revealed no significant role for biofeedback therapy alone in the improvement of manometric evaluation. However, the Wexner score,

which is an indicator of patient satisfaction, increased with BF following sphincteroplasty.The conclusion was that currently there is no conclusive evidence for the effectiveness of BF in the treatment of FI in patients with significant sphincter defects.

Comparison of Different Biofeedback Regimes

In a RCT of 332 women and 18 men with FI Young *et al.* (300), compared the effectiveness of four different BF treatment regimes, stratifying the study population into two groups (metropolitan and rural) and then randomized into two subgroups (groups 1 and 2 within metropolitan, groups 3 and 4 within rural) with varying face-to-face and telephone BF components. All patients received standardized counselling and education, dietary modification and the use of anti-diarrhoeal medications. Group 1 received four monthly face-to-face BF treatments, groups 2 and 3 received one face-to-face BF followed by telephone BF and group 4 received a one-off face-to-face BF treatment. Primary outcomes were patient-assessed severity of FI and quality of life as assessed by the 36-item Short Form Health Survey and direct questioning of objectives. Secondary outcomes included St Mark's incontinence score, anxiety, depression and anorectal physiology measures (resting, squeeze pressures; isotonic, isometric fatigue times). All groups had significant improvements in FI, quality of life, incontinence score and mental status There were no differences in improvements in FI between groups although patient satisfaction was less with reduced face-to-face contact. There were modest improvements in isotonic and isometric fatigue times suggesting improved sphincter endurance. The authors concluded that BF is effective for FI. Although face-to-face and telephone BFis not necessary to improve FI, it is important for patient satisfaction.

Biofeedback Compared to Standard Conservative/ Medical Care

Jelovsek *et al*.(107), studied the effect of loperamide and anal muscle exercises with BF compared with oral placebo and an educational pamphlet in 300 randomly assigned women with FI. They also compared the effect of combination therapy to each individual therapy. Because oral placebo and education was compared with oral placebo and anorectal manometry-assisted BF, and loperamide plus education only, and loperamide plus anorectal manometry-assisted BF, the authors were able to compare BF with education (as a standard conservative care). At 24 weeks, there were no differences between loperamide versus oral placebo, BF versus education, loperamide and BF versus oral placebo, and BF versus loperamide plus education.

Some benefits were observed with combined treatments compared with individual treatments. Because these are common first-line treatments for FI, the authors suggested that clinicians could consider combining loperamide, anal manometry-assisted biofeedback, and a standard educational pamphlet, but this is likely to result in only negligible improvement over individual therapies and patients should be counselled regarding possible constipation.

Home Biofeedback Training

Xiang *et al.* (301), investigated if home biofeedback therapy (HBT) is non-inferior to office biofeedback therapy (OBT). Thirty patients with FI were randomized to HBT or OBT for 6 weeks. HBT was performed daily using a novel device that provided resistance training and electrical stimulation with voice-guided instructions. OBT consisted of six weekly sessions. Both methods involved anal strength, endurance, and coordination training. The study primary outcome was change in weekly FI episodes. FI improvement was assessed with stool diaries, validated instruments (FISI, FISS, and ICIQ-B), and anorectal manometry using intention-to-treat analysis.

Weekly FI episodes decreased significantly after HBT and OBT compared with baseline,. The authors concluded that HBT was non-inferior to OBT, based on significant results from the FISI and FISS scores, bowel pattern, bowel control, and quality of life (QOL) domains (ICIQ-B). Resting and maximum squeeze sphincter pressures significantly improved in both HBT and OBT groups and sustained squeeze pressure in HBT, without group differences. The authors suggest that home biofeedback is safe, effective, improves QOL, and through increased access could facilitate improved management of FI.

Electrical Stimulation

No new studies/RCTs related to ES were identified.

Table 15-5. New Evidence for the Efficacy of Biofeedback, Pelvic Floor Muscle Therapy, Electrical Stimulation, and Tibial Nerve Stimulation

First author, Year, Reference	Aims	Subjects	Study Design	Results	Comments
Sjodahl, 2014 (209)	Compare 3 conditions: EMG BF (median of 3 visits in 4-6 months); medical treatment only (1 mg loperamide 2 g fibre for 2 months); and combined BF and medical treatment	64 females aged 18+ with at least 1 episode FI in 2 weeks Excluded patients with any disease explanation for FI but allowed those with sphincter tears Analysis limited to 57 who completed study	Crossover design: Patients randomized to either BF or medical treatment in Phase 1; second treatment added in Phase 2 Anorectal manometry tested at baseline and after each treatment phase.	FI frequency did not differ between groups in Phase 1, but decreased significantly for both groups following combined treatment. Anal resting and squeeze pressures did not change significantly in either study phase.	Authors conclude that combined treatment was effective but neither BF nor medical treatment alone was effective. Study limitations: Number of BF sessions and loperamide dose are lower than most published studies. Study was not adequately powered.
Damon, 2014(302)	Compare BF to standard medical care	157 randomized but analysis was per protocol in 142 who did not drop out Trial duration was 4 months	Primary outcome was self-rating of improvement (-5 to 5). Secondary measures were diary, questionnaires, & manometry.	Significantly more BF patients met success criterion (defined as >3 on -5 to 5 scale) at 4 months.	This study supports the efficacy of home-based BF training. Limitations: data analysis in completers only (there were more drop-outs in the BF condition), and lack of long-term follow-up. A strength was that standard care followed French national guidelines and BF training protocol was developed by consensus of physical therapists.
Dehli, 2013 (303)	Compare biofeedback to dextranomer injection	126 adults with FI, minimum severity of 4 on St Mark's scale. Patients with any prior treatment for FI were excluded.	BF was performed 5 days/wk for 6 mo at home using a portable device. BF patients met with PT 5-6 times and 28/62 received supplemental ES. Anal injection of 4 ml bulking agent was repeated in 21/64 at 3 mo.	Primary assessment at 6 mo showed significant improvement in both groups but no between-group difference. Also, no difference at 24 mo. QOL also showed no between-group difference. More adverse events seen in anal injection group, but most could be prevented by antibiotic prophylaxis.	Well designed, adequately powered study showed nodifference between BF and dextranomer injection in moderately severe, treatment naïve patients. Study limitation: no minimum severity requirement for eligibility except St. Mark's score >3.

First author, Year, Reference	Aims	Subjects	Study Design	Results	Comments
Bartlett, 2015 (304)	(1) Assess accept-ability of home biofeedback (BF); (2) Compare clinic home BF to clinic-only BF	75 FI patients aged 18-80, average of 61 years	Unblinded, parallel group study of 6 wks duration All patients had 4 BF sessions in the clinic, but the home BF group practiced daily with a BF device while standard group practiced using PFMT instructions.	Supplementing BF with home practice had no overall effect but post hoc analysis found that patients younger than 61 yrs improved more when treated with home BF than with clinic-only BF; home BF was acceptable to most patients.	Daily home practice with a BF device improves FI and QOL more than standard BF with PFMT practice at home. Study limitations: Only 4 sessions of BF in clinic, which may be insufficient.
Peirce, 2013 (305)	Compare home BF to PFMT for prevention of FI in women with 3rd degree obstetric tears.	120 women with 3rd degree tears were randomized to begin EMG BF (n=30) or PFMT (n=90) prior to discharge.	All were assessed 3 months later. BF and PMTF were taught in hospital before discharge. Both groups were told to practice twice daily.	There were no between-group differences in Cleveland Clinic Continence Scores, QOL, anal canal resting or squeeze pressures.	This study shows no added value for home BF compared to PFMT. It is unclear whether either helps to prevent postpartum FI in women with obstetrical tears.
Cohen-Zubary, 2015 (306)	Compare daily electrical stimulation (ES) at home to weekly BF in the clinic on continence scores and cost.	Analysis limited to 18 in each group who completed the protocol. Eligibility required normal colonoscopy, normal ultrasound, no diabetes or other severe comorbidity.	BF was 6 weekly 30-45 min sessions for strength and sensory factors, supplemented by home PFE. ES was 25 min twice daily for 6 weeks with no clinic training.	No significant differences between groups. ES improved FI from baseline to end of treatment but BF did not. Costs were lower for ES than BF.	Authors argue that ES is at least as effective as BF, and it is less costly and more widely available.
Schwandner, 2011 (307)	Triple Therapy (3T) compared to low frequency ES	80 patients with FI of any severity including gas only	Two 20-min sessions per day for 6 months For 3T group, morning BF session included alternating between ES and voluntary Contraction. Afternoon session involved medium frequency ES triggered by voluntary contractions above a threshold determined by ability. Control group received low frequency ES in both sessions each day.	Cleveland Clinic scores improved more in 3T than in low frequency ES at 3 and 6 months QOL was also significantly better in 3T group. 54% of 3T group were continent at 6 mos. vs. none in the low frequency ES group. The attrition rate was low in this trial (8% in the 3T group vs. 15% in the low frequency ES group).	3T was superior to low frequency ES and was better tolerated. Limitation: Trial could not be blinded, and 6 mos. of twice daily practice may be more than most patients will tolerate.

First author, Year, Reference	Aims	Subjects	Study Design	Results	Comments
Schwandner, 2010 (308)	9 mos of twice daily ES combined with EMG BF (3T) compared to EMG BF only	158 patients from 8 sites were enrolled. Severity varied from loss of flatus only to solid or liquid stool loss.	For 3T protocol, see above. Control group received only EMG BF in morning and afternoon.	3T group improved significantly more than BF only group (8 points vs. 3 points) improvement on Cleveland Clinic scale from baseline to 9 months. More subjects dropped out in the BF only group. Significant differences between groups did not emerge until 6 mos. of twice daily therapy. Dropout rate was higher in BF only group.	Data show 3T is superior to EMG BF only, but the high burden of undergoing training twice daily for at least 6 mos. may be a limitation.
Leroi, 2012 (309)	Compare TTNS to sham ES	144 patients with FI >1/week and no response to conservative treatment were recruited from 9 centres in France.	Multisite RCT; Patients used battery operated stimulator twice daily at home for 3 mo. Electrodes were on calf and ankle in both active and sham groups. No current was used for sham group. Primary outcomes were frequency of FI and urgency/week. QOL and time to defer defaecation was also measured.	No significant differences between groups on any outcome. Active TTNS tended to show greater decreases in frequency of FI and urgency, but differences were not significant.	TTNS showed no evidence of efficacy in this large RCT.
George, 2013 (310)	Comparison of PTNS, TTNS, and sham TTMS in parallel groups	30 patients with >2/ week episodes of FI were randomly assigned to 3 groups.	RCT conducted at one centre. 12 treatment sessions scheduled 2/week for 6 weeks. Primary outcome was >50% reduction in FI frequency.	PTNS but not TTNS patients improved significantly more than sham group on number with >50% decrease in FI, number of FI episodes per week, and ability to defer defaecation. No differences in QOL or St Mark's scale.	Underpowered study which nevertheless suggests PTNS is superior to TTNS and sham.
Knowles, 2015 (311)	Comparison of PTNS to sham ES	Inclusion based on FI sufficiently severe to warrant intervention as recommended by PI at each of 17 sites and failure to respond to conservative treatment.227 women were randomized.	RCT comparing 12 sessions of PTNS to 12 sessions of sham (ES between 2 electrodes on one foot). Responder was defined by >50% decrease in FI frequency on diary.	Responder rates were no different (38% for PTNS, 31% for sham, N.S.). However, FI frequency decreased significantly more in PTNS group, especially in patients with urge-related FI.	This RCT fails to support the efficacy of PTNS, but the differences seen in secondary outcomes make it unclear whether PTNS may have a specific benefit for urge FI. Further research is needed.

First author, Year, Reference	Aims	Subjects	Study Design	Results	Comments
Thin, 2015 (312)	Pilot study aimed to estimate effect sizes for SNS vs. PTNS as well as acceptability of these treatments to patients	FI patients meeting NICE criteria for SNS and PTNS were randomized: 23 to SNS and 17 to PTNS (unbalanced to allow for failure of trial stimulation in 25%). Qualitative interviews were done in 5 patients from each group.	SNS and PTNS followed standard protocols. 15 30-min PTNS sessions over 5 months Assessed at baseline, 3, and 6 months after end of treatment Within group effect sizes were estimated but between-group differences were not tested.	19 patients underwent temporary SNS and 15 had permanent implants. 16 received all 15 PTNS sessions. At 6 months, ITT analysis showed 61% of SNS and 40% of PTNS patients had >50% reduction in FI. Significance of between group differences were not tested.	Both SNS and PTNS significantly improved FI. Effect sizes tended to be larger in SNS, but a definitive RCT comparing SNS to PTNS would require a sample size that is not feasible. Both treatments were acceptable to patients but some preferred one over the other.
Glazener, 2014 (313)	Assess 12 year FU of study comparing brief PFMT to standard care for UI and FI	747 women with UI 3 months after vaginal delivery. 15.7% also reported FI at study initiation.	Nurses taught PFMT in 3 home visits 5, 7, and 9 months after delivery. Controls received standard medical care. FU was at 1, 6, and 12 years.	FI rate was significantly lower after PFMT at 1 year (4% vs. 11%, p= .01), but not at 12 years (19% vs. 15%, p=.22). 52% were still using PFMT after 12 years.	Benefits of PFMT at 12 mos. were not evident 12 years later. Study limitations: 12-year follow up is of questionable relevance. FI increases with age, and in 12 years women may try other treatments.
Peirce, 2013 (305)	Compare home BF to PFMT for prevention of FI in women with 3rd degree obstetric tears	120 women with 3rd degree tears were randomized to begin EMG BF (n=30) or PFMT (n=90) prior to discharge.	All were assessed 3 months later. BF and PMTF were taught in hospital before discharge. Both groups were told to practice twice daily.	There were no between-group differences in Cleveland Clinic Continence Scores, QOL, anal canal resting or squeeze pressures.	This study shows no added value for home BF compared to PFMT. It is unclear whether either helps to prevent postpartum FI in women with obstetrical tears.
Lin, 2016 (314)	(1) Test whether FI improves with time following LARS for rectal cancer; (2) determine whether PFMT augments improvement	60 patients in Taiwan with rectal cancer were randomised to PFMT instructional DVD pamphlet or pamphlet alone.	PFMT taught just before hospital discharge. Weekly phone calls for first month in both groups. FU at 1, 3, 6, and 9 months	FI severity (CCI scale) decreased over time and was significantly less in PFMT group vs. controls at 1, 3, and 6 month FU. No difference at 9 months	Persuasive evidence that brief PFMT training plus a pamphlet and DVD accelerates improvement in FI following LARS procedure.
Laforest, 2012 (315)	Test whether BF improves functional outcomes more than PFMT following laparoscopic rectal resection for cancer	22 patients undergoing total mesorectal excision for rectal cancer was provided BF 3 mos. after surgery. Matched controls were selected from a registry.	Cohort study. BF group received 15 weekly sessions. PFMT group received one session of training. Assessed 8-46 mos. after surgery.	No differences in FI severity but BF group reported less dyschezia and greater improvement in QOL.	Authors conclude BF conferred a benefit in functional outcomes and QOL over PFMT alone. Study limitations: Cohort design does not match groups for time and attention. PFMT group may have had lower expectations because they were not study participants.

Ghahramani 2016 (299)	Evaluation of the efficacy of BF in combination with surgery in the management of FI	27 women with FI because of delivery trauma	RCT. 3 groups via the permuted block randomization method. Group I, BF 3 months before and 6 months after surgery. Group II, BF only 6 months after surgery. Group III, only surgery (sphincteroplasty and levatorplasty) without BF	Significant difference between preoperative and postoperative FI Wexner scores in all groups. Sign. difference between preop and postop scores only in Group I and III, but not in Group II. No significant difference between groups in mean difference preop-postop. manometry	No significant role for BF alone in manometry improvement, but yes in Wexner (patient satisfaction). following sphincteroplasty. Important development!
Young 2017 (300)	Comparison of effectiveness of four different BF regimes	350 patients with FI (332 women, 18 men)	RCT: stratified into metropolitan and rural) then randomized into two subgroups (groups 1 and 2 within metropolitan, groups 3 and 4 within rural) with varying face-to-face and telephone BF components. All standardized counselling and education, dietary modification and anti-diarrhoeal medications. Primary outcome: 36-item Short Form Health Survey	All groups had significant improvements in FI, quality of life, incontinence score and mental status. No differences in improvements in FI between groups although patient satisfaction less with reduced face-to-face contact. Modest improvements in isotonic and isometric fatigue times suggesting improved sphincter endurance	BF effective for FI. Although face-to-face and telephone BF is not necessary to improve FI, it is important for patient satisfaction
Jelovsek 2019 (107)	Comparison of different combinations of anorectal manometry-assisted BF, loperamide, education, and oral placebo	300 women with FI at least 1x/month during last 3 months. (education n-42; placebo+BF n=84; lop+ed n=88; lop+BF n=86)	RCT: randomly assigned 0·5:1:1:1. BF six visits, including strength and sensory BF ; (placebo) lop 2 mg/day with option change). primary endpoint Vaizey score 0-24 weeks; intention-to-treat.	At 24 weeks, no differences between lop vs placebo (model estimated score change –1·5 points, 95% CI –3·4 to 0·4, p=0·12), BF vs ed (–0·7 points, –2·6 to 1·2, p=0·47), and lop and BF vs placebo and BF(–1·9 points, –4·1 to 0·3, p=0·092) or vs lop+ed (–1·1 points, –3·4 to 1·1, p=0·33)	Clinicians could consider combining lop, anal manometry assisted BF, and a standard educational pamphlet, but this is likely to result in only negligible improvement over individual therapies

First author, Year, Reference	Aims	Subjects	Study Design	Results	Comments
Xiang 2021 (301)	Investigation if home BF training (HBT) is non-inferior to office BF training (OBT)	30 (F/M = 26/4) FI patients (20 in HBT, 10 in OBT)	RCT: 6 weeks HBT daily using novel device that provided resistance training and ES with voice-guidedinstructions. OBT 6 weekly sessions. Both methods involved anal strength, endurance, and coordination training. Primary outcome change in weekly FI episodes	Weekly FI episodes decreased significantly after HBT (Δ ± 95% CI: 4.7 ly FI episodes decreased signifp = 0.003) and OBT (3.7 reased p = 0.0003). HBT non-inferior to OBT (p = 0.2). Resting and maximum squeeze sphincter pressures sign. improved in HBT and OBT and sustained squeeze pressure in HBT, without group differences	Home biofeedback is safe, effective, improves QOL, and through increased access could facilitate improved management of FI.
Ussing 2019 (297)	Investigation whether supervised PFMT in combination with conservative treatment is superior to attention-control massage treatment and conservative treatment in adults with FI (FI)	98 patients with FI (F/M 89/9)	RCT: Group I: supervised PFMT +BF + conservative treatment 6 sessions 45min each intensive PFMT. Group II: attention-control treatment + conservative treatment. 30 minutes of massage of neck and back. Participants no instructions in PFMT. Primary outcome was rating of symptom changes, after 16 weeks, based on scores from the Patient Global Impression of Improvement scale. Secondary outcome Vaizey score. Intention-to-treat.	PFMT group significantly improvement in FI symptoms based on Patient Global Impression of Improvement scale scores (unadjusted odds ratio, 5.16; 95% CI, 2.18–12.19; p=.0002). PFMT group larger reduction in the mean Vaizey Score (reduction, -1.83 points; 95% CI, –3.57 to –0.08; (p= .04). No significant differences in condition-specific quality of life.	Participants who received supervised PFMT had 5-fold higher odds of reporting improvements in FI symptoms and had a larger mean reduction of FI severity based on the Vaizey Score compared with attention control massage treatment

First author, Year, Reference	Aims	Subjects	Study Design	Results	Comments
Johannessen 2017 (298)	Evaluation effect of PFMT for postpartum AI	109 post-partum women	Parallel two-armed RCT stratified on obstetrical anal sphincter injury with primary sphincter repair and hospital affinity. Intervention group 6 months of individual physiotherapy-led PFMT and the control group written information on PFMT. Changes in St. Mark's scores and predictors of post-intervention AI were assessed by independent samples t-tests and multiple linear regression analyses, respectively. Study not blind.	Significant difference in reduction St. Mark's scores from baseline to post-intervention in favour of PFMT (2.1 versus 0.8 points, p = 0.04). No differences in secondary outcome measures between groups. Baseline St. Mark's, PFMT group affinity and EAUS defect score predicted post-intervention St. Mark's score in the imputed intention-to-treat analyses. Analysis on unimputed data showed that women performing weekly PFMT improved their AI scores > women in controls	PFMT was not commenced until patient able to perform correct voluntary pelvic floor muscle contraction (VPFMC) Individually adapted PFMT reduces postpartum AI symptoms
Horrocks 2015 (316) Similar RCT as Knowles et al. 2015 (311) (CONFIDeNT trial)	Comparison of PTNS to sham ES in patients with FI in whom initial conservative strategies have failed	Inclusion based on faecal incontinence sufficiently severe to warrant intervention as recommended by PI at each of 18 sites and failure to respond to conservative treatment. 227 women were Randomized, 115 PTNS; 112 sham PTNS	RCT comparing 12 sessions of PTNS with Urgent® PC device (Uroplasty Limited, Manchester, UK) to 12 sessions of sham (ES between2 electrodes on one foot). Responder was defined by >50% decrease in FI frequency on diary.	Responder rates were no different (38% for PTNS, 31% for sham, N.S.). However, FI frequency decreased significantly more in PTNS group, especially in patients with urge-related FI	This RCT fails to support the efficacy of PTNS, It would be difficult to recommend this therapy for the patient population studied. Further research will concentrate on particular subgroups of patients, for example those with pure urge FI

First author, Year, Reference	Aims	Subjects	Study Design	Results	Comments
Van der Wilt 2017 (317)	Comparison of PTNS to sham ES in patients with FI in whom initial conservative strategies have failed for at least 6 months. Failure to control FI with loperamide was not a specific criterion for inclusion	59 (F/M 51/8)patients > 18 years with FI to solid or liquid stool causing significant disruption to lifestyle.,	Multicentre, single-blinded RCT. PTNS n=29(24/5); sham 30(27/3). Urgent® PC. First 6 weeks, all patients underwent 30min 2x/week, and 30min 1x/week in 3 weeks thereafter. All patients 15 treatment sessions Primary endpoint reduction in median or mean number FI/week. Secondary endpoints FI severity, and disease-specific and generic QoL compared between PTNS and sham stimulation after 9 weeks treatment	> PTNS (13 of 29) than sham (6 of 30) group reduction ≥ 50 % median number FI//week (incidence rate ratio (IRR) 2·40, 95 per cent c.i. 1·10 to 5·24; P = 0·028), but not in mean number episodes/week (10 of 29 vs 8 of 30; IRR 1·42, 0·69 to 2·92; p =0·347). Absolute median number FI/ week decreased in PTNS but not in sham (IRR 0·66, mean number (IRR 0·65 (0·45 to 0·97); p = 0·034). 0·44 to 0·98; p = 0·041. Secondary outcomes pre-post sign. > in PTNS, not in sham.	PTNS may offer a small advantage in the clinical management of FI that is insufficiently responsive to conservative treatment. The key challenge will be to identify patients who may benefit most from this minimally invasive surgical procedure.

Systematic Reviews and Meta-Analyses

Table 15-6 lists the systematic reviews and guidelines documents published since January 2016 that address the use of BF, ES, and PFMT for the treatment of FI. The Cochrane review of Woodley *et al.* (318), reported hat it was uncertain whether PFMT reduced incontinence in the late postnatal period compared to usual care and that there was little evidence about PFMT effects on FI beyond 12 months' postpartum.

The review of Lal *et al.* (319), included 60 RCTs reporting on 4838 patients with mean ages ranging from 36.8 to 88 years. From the included RCTs, 32 did not identify a significant difference between the treatments compared. Contradictory results were identified in RCTs comparing BF-PFMT versus PFMT. Combination treatment of amplitude-modulated medium frequency stimulation and EMG-BF was noted to be superior to EMG-BF and low-frequency electrical stimulation alone.

Tibial Nerve Stimulation

In a double-blind RCT of 227 patients with FI in whom initial conservative strategies had failed Horrocks *et al.* (316), assessed the effectiveness of PTNS via the Urgent® PC device (Uroplasty Limited, Manchester, UK) for 30 minutes weekly for a duration of 12 treatments compared with sham ES. The primary outcome classified patients as responders or non-responders, with a responder defined as someone having achieved ≥e50% reduction in weekly FI episodes (FIEs). For the secondary outcomes, significantly greater decreases in weekly FIEs were observed in the PTNS arm than in the sham arm, comprising a reduction in urge FIEs rather than passive FIEs. No significant differences were found in the St Mark's Continence Score or any quality-of-life measures. No serious adverse events related to treatment were reported. The authors concluded that PTNS did not show significant clinical benefit over sham electrical stimulation in the treatment of FI based on number of patients who received at least a 50% reduction in weekly FIE. It would be difficult to recommend this therapy for the patient population studied.

Knowles *et al.* (311), reported on the same double-blind, multicentre, pragmatic, parallel-group, RCT of 277 adult patients in whom conservative treatments had not worked. Van der Wilt *et al.* (317), in an RCT assessed the effects of PTNS in 59 adult patients CT. The primary endpoint was reduction in the median or mean number of FI episodes per week. Secondary endpoints were changes in measures of FI severity, and disease-specific and generic quality of life. Outcomes were compared between PTNS and sham stimulation after 9 weeks of treatment. A higher proportion of patients in the PTNS (13 of 29) than in the sham (6 of 30) group showed a reduction of at least 50 per cent in the median number of FIEs/week but not in the mean number of episodes/week (10 of 29 vs 8 of 30). The absolute median number of FI episodes per week decreased in the PTNS but not in the sham

group. Scores on the Cleveland Clinic Florida FI scale decreased significantly in both groups, but more steeply in the PTNS group.

Van der Wilt *et al.*(317), concluded that PTNS may offer a small advantage in the clinical management of FI that is insufficiently responsive to conservative treatment and that the key challenge will be to identify patients who may benefit most from this minimally invasive procedure.

Table 15-6. New Systematic Reviews of the Efficacy of Biofeedback, PFMT, Electrical Stimulation, and Tibial Nerve Stimulation

First Author, Year, Reference	Aims/Scope	Analysis Sample	Conclusions Level of Evidence	Comments
Norton, 2012 (Update of Cochrane 2003) (320)	Determine effects of biofeedback (BF) and/or pelvic floor exercises (PFMT) in adults	1525 subjects in 21 studies	While there is a suggestion that some elements of BF and sphincter exercises may have a therapeutic effect, this is not certain. Larger well-designed trials are needed to enable safe conclusions.	Treatment protocols, outcome measures, and training of providers varied across trials. Risk of bias was judged to be low in 13/21 trials.
Rao, 2015 (321)	Define indications, training protocols, and efficacy of BF	731 patients (11% males) in 8 studies	BF is recommended for short-term & long-term treatment of FI; Level II recommendation; Grade B evidence.	Treatment protocols, outcome measures, and training of providers varied across trials. Risk of bias was not assessed.
Berghmans, 2015 (322)	Assess efficacy of BF alone or combined with PFE or ES	Not described 13 RCTs and Norton's Cochrane review are cited in the narrative summary.	BF PFE appears to be more effective than PFE alone, and BF ES appears to be more effective than ES alone. Level 3 evidence	
Vonthein, 2013 (295)	Assess efficacy of BF, ES, and/or BF ES	13 studies met criteria. Primary outcome was remission of FI.	BF was superior to all control groups but ES was not. BF ES was superior to BF alone or ES alone. BF ES is recommended as second line treatment for FI.	Only 3/13 trials met all quality criteria and 2/3 were by one of the authors, suggesting possible bias. 4 other studies rated as being of moderate quality. Type of ES was important: amplitude modulated medium frequency ES was superior to low frequency ES.
Rao S, Am College of Gastroenterology Practice Parameters Committee, 2004 (323)	Assess efficacy of BF for faecal Incontinence in adults Broader goals of review were evaluation of reliability of diagnosis and efficacy of treatment for all benign anorectal disorders	Not described	Pelvic floor rehabilitation with BF and PFE is superior to PFE alone in patients with faecal incontinence who do not respond to conservative measures.	
Visser, 2014 (324)	Assess efficacy of BF for FI secondary to low anterior resection for rectal cancer (LARS)	321 patients in 5 studies	Pelvic floor rehabilitation with BF and/or PFE improves functional outcomes after low anterior resection for cancer.	Quality of these studies was rated as low.
Horrocks, 2014 (296)	Assess efficacy of percutaneous and transcutaneous PTNS	375 patients in 12 studies, including 2 RCTs which had good quality Ratings Review predates large RCT of PTNS	TTNS was no better than sham in large RCT. However, in a second RCT comparing PTNS to TTNS and sham TTNS, PTNS was significantly more effective than TTNS, which was significantly more effective than sham ES.	RCT comparing PTNS to TTNS and sham was underpowered with 10 patients per arm.

First Author, Year, Reference	Aims/Scope	Analysis Sample	Conclusions Level of Evidence	Comments
Woodley 2017 (318)	Assess effectiveness of PFMT in the prevention or treatment of FI in pregnant or postnatal women	6 (quasi-)RCTs, one arm including PFMT, other arm no PFMT, usual antenatal or postnatal care, another control condition, or an alternative PFMT intervention ,	There are insufficient data on FI to state whether or not PFMT is effective to prevent or treat this problem in pregnant or postpartum women.	First, the lack of FI data was obvious. It is acknowledged that assessing the long-term effects of PFMT is challenging, as women may go on to have subsequent pregnancies,be offered a specific PFMT programme if they had taken part in the control arm of a trial or initiate their own PFMT
Lal 2019 (319)	Comparison of treatments for FI in adults	4838 patients in 60 RCTs	32 RCTs no significant difference between treatments compared. Contradictory results in RCTs comparing PTNS and TTNS vs sham stimulation, BF-PFMT vs PFMT, In two separate RCTs, combination treatment of amplitude-modulated medium frequency stimulation and EMG-BF, superior to EMG-BF and low-frequency ES alone. Combination of non-surgical treatments such as BF with sphincteroplasty sign.> continence scores compared to sphincteroplasty alone. Surgical treatments higher rates serious adverse events compared to non-surgical interventions	Current evidence no sign. differences between treatments for FI, and where differences identified, contradictory results between RCTs

Summary of Pelvic Floor Muscle Training, Biofeedback, and Electrical Stimulation

- Some studies support the hypothesis that biofeedback augmented by PFMT, when provided by an experienced therapist, is more effective than PFMT alone, but studies suggest that results may be dependent on the training and experience of the therapist (Level of Evidence 1).
- PFMT is possibly effective for the treatment of FI. Studies comparing PFMT alone to BF augmented by PFMT and ES have shown mixed results, and the optimal protocol for teaching PFMT has not been standardised, limiting the generalizability of findings (Level of Evidence 2). There is some evidence that BF may enhance the outcome of standard medical care (Level of Evidence 2).
- Home practice of BF and/or ES using battery-operated portable devices, appears to improve treatment outcomes when compared to clinic-based treatment. Younger patients may benefit more from home practice than older patients, and it may take up to 6 months to see benefits from home practice (Level of Evidence 2).
- Mixed results suggest that low frequency ES is weakly effective or ineffective when used alone, or in combination with BF. However, findings from a single group suggest that the Triple Therapy protocol involving electrical stimulation at a frequency of 3000 Hz combined with BF, when practiced twice daily for at least 6 months, may be more effective than biofeedback alone or low frequency (100 Hz) electrical stimulation alone (Level of Evidence 2).
- Despite mixed results and varying quality of studies, percutaneous electrical stimulation of the tibial nerve might be a possibly effective approach to the treatment of FI (Level of Evidence 2). There may be a small advantage in the treatment of FI when there is insufficient initial response to other conservative treatment (Level of Evidence 2).

Recommendations for Clinical Related to Pelvic Floor Muscle Training, Biofeedback, and Electrical Stimulation

- PFMT should be recommended as an early intervention in the treatment of FI as part of a conservative management bundle of interventions, based upon low cost, low morbidity, and at least weak evidence of efficacy (Grade of Recommendation B).
- Biofeedback, usually combined with PFMT and sensory training with a rectal balloon, is recommended as second line treatment for FI after other behavioural and conservative/medical management have failed to provide adequate symptom relief (Grade of Recommendation A).
- Biofeedback training may employ either pressure sensors or electromyographic (EMG) electrodes to provide feedback on pelvic floor muscle contractions. (Grade of Recommendation = C). Home biofeedback using portable battery-operated device may be recommended as an adjunct to biofeedback training in the clinic, especially for younger patients (Grade of Recommendation B).
- Based on currently available evidence it is not possible to recommended low frequency of (i.e., 100 Hz) electrical stimulation for FI. The Triple Therapy protocol for combining biofeedback with 3000 Hz electrical stimulation appears to be effective, but this recommendation is tentative pending confirmation of the findings by other research groups (Grade of Recommendation B).
- Percutaneous tibial nerve stimulation cannot currently be recommended for clinical practice (Grade of Recommendation B).

Recommendations for Research on Pelvic Floor Muscle Training, Biofeedback, and Electrical Stimulation

There is a need to conduct further RCTs to determine which specific biofeedback protocols alter physiological parameters of anorectal function with concomitant changes in bowel control. These studies should address:

- Clear description of modalities and evaluation of different components of BF
- Long term follow up
- Adherence monitoring
- Standardisation of outcome measures
- Exploration of possible synergies between urinary and FI interventions and diagnostic evaluations
- Standardisation of protocols for teaching PFMT are needed.
- Pelvic floor rehabilitation, as practiced by physical therapists for the treatment of FI, is not adequately described in the medical literature. Can this be standardized that it can be compared to biofeedback and to the PFMT protocols described in the literature?
- Compare the effectiveness of PFMT taught by verbal or printed instructions (as is commonly done) to PFMT taught during digital rectal examination.
- Standardise techniques for teaching PFMT via digital rectal examination.
- RCTs of the Triple Therapy protocol or other ways of combining electrical stimulation with biofeedback are needed.
- Investigate different modalities of ES, specifically distinguishing high frequency stimulation (e.g., 3000 Hz) from low frequency (e.g., 100 Hz) stimulation.
- Investigate ways to shorten the amount of training required to see benefits for FI.
- Percutaneous tibial nerve stimulation requires additional randomised controlled trials, specifically addressing:
  - Whether urgency associated FI is more responsive to treatment than passive FI and why this might be the case
  - Patient characteristics and physiological mechanisms associated with successful PTNS vs BF or PTNS vs ES or PTNS vs controls

VII. SPECIAL DIAGNOSIC TESTING FOR SECONARY AND TERTIARY MANAGEMENT OF FI

1. ANORECTAL FUNCTION TESTS (ANORECTAL MANOMETRY, THE RECTAL SENSORY TEST, AND THE BALLOON EXPULSION TEST)

1.1. Introduction

When the initial conservative management of FI fails to improve symptoms sufficiently, specialised diagnostic testing to assess the causes of FI and assist in stepwise selection of appropriate treatment is indicated (23, 325). Anorectal function tests (AFTs) (anorectal manometry [ARM], the rectal sensory test [RST] and the balloon expulsion test [BET]) are the most commonly used investigations for evaluation of anorectal function. ARM records mechanical activity of the distal rectum and anal canal through measurement of changes in intraluminal pressure, the RST evaluates parameters of perceived rectal filling though distension of the rectum, and the BET describes evacuation though measurement of ability to expel an intra-rectal balloon (326). Previously considered as tests performed and reported separately, recent consensus by the International Anorectal Physiology Working Group has recommended that these investigations are now considered as complementary and interpreted together to reflect the understanding that symptoms of incontinence and evacuatory difficulty are commonly generated secondary dysfunction of multiple parts of the anorectal unit (327).

1.2. Indications

Anorectal function tests are typically indicated during the assessment of patients with FI to facilitate the evaluation of rectoanal sensorimotor function, typically at the point of triage to advanced therapies. They are also indicated in the evaluation of patients with symptoms of constipation/evacuatory dysfunction (which co-exists in 41% of patients presenting with incontinence (328), during investigation of symptoms of functional anorectal pain, as part of preoperative assessment of anorectal function (where intervention may impact on the continence mechanism [e.g. sphincter repair, fistulectomy, rectopexy]) and in patients following an obstetric anal sphincter injury (327).

1.3. Test Specifications

1.3.1. Anorectal Manometry

Several ARM techniques exist. At the time of the 6th ICI, conventional ARM (reporting data from single points within the anal canal utilising catheters containing fewer than 6 sensors) prevailed (329). Although these systems are still available for use in clinical practice, the technology has advanced with the development of portable bedside systems (330, 331), and high-resolution / high-definition techniques. High-resolution anorectal manometry (HRAM) and High-definition anorectal manometry (HDAM) have the advantage of capturing data from the entire length of the anal canal and distal rectum using catheters containing between 12 to 256 sensors (332-334). These data are displayed in real time as colour contour plots which facilitate a more intuitive phenotypic interpretation. Emerging studies suggest high resolution measurements may offer diagnostic benefit over conventional ones (335, 336). Additionally, HDAM which allows 3D visualisation of pressure data, improves appreciation of functional sphincter morphology (337-340). Few data exist to suggest superiority of one catheter configuration over another, however it is generally accepted that studies should be performed with catheters that have a recording length of 6 cm and measure circumferential (as opposed to unidirectional) pressure (335).

ARM studies are typically performed in the left lateral position (even though recent evidence suggests that studies performed in the seated position may provide a more accurate description of recto-anal coordination (341, 342). A digital rectal examination prior to intubation not only excludes faecal loading, pain, and structural abnormalities; but also allows the clinician to check the patient's understanding of manoeuvre commands (push and squeeze). The catheter is then positioned so that the sensors span the length of the anal canal and distal rectum and a standard series of manoeuvres are performed which evaluate anorectal reflexes, anal tone and contractility and rectoanal coordination (see section 1.5 below) (327).

1.3.2. The Rectal Sensory Test

The RST is performed following anorectal manometry in the left lateral position and measures patient-reported sensory thresholds to ramp or phasic distension of a balloon with air (343). A commer-

cially available, latex-free balloon (often integrated within the ARM system) is placed within the rectum 3 - 5cm cm above the upper border of the anal canal. The balloon used should have a capacity of no less than 400mls and insufflation with air should be performed at a rate of between 1 - 5 mls per second.

1.3.3. The Balloon Expulsion Test

The BET measures the ability of a patient to evacuate a balloon from the rectum. Following the RST, a customised latex-free balloon mounted on a flexible catheter is placed inside the rectum and filled with 50mls of tepid water. The patient then sits on a commode and the time taken to expel the balloon is measured (344). Should local facilities exist, alternative investigations such as defaecation proctography / MR defaecography as an addition to the BET to describe evacuation in more detail.

1.4. Study Protocol

Recommendations for the performance of anorectal function tests were developed and published following consensus driven by the International Anorectal Physiology Working Group in 2019. This protocol outlines a standardised sequence of manoeuvres for all 3 AFTs and describes the suggested measurements to be reported. Of note, specific normal values were not recommended to the variability in equipment and patient population. Description of normality should be based on published data or local study of control subjects (327).

Recommended study protocol:

- *Stabilisation period:* After intubation, a 3-minute period of stabilisation is recommended to allow anal pressure to return to baseline. No measurements are reported during this manoeuvre.
- *Rest:* This evaluates anal tone and represents the composite pressure generated by the internal anal sphincter (which accounts for approximately 70% of the anal pressure during the relaxed state), external anal sphincter and the anal cushions [71] Measurements are taken while the patient is relaxed to avoid excessive contributory effects of the voluntarily controlled external anal sphincter. A 60-second period of rest is measured with quantitative measures and qualitative descriptors of anal tone reported.
- *Short squeeze:* This describes anal contraction strength which is predominantly generated by voluntary contraction of the external anal sphincter and puborectalis (345). Three short squeezes each of 5-second duration are performed. Following each short squeeze, a 30-second recovery period is allowed. The strongest manoeuvre is used for analysis and quantitative measures (the incremental increase in pressure over baseline rest) are reported.
- *Long squeeze:* This describes voluntary anal sphincter fatigability which is a commonly used as a target measurement in biofeedback (346, 347). A single 30-second squeeze is performed, followed by a 60-second recovery period. Quantitative measures of anal contractile fatiguability are recorded.
- *Cough:* This describes the reflex response of the anus to a sudden Valsalva manoeuvre (348). Two single coughs are performed, each separated by a 30-second recovery interval, with the best manoeuvre used for analysis. Quantitative and qualitative descriptions of both anal and rectal pressure are reported to describe the rectal pressure increase and reflex anal contractility.
- *Push:* This describes rectoanal coordination during simulated evacuation (349). Elevation of rectal pressure during Valsalva together with a reduction in anal pressure is considered a 'normal' rectoanal gradient, although paradoxical contraction or failure to relax the anal sphincter is frequently seen in healthy controls (350-352). Three pushes each of 15-second duration are performed, during which the patient is asked to bear down as if to evacuate. Following each push, a 30-second recovery period is observed, and the most phenotypically 'normal' manoeuvre is used for analysis. Quantitative measures of rectal pressure changes (propulsion) and anal pressure changes (if abnormal described as dyssynergia) are reported.
- *The rectoanal inhibitory reflex:* During this manoeuvre, rapid distension of the rectum is used to elicit reflex relaxation of the internal anal sphincter which manifests as a reduction of anal pressure (353). With the patient relaxed during recording of anal tone, the rectal balloon is quickly inflated and presence / absence of reflex reduction in anal pressure is qualitatively noted.
- *The rectal sensory test:* This measures consciously perceived sensory thresholds to progressive distension of an intrarectal balloon. Three measurements are described, the first constant sensation volume, the defaecatory desire volume and the maximum tolerated volume.
- *The balloon expulsion test:* This manoeuvre describes parameters of evacuation, also described as defaecation dynamics and is used to compliment the push manoeuvre during the description of recto-anal coordination. Agreement between these two tests is required before results are considered significant because a considerable number of healthy controls display abnormal patterns of rectoanal coordination by ARM (350). Quantitative features of evacuation are described.

1.5. AFT Measurements

The measurements used to describe outcomes of AFTs described in Table 1 (354). These measurements are used to describe physiological phenotypes described according to the London Classification in section 1.7 below.

1.6. The London Classification

The newly published London Classification is a diagnostic algorithm that uses the combined findings of AFTs to describe results from ARM, the RST and the BET. The classification is divided into four parts: I - disorder of the rectoanal inhibitory reflex; II - disorders of anal tone and contractility; III - disorders of rectoanal coordination and IV - disorders of rectal sensation (327). Within each part of the classification, findings are classified as major, minor, or inconclusive. Despite using newly introduced terminology, these diagnoses describe physiological phenotypes described in previously published literature. Each part of the classification is described below.

1.6.1. Disorder of the Rectoanal Inhibitory Reflex

Anorectal areflexia describes loss of the rectoanal inhibitory reflex. Classically, absence of this reflex is used as a screening tool for diagnosis of Hirschsprung's disease (355). Although anorectal areflexia is not classically associated with FI, studies have demonstrated alteration of the rectoanal inhibitory reflex morphology in patients with both idiopathic FI (356), and in patients with FI associated with neurological conditions such as scleroderma (357), and multiple sclerosis (358). Secondary anorectal areflexia (absence of the RAIR at low distension volumes) may be seen in patients with megarectum (359).

1.6.2. Disorders of Anal Tone and Contractility

Disorders of anal tone and contractility are commonly seen in patients with FI (328). Anal hypotonia is seen in approximately 10% of males and 20% of females with FI (360). It is particularly associated with symptoms of passive leakage (15), and is commonly associated with morphological abnormalities of the internal anal sphincter (361), and with rectal intussusception / prolapse (362,

363). Anal hypocontractility is typically associated with symptoms of faecal urgency (15) and may be associated with structural defects of the external sphincter (364, 365). In addition, endurance squeeze pressure (a measurement recommended to assist as an additional descriptor of sphincter fatiguability, though not utilised in the Classification) is significantly shortened in patients with incontinence (346), and is commonly used as a target for manometric biofeedback (118).

1.6.3. Disorders of Rectoanal Coordination

Although more commonly seen in patients presenting with primary symptoms of constipation, over 20% of patients with FI have functional abnormalities of evacuation (328). Recent studies have demonstrated that anorectal manometry alone is of limited accuracy for discriminating between symptomatic patients and healthy controls (350), the London Classification requires agreement between anorectal manometry and balloon expulsion for findings to be considered significant. In patients with overflow incontinence, disorders of evacuation commonly underlie their symptoms (323). Furthermore, interventions to improve emptying are commonly used to treat children and adults with incontinence secondary to incomplete evacuation (366, 367). As the London Classification is relatively contemporary, the incidence and particular importance of individual disorders of rectoanal coordination (abnormal evacuation with poor propulsion, abnormal evacuation with dyssynergia and abnormal evacuation with poor propulsion and dyssynergia) is yet to be described, however aspects of each could be considered as targets for interventions such as behavioural training with biofeedback.

1.6.4. Disorders of Rectal Sensation

Disorders of rectal sensation contribute to the development of FI. Rectal hypersensitivity is seen in 44% patients with faecal urgency (94), and may be associated with abnormal rectal compliance, not only in patients with idiopathic incontinence (94), but also in inflammatory bowel disease and fibrotic or inflammatory conditions affecting the rectal wall (e.g. post radiotherapy (368) (369). Rectal hypersensitivity can be successfully modulated with pharmacological therapies such as loperamide (370), sensory biofeedback (371), and neuromodulation (34). Rectal hyposensitivity is less commonly seen in FI, however it has been described in up to 18% of male patients with concurrent constipation (372).

New Evidence about Anorectal Function Tests

- Anorectal function tests (anorectal manometry, the rectal sensory test and the balloon expulsion test) should now be performed and interpreted as complimentary investigations
- The London Classification describes a standardized method and nomenclature for describing the results of these tests
- Emerging evidence suggests that novel metrics derived from high resolution anorectal manometry may improve diagnostic accuracy; however, these are yet to be incorporated into recommended measurement protocols

Summary of Anorectal Function Tests

- Anorectal function tests are indicated to facilitate the evaluation of rectoanal sensorimotor function prior to advanced tertiary level interventions and following an obstetric anal sphincter injury. There are several anorectal function tests available and results of three of the most common ones (anorectal manometry, the rectal sensory test and the balloon expulsion test) should be interpreted together (Level of Evidence C).
- The London Classification offers a guide for standardizing interpretation of anorectal function tests (Level of Evidence C).

Recommendations for Practice Related to Anorectal Function Tests

- Anorectal function tests should be performed as part of tertiary level diagnosis and management of FI (Grade of Recommendation C).
- Anorectal manometry should be performed and interpreted in conjunction with the rectal sensory test and the balloon expulsion test (Grade of Recommendation C).
- Use of the London Classification as a diagnostic algorithm is recommended when deciding to use anorectal function tests (Grade of Recommendation C).

Recommendations for Research on Anorectal Function Tests

- Further exploration of methods to improve accuracy of manometric measures for diagnosis of sphincter dysfunction and rectoanal coordination.
- Assess capability of anorectal function tests to predict outcomes of conservative, medical and surgical treatments for FI.
- Critical assessment of the utility of the London Classification protocol as a communication and decision making tool.

2. ENDOANAL ULTRASOUND IMAGING

Endoanal ultrasound (EAUS) is established as an important part of a colorectal diagnostic work-up (373), and is recommended as the gold standard investigation to identify anal sphincter injury by the International Urogynecological Association (IUGA) / International Continence Society (ICS) joint report (374). EAUS is usually performed with high multi-frequency (9-16 MHz), 360° rotational mechanical probe or radial electronic probe (frequency: 5-10 MHz) (373). High-resolution three-dimensional (3D) EAUS provides better visualisation performance by multiplanar reconstruction and rendering of the 3D data volume (373). With EAUS, the anal canal is divided into three levels of assessment. The upper level corresponds to the hyperechoic sling of the puborectalis muscle and the concentric hypoechoic ring of the internal anal sphincter (IAS). In males, the deep part of the external anal sphincter (EAS) is also identified at this level. The middle level corresponds to the superficial EAS (concentric band of mixed echogenicity), the conjoined longitudinal layer, the IAS, and the transverse perineal muscles. The lower level corresponds to the subcutaneous part of the EAS (375).

Alternative ultrasound modalities (transperineal/TPUS and endovaginal/EVUS) can be used for the investigation of sphincter integrity in FI (373, 376-382). Advantages of these procedures include wider, absence of distortion of the anal canal, better patient acceptability, and the possibility for functional studies and for the assessment of levator ani muscle injuries (373, 383).

2.1. Endoanal Ultrasonography in FI

EAUS is currently the gold standard for the morphological assessment of the anal canal in FI and is a simple, well-tolerated and inexpensive technique. Most studies reveal high accuracy in identifying sphincter defects. EAUS can differentiate between incontinent patients with intact anal sphincters and those with sphincter lesions (defects, scarring, thinning, thickening, and atrophy) due to vaginal delivery or anal surgery (e.g., haemorrhoidectomy, fistula surgery or sphincterotomy) (373, 374).

Tears are defined by an interruption of the circumferential fibrillar echo texture. Scarring is characterized by loss of normal architecture, with an area of amorphous texture that usually has low reflectivity. Number, circumferential (radial angle in degrees or in hours of the clock site) and longitudinal (proximal, distal or full length) extension of the defect should be reported.

3D EAUS is used and accepted for sphincter evaluation in FI, improving diagnostic accuracy and knowledge of physiological and pathological sphincter alterations. It allows measurement of length, thickness, and the area of sphincter defect in the sagittal and coronal planes in addition to the volume of sphincter damage (375). Two scoring systems have been proposed to define the severity of the sphincter damage (384, 385). Both systems have demonstrated good correlation between the extent of sphincter defect and the degree of FI. EAUS has an important role in detecting clinically occult anal sphincter injuries after vaginal delivery (386-388). FI related to occult sphincter lesions is likely to occur even in an elderly population of women who experienced vaginal deliveries earlier in life (late-onset FI) (389). US imaging is useful to evaluate the result of treatments (e.g., sphincteroplasty, bulking agents, injections) (390-392).

2.2. Endoanal Ultrasonography in Anorectal Surgery

Haemorrhoidectomy, fistulectomy or fistulotomy, anal dilatation, or internal lateral sphincterotomy can cause FI, due to anal sphincter injury. Clinical severity of FI after anorectal surgery is related to EAUS features. More frequently, in patients with higher clinical severity score the IAS is always affected and thicker (393). EAUS has been used to select the surgical treatment in patients with FI and to assess the clinical efficacy of the treatment. In a multicentre observational study on the implantation of prostheses in patients with FI, EAUS was used preoperatively to select cases (either intact sphincters or IAS lesions extending for less than 60° of the anal circumference), intraoperatively to perform the implants into the intersphincteric space and postoperatively to evaluate the results of surgery and complications (prostheses dislodgement) (394, 395).

3D-EAUS can quantify how much sphincter can be safely divided during fistulotomy. In a prospective, consecutive study, there was a strong correlation between preoperative 3D-EAUS measurements of fistula height with intraoperative and postoperative 3D-EAUS measurements of IAS and EAS division. Fistulotomy limited to the lower two thirds of the EAS is associated with excellent continence and cure rates (396).

2.3. Endoanal Ultrasound and Obstetric Anal Sphincter Injury (OASI)

Obstetric anal sphincter injury (OASI) is a term used to define trauma to the perineum during vaginal childbirth that includes third- (injury to perineum involving the anal sphincter complex – EAS and IAS) and fourth-degree (injury to perineum involving the anal sphincter complex and anal epithelium) tears. Within 2 months of delivery, the incidence of any degree of anal sphincter defect in primiparous women is reported to be as high as 27% -35% using EAUS. Between 4% -8.5% of multiparous women have a new sphincter defect (397). When women sustain an OASI, they are at increased risk of developing FI either immediately following childbirth or later in life. The true prevalence of FI related to OASI may be underestimated. The reported rates of FI following the primary repair of OASI range between 15% and 61%, with a mean of 39% (397). There is some evidence to suggest that EAUS performed after vaginal birth and before the tear has been repaired could lead to improved primary repair of the IAS and EAS resulting in reduced rates of FI and improved quality of life for women. One randomised trial of 752 primiparous women compared clinical examination (routine care) to the use of EAUS prior to perineal repair. EAUS was associated with a reduction in the rate of severe FI at greater than six months postpartum (risk ratio RR 0.48) (398). More high quality randomised controlled trials are needed before the routine use of EAUS on the labour ward can be supported. Cost and training required to implement EAUS requires consideration.

Data are controversial for asymptomatic patients. There are no cost-benefit studies of EAUS in this setting, nor any data on whether asymptomatic patients could benefit from it. Currently, there is no recommendation about screening women later after vaginal delivery for occult sphincter defects. EAUS may have a role after perineal repair in the evaluation of residual injury and in the management of subsequent pregnancies (399). There are no systematic reviews or randomised controlled trials to suggest the best method of follow-up after OASI.

Studies show a high frequency of endosonographic sphincter defects after primary repairs in between 54% -93% of women (400, 401). These data emphasize the importance of adequate repair of OASI and demonstrates that repair can be difficult or underestimated. The current guidelines of the United Kingdom Royal College of Obstetricians and Gynecologists (RCOG) do not make recommendations about using EAUS for confirming a complete primary repair (RCOG Guideline, 2007). According to this guideline, if a woman experiences FI at follow-up after repair, referral for EAUS should be considered. A persistent ultrasound-detected defect in the anal sphincter muscles after OASI is associated with FI (402). Reconstruction of the entire length of the EAS is crucial. Incontinence after primary repair of OASI is related to relative length of reconstructed EAS and to the extent of the ultrasonographic defects demonstrated by 3D-EAUS (403). In a prospective study assessing long term function and morphology of the anal sphincters and the pelvic floor after primary repair of OASI, women who experienced deterioration of continence over time following repair had a significantly shorter anterior EAS at 3D-EAUS. EAS length correlated with increased severity of FI (404).

A decision about the mode of delivery of pregnancy after OASI based on symptoms, anal manometry, and EAUS helps in preserving anal sphincter function and avoiding unnecessary Caesarean sections (405). In a descriptive study on a cohort of women who had OASI from 2006 to 2013, vaginal delivery was recommended to asymptomatic women with normal investigations (EAUS and anal manometry) and elective Caesarean section was recommended for women with faecal symptoms, anal sphincter defects of more than 30° or low resting or incremental anal pressures. Caesarean section was done in 22 women and 28 women delivered vaginally. Worsening of FI symptoms and reduction in anal pressures were not observed in either the planned vaginal delivery or elective Caesarean section groups. There were no new sphincter defects or recurrent OASI in any of the women in the study group.

EAUS can be useful to select patients that could benefit from rehabilitation. Therapy may be less effective in patients with sphincter lesions, and there is a linear relationship between post-rehabilitative scores of FI severity and severity of sphincter defects (406).

Currently, there is no evidence to support the use of real time elastography in the diagnostic workup of FI. There was an absence of a correlation in elastogram colour distributions of the IAS and EAS with major clinical and functional parameters (407).

2.4. Alternative Ultrasound Modalities (Transperineal and Endovaginal) in FI

Transperineal and endovaginal ultrasound have been evaluated as alternatives to EAUS for the investigation of sphincter integrity in FI (373, 376-379). Advantages of these procedures include the availability of commonly used transducers, absence of distortion of the anal canal, better patient acceptability and possibility for functional studies (380). Two-dimensional transperineal US (2D-TPUS) is performed with conventional convex transducers (main frequency between 3 and 6 MHz, field of view at least 70°) applied in the perineum between the mons pubis and the anal margin (373). Perineal ultrasound provides an overall assessment of all anatomical structures in the midsagittal plane (bladder, urethra, vaginal walls, anal canal and rectum) between the posterior surface of the symphysis pubis (SP) and the posterior part of the levator ani (LA). Imaging is usually performed at rest, on maximal Valsalva manoeuvre and on pelvic floor muscle contraction (dynamic assessment). Three/four dimensional (3D/4D) TPUS are performed with volumetric probes. The most important clinical application of 3D-TPUS is the assessment of LA injuries (408). The disconnection of the muscle from its insertion on the inferior pubic ramus and the pelvic sidewall, a consequence of overstretching during the second stage of labour, is defined as LA avulsion (409, 410).

Three-dimensional endovaginal US (3D-EVUS) is performed with a multi-frequency (9-16 MHz), 360° rotational mechanical probe. The pelvic floor is divided into four levels of assessment (411). At level I, the bladder base and the inferior third of the rectum are visualized. Level II corresponds to the bladder neck, the intramural region of the urethra and the anorectal junction. Level III corresponds to the midurethra and the upper third of the anal canal and Level IV to the perineal muscles, the perineal body, the distal urethra and the middle and distal third of the anal canal. 3D-EVUS provides information on the LA/ levator hiatus integrity (373).

There are limited studies that directly compare these techniques with EAUS (381, 382). Although the sensitivity for the detection of sphincter defects ranges from 44% for EVUS to 50% for TPUS, they can be used in combination with EAUS, to provide additional information on pelvic floor muscles and levator hiatus damage. In a prospective, observational study, defects of the pubovisceral muscle (PVM) were identified with 3D-EVUS in 27% of women with FI who had undergone vaginal delivery. Severity of incontinence was related to the extent of damage of the PVM and to the enlargement of the levator hiatus (383). These findings were not confirmed in a retrospective study where there was no statistically significant association of FI with worsening of LA deficiency among patients with major FI(412).

TPUS may be used as screening modality for the detection of occult anal sphincter injuries after vaginal delivery. In a prospective, randomised controlled trial, the occult tear rate increased from 3.5% (clinically detected) to 11.5% by US technique (413). Future studies should focus on technique standardisation and method as well on the predictive value of both EVUS and TPUS compared with EAUS in the detection of sphincter defects.

New Evidence about Ultrasonography for OASIS

Three-dimensional EAUS remains the most accurate diagnostic imaging modality for diagnosis and classification of sphincter defects after childbirth (414). This method makes it possible to detect small sphincter defects that otherwise would have gone unnoticed, as 30% of patients with sphincter injuries are asymptomatic. EAUS has the strongest association with FI symptoms after OASIS compared to introital US or TPUS (415, 416). With low positive predictive values, 2D-TPUS and 3D-EVUS are not accurate modalities for the assessment of anal sphincter complex in women with OASI (386, 415). 3D-TPUS shows good agreement with the gold-standard 3D-EAUS and a high sensitivity in detecting residual defects (386, 414). The optimal cut-off number of slices on tomographic ultrasound imaging for external and internal anal sphincters allows for standardization of a significant defect. Significant obstetric anal sphincter injuries (OASI) have been defined as visible defects of at least 30° in at least 4/6 slices using tomographic ultrasound imaging (TUI) with TPUS (417, 418). TPUS without TUI technique has proven to be effective as well (419). OASI have been graded as a 3a tear if the EAS was abnormal in <4/6 slices, 3b tear if the EAS was abnormal in ≥ 4/6 slices and 3c/4 tear if both the EAS and the IAS were abnormal in ≥ 4/6 slices. In a study on 215 women who sustained OASI, TPUS-based grading of OASIS showed fair agreement with clinical grading of the Royal College of Obstetricians and Gynecologists guidelines (420).

In women with a history of OASI, EVUS and TPUS are suitable to screen for an intact sphincter if EAUS is not available. In a cross-sectional study (421), including 563 women who delivered their first child, defects of EAS and IAS were found on TPUS in 10% and 1% of cases after normal vaginal delivery, in 32% and 7% of cases after forceps delivery and in 15% and 4% of cases after vacuum delivery, respectively. No defects were found after Caesarean section. EAS and IAS defects were associated with increased risk of development of FI. Of the ultrasonographic sphincter defects, 80% were not recorded as OASI at delivery. When defects are found, women should have EAUS to verify the diagnosis (415). Even after postpartum, diagnosis and primary repair, 25-50% of patients will have persistent FI due often to sub optimal repair of the anal sphincter tears. Ultrasound has demonstrated a high rate of residual defects after reconstruction (392, 415-417, 419).

In a retrospective review of 1495 women with OASI, EAUS demonstrated that primary repair was unsuccessful in the majority of cases (422). Sphincter defects detected using all ultrasound methods were associated with lower anal pressures (416). The extent of the residual EAS defect was the most relevant factor correlating with FI (418). Defects measured with EAUS and TPUS six months postpartum correlated to initial OASI grade and symptoms of FI (417). Women who had a higher tear grade, i.e., OASIS 3c/4, had more symptoms, lower maximal resting and squeeze pressures and more residual external and internal sphincter defects in comparison with those who had a 3a/3b tear (418). The offer of a sonographic follow-up at 10-12 weeks after vaginal delivery in high-risk women (maternal age ≥ 35, vaginal birth after Caesarean, forceps, prolonged second stage, overt OASI, shoulder dystocia and macrosomia) may help to reduce morbidity arising from anal sphincter tears (423). With a neonatal head circumference of 34cm or more (cut-off value), probability for FI was 33%, while below that value it was just 2% (424). Mediolateral episiotomy does not seem to be protective against clinically or sonographically diagnosed OASI. It should be considered only when shortening the second stage of labour is indicated due to fetal distress, and not as a means of OASI prevention.

EAUS allows a significantly better detection of symptomatic OASI compared to clinical examination alone (400). Missed OASI at delivery had worse functional outcomes than primary repair immediately following delivery (425). In a matched retrospective cohort study (426), comparing missed to recognized and repaired OASI, the consequences of undiagnosed tears were higher anal and urinary incontinence symptoms. All missed OASI had a shorter perineal body and larger sphincter defect on EAUS. In the EPIC multicentre randomised controlled trial (427), women

with asymptomatic OASI diagnosed by EAUS were planned to Caesarean section or a vaginal delivery. At 6 months after the second delivery, there were no significant differences in anal and urinary continence or sexual function between the two groups. These results do not support advising elective caesarean section for this indication.

It has been reported that 10% to 30% of woman with vaginal childbirth sustain LA avulsion (428), more commonly among those who had undergone forceps-assisted delivery. In women who had either first- and second-degree perineal tears or episiotomy, 3D-EAUS/EVUS showed signs of abnormal pelvic morphometry (429). Partial avulsion of the right or left puborectalis muscle was 16.2% in women affected by second-degree tears. Women receiving Kristeller manoeuvre during labour had a higher incidence of either right or left puborectalis muscle avulsion (429). A systematic review (430) reported that vaginal delivery was associated with a higher number of LA injuries, puborectalis defects, increase in bladder neck mobility and enlargement of the hiatal area than Caesarean section as determined by 3D-TPUS evaluation. Transperineal ultrasound demonstrated that LA avulsion is strongly associated with pelvic organ prolapse (POP). In contrast it doesn't increase the risk of stress urinary incontinence, overactive bladder and AI (431).

New Evidence about Endoanal Ultrasonography in Anorectal Surgery

Intersphincteric injectable bulking agents or implants are one of the current treatment options for FI after failure of behavioural and medical therapy (432). Preoperative 3D-EAUS has been recommended for patient selection and to exclude coexistent clinical conditions that may negatively affect outcomes. Postoperatively, 3D-EAUS has been used to demonstrate the normal localization or displacement of the prosthesis (432-434). A systematic review and meta-analysis, including a total of 889 patients in 23 articles, investigated the midterm outcomes of treatment with injectable bulking agents to identify predictive factors for improvement in incontinence (432). Meta-regression revealed that implants intact on EAUS were predictive of greater improvement in incontinence.

Endoanal ultrasound is a recommended preoperative investigation for anal fistulae which aims to provide the best chance of healing and preservation of continence function (435, 436). A retrospective analysis of 339 patients, EAUS had significant effects on functional outcome and FI after fistula surgery (435). 3D-EAUS is an accurate and reproducible modality for the assessment of type and height of anal fistulae, reducing the potential risk of FI and recurrence associated with the surgical treatment (436).

Patients with chronic anal fissure can be treated with sphincterotomy after failure of medical therapy. Preoperative measurements of the IAS by 3D-EAUS help the surgeon to plan the length of sphincterotomy. Open left lateral internal sphincterotomy extended for about 20% of total left lateral IAS length seems to be safe and effective in the treatment of chronic anal fissure achieving a high success rate without compromising anal continence.

Rectal prolapse can be associated with FI that may not completely resolve after surgical treatment. Preoperative EAUS has a role in grading anal sphincter integrity in rectal prolapse and in predicting improvement in the continence state after surgery (437). Higher grades of sphincter injury are associated with less improvement in continence than lower grades (437).

Summary of Endoanal Ultrasonography

- EAUS has the strongest association with FI symptoms after OASIS compared to introital US, 3D-EVUS or 2D-TPUS (Level of Evidence 3).
- 3D-TPUS shows good agreement with the gold-standard 3D-EAUS and a high sensitivity in detecting residual sphincter defects (Level of Evidence 3).
- Sphincter defects measured with EAUS and TPUS six months postpartum correlated to initial OASI grade and symptoms of FI (Level of Evidence 3).
- 3D-TPUS demonstrated that LA avulsion is strongly associated with pelvic organ prolapse. LA evulsion doesn't increase the risk of stress urinary incontinence, overactive bladder and FI (Level of Evidence 3).
- Detection of intact bulking agent on postoperative 3D-EAUS is predictive of improvement in incontinence after treatment with injectable bulking agents (Level of Evidence 2).

Recommendations for Practice Related to Ultrasound Imaging

- In women with asymptomatic OASIS diagnosed by EAUS, elective caesarean section to prevent AI is not recommended in the second delivery (Grade of Recommendation A).
- Sonographic follow-up at 10-12 weeks after vaginal delivery in high-risk women (maternal age ≥ 35, vaginal birth after cesarean, forceps, prolonged second stage, overt OASIS, shoulder dystocia and macrosomia) may help to reduce morbidity arising from anal sphincter tears (Grade of Recommendation 3).
- Mediolateral episiotomy is not protective against clinically or sonographically diagnosed OASIS. It should be considered only when shortening the second stage of labour is indicated due to fetal distress, and not as a means of OASIS prevention (Grade of Recommendation 2).

3. DEFAECOGRAPHY

3.1. Introduction

Defaecography, also referred to as evacuation proctography, is the radiological assessment of the voluntary rectal evacuation of semi-solid contrast material, and it provides information on both static and dynamic anorectal structure and function. Conventional fluoroscopic defaecography is an established tool for the diagnosis of evacuation disorders. MRI defaecography has the advantage of evaluating all pelvic components, although it is less utilized than fluoroscopic defaecography due to its higher cost and unnatural examination posture in the supine position.

Defaecography has been widely used in the diagnosis and management of evacuation disorders including pelvic floor incoordination, rectocele, rectal intussusception and so forth. The technique has been less often utilized in the assessment of FI until the advent of laparoscopic ventral rectopexy (LVR) (438-440). LVR improves FI through the anatomical correction of rectal intussusception (internal rectal prolapse) although there are conflicting data (441). Since LVR has been shown to be effective in the treatment of FI in patients with rectal intussusception and complicated rectocele, defaecography has become more important in diagnosing these conditions.

3.2. Examination Techniques of Fluoroscopic Defaecography
There has been no universally agreed standard method for the conduction of defaecography, but the Pelvic Floor Consortium of the American Society of Colon and Rectal Surgeons and other five societies published "Consensus Definition and Interpretation Templates for Fluoroscopic Imaging of Defaecatory Pelvic Floor Disorders" (442). Usually, a viscous barium contrast material is injected into the rectum of the patient in the left decubitus position. The semisolid contrast material can be made by mixing barium with flour, oatmeal or mashed potato, whilst ready-made barium paste can be used where it is commercially available. The volume of the injected material is either fixed at around 150ml or up to the volume at which the patient feels the urge to defaecate.

A radiopaque marker should be placed on the perineal body as a point of anatomical reference (442), while other radiopaque markers can be placed on pubic symphysis and the apex of the coccyx to facilitate interpretation. Vaginal contrast should be used to provide relevant clinical information regarding pelvic organ prolapse, whilst bladder contrast does not need routine use (442). Small-bowel contrast can assist in the identification of enterocele but is not recommended for the routine evaluation of pelvic organ prolapse, including enterocele (442).

During fluoroscopic defaecography, the patient sits on a commode attached to the footboard of the fluoroscopy table and lateral views of the film are taken at rest and maximum squeeze. Then rapid film sequences are taken during evacuation, followed by a film taken after the completion of the evacuation at maximum straining cine-defaecography.

3.3. Parameters To Be Studied at Fluoroscopic Defaecography
The anorectal junction is the distally tapered point of the rectal contrast column caused by posterior impression of the puborectal muscle. The anorectal angle (ARA) is measured by the angle between a line parallel to the posterior wall of the ampullary portion of the rectum and a line drawn along the anal canal (442). In healthy subjects, the ARA at rest is approximately 85 to 96 degrees, which becomes more acute by 10 to 15 degrees during maximum squeeze and becomes more obtuse during straining in comparison to the angle at rest (442). The degree of perineal descent should be described routinely as either "present" or "absent" if the anorectal junction drops by more than 2 cm. Perineal descent should then be further quantified in centimetres by measuring the movement of the anorectal junction from its position at rest toward the point of maximum descent with defaecation of contrast (442). The pubococcygeal line (PCL) should be the reference point from which to quantify prolapse of abdominal organs (442).

Normal subjects should be able to evacuate more than two thirds of rectal contrast material within 30 seconds. After maximal evacuation or after maximal patient effort, the degree of rectal emptying should be quantified relative to initial rectal contrast volume ("1/3 volume evacuated," "2/3 volume evacuated," and "complete evacuation") (442). In addition to assessing the functional aspect of rectal evacuation, defaecography can also reveal the structural aspects including rectal intussusception, rectocele, sigmoidocele and enterocele. Rectal intussusception is defined as the invagination of the rectal wall into itself. It should be quantified as either "intrarectal," "intra-anal," or "external". An additional scoring system (Oxford Scale) (443), to quantify the degree of rectal intussusception might be useful, but Paquette *et al.* (442), reported that "experts voted against mandating its routine use in clinical practice as the bare minimum reportable threshold." Rectocele is defined as the outpouching of the anterior rectal wall beyond the normally expected anterior rectal wall at straining. It should be quantified in centimetres by measuring the maximal displacement of the anterior rectal wall from the expected resting position during defaecation. Further characterization should include information regarding rectocele emptying, rectal emptying, need for digitation or pressure to achieve complete emptying, and degree of concomitant displacement of the posterior vaginal wall, if any (442).

All middle compartment structures and herniatione into the rectovaginal septum, such as enteroceles, sigmoidoceles, or peritoneoceles, should be described by observing their movement in relationship to the PCL in centimetres (442). Sigmoidocele and enterocele are defined as the herniation of the lining of the peritoneum by the sigmoid colon or the small bowel, respectively, into the rectovaginal septum and may push on the anterior rectal wall. Additional details should include size and location in relationship to the vagina by specifying the lowest extent of the hernia as being to the "top of vagina," "middle of vagina," or "on pelvic floor" (442). Dobben *et al.*(444), reported good reproducibility for enterocele, rectocele and their severity grading as well as fair to moderate reproducibility for rectal intussusception in a prospective assessment of inter-observer agreement for defaecography in FI.

3.4. Clinical Utilitys of Fluoroscopic Defaecography
Defaecography can be useful in the diagnosis and management of FI by measuring perineal descent and ARA, evaluating involuntary leakage of the contrast material as well as diagnosing rectal intussusception and rectocele. Perineal descent may be a sign of weak pelvic floor muscles and possible pudendal neuropathy, which may be associated with FI. An obtuse ARA implies weakening of the puborectal muscle and possibly the entire pelvic floor muscles. In a study by Piloni *et al.* the mean ARA at rest differed significantly between patients with FI and those without (445),. The normal range of ARA, however, is wide, and some patients with normal ARA are incontinent to stool, whilst some with abnormally obtuse ARA are continent. Paradoxically, Kollmann *et al.* reported that a wide anorectal angle at rest in preoperative defaecography was the only independent predictor of favourable outcome of sacral nerve stimulation in 54 patients with idiopathic FI in multivariate analysis (favorable 134.1 ± 13.9° vs. unfavorable 118.6 ± 17.1°) (446).

Continent subjects with normal anal sphincter function can easily retain the contrast material in the rectum while sitting on a commode. The involuntary leakage of material during its injection or on sitting before evacuation indicates weak anal sphincters. This finding can be utilized to evaluate whether patients are actually incontinent to semisolid stool or not when their complaints are equivocal. In a study by Savoye-Collet *et al.* of 50 women with FI, 24 showed a leakage of barium paste in upright position during defaecography (447). The finding of the involuntary leakage is beneficial in evaluating surgical outcomes by performing defaecography before and after the operation. Versluis *et al.* reported a significant correlation between the continence score and the finding of the involuntary leakage on defaecography performed before and after dynamic graciloplasty (448). This finding can be utilized in pre-operative evaluation for stoma closure to predict FI in patients with diverting stoma after surgery such as intersphincteric resection of the rectum or restorative proctocolectomy (449).

Karasick, stated that the major indication for performing defaecography in patients with FI is to diagnose rectal intussusception (450). There is controversy regarding the correlation between symptoms and defaecographic findings. Abnormal findings of defaecography can be seen in many normal subjects without symptoms (451, 452), whilst there are some convincing and increasing evidence that

rectal intussusception is associated with FI where this cannot be explained by anorectal physiology and endoanal ultrasound (443, 453-458), Hawkins *et al.* demonstrated in 147 consecutive patients that increasing grades of rectal intussusception were associated with increasing severity of FI (454). Tsunoda et al. also reported that the degree of anterior rectal intussusception descent was significantly associated with the severity of FI in 80 patients (459).

One possible mechanism of FI in rectal intussusception is thought to be the intermittent activation of the rectoanal inhibitory reflex by the redundant mucosa and faecal trapping in the rectum allowing post-defaecatory leakage (443). Harmston *et al.* demonstrated a significant reduction in the mean maximum resting pressure in association with increasing grade of rectal intussusception, concluding that the effect of rectal intussusception on continence occurs mainly through a reduction of internal anal sphincter tone (453). Surgical correction of rectal intussusception can be found in the chapter of "Surgery for FI."

Whether a rectocele can cause FI remains controversial. Collinson *et al.* claimed that one of the causal mechanisms is faecal trapping in the rectocele that allows post-defaecatory leakage to occur (443). Formijne *et al.* performed LVR in patients with combined rectocele and enterocele, and the proportion of patients with FI significantly decreased from 63% to 18% after surgery (460). However, when Wong *et al.* performed LVR in 84 patients with symptomatic complex rectocele, there was no significant improvement in FI, whilst vaginal discomfort and obstructed defaecation symptoms improved significantly (441). Tsunoda *et al.* reported an equivocal result that FI improved in two-thirds of patients, while four patients developed new-onset of FI when they performed transanal repair of rectocele in 30 patients with symptomatic rectocele (461).

Defaecography was not included as a diagnostic examination for FI in the guidelines of the American College of Gastroenterology in 2014 (23), or by the American Society of Colon and Rectal Surgeons in 2015 (22). On the other hand, it is mentioned, albeit briefly, in recent review papers for the management of FI (326, 462, 463). Since D'Hoore *et al.* (438), reported LVR for the treatment of total rectal prolapse, there has been increasing evidence that FI can be improved with ventral rectopexy by surgically correcting rectal intussusception. (437, 439, 440, 464). A consensus meeting on ventral rectopexy has reported that symptomatic high-grade rectal intussusception and complex rectocele are the relative indications for ventral rectopexy after the failure of maximal conservative therapies in patients with obstructed defaecation and/or FI (465). Thus, rectal evacuation disorders including rectal intussusception, which are diagnosed by defaecography, were incorporated into the algorithm of surgery for FI by 6th International Consultation on Incontinence in 2017(466).

3.5. Magnetic Resonance Defaecography

Magnetic resonance defaecography (MRD) can also provide information on both static and dynamic anorectal structure and function. It has advantages over conventional fluoroscopic defaecography (FD) in the avoidance of radiation exposure as well as its ability to evaluate other pelvic organs including vagina, uterus, bladder and small intestine (467, 468). MRD has been utilized not only for evacuation disorders but also for FI in their management (469). Its disadvantage is that it is usually performed in the supine position and is not physiological. Upright MRD with an open-configuration may solve this problem, but is not widely available and therefore infrequently utilized (467).

Similar to FD, the protocols for MRD vary by institutions, but some standardized techniques, recommended landmarks, parameters to be evaluated and their interpretations have been reported (467). The Society of Abdominal Radiology Pelvic Floor Dysfunction Disease Focused Panel has recommended a structured reporting template, which can be accessed from its webpage (470).

The most important aspect of MRD is that patients are required to make their best efforts to expel the rectal gel completely, which might be more difficult in the supine than in the upright position. Inadequate effort may lead to the failure to empty the rectum, resulting in the underestimate of rectal intussusception, rectocele and enterocele. Pilkington *et al.* demonstrated that MRD underestimated pelvic floor abnormalities including rectal intussusception compared with FD, especially when the rectal evacuation was poor (471),. Some studies have shown that FD is superior to MRD in detecting rectal intussusception either in the supine (472), or in the upright position (376), whilst some have reported that MRD better detects rectal intussusception than FD (473) and that both are equivalent in its diagnosis (474). Ramage et al.(475), has concluded in a meta-analysis of 16 studies including 1,703 patients that MRD has a lower detection rate than FD for rectocele (61.8 vs 73.7%; OR 0.48, 95% CI: 0.30–0.76, $p = 0.002$) and rectoanal intussusception (37.9 vs 57.1%; OR 0.32, 95% CI: 0.16–0.66, $p = 0.002$).

Therefore, FD seems more useful than MRD for the management of FI, because FD is superior to MRD in diagnosing rectal intussusception and rectocele, which could be the cause of FI.

New Evidence from the Current Review about Defaecography

- Regarding examination techniques and parameters to be studied, "Consensus Definition and Interpretation Templates for Fluoroscopic Imaging of Defecatory Pelvic Floor Disorders" was published by the Pelvic Floor Consortium of the American Society of Colon and Rectal Surgeons and other five societies (442).
- A meta-analysis demonstrated that the weighted mean rate of improvement of FI was 60.2% by abdominal rectopexy for rectal intussusception, reinforcing the possibility that rectal intussusception can be a cause of FI (437).
- There were two studies which demonstrated that rectal intussusception and its severity were associated with FI and its severity (454), (476).
- There were two studies that reported that preoperative defaecographic findings could predict the outcomes of surgery for FI: one was for sacral nerve stimulation (446), and the other was for laparoscopic ventral rectopexy (477).
- A structured template for reporting the results of MR defaecography, was recommended by the Society of Abdominal Radiology Pelvic Floor Dysfunction Disease Focused Panel (470).
- A meta-analysis demonstrated that MR defaecography had a lower detection rate than fluoroscopic defaecography for rectocele and rectoanal intussusception (475), suggesting that fluoroscopic defaecography might be more useful than MR defaecography for the management of FI.

Summary of Defaecography

- The importance of defaecography has further increased for the management of FI, since the advent of laparoscopic ventral rectopexy, which has been shown to improve FI through the

surgical correction of rectal intussusception and/or complex rectocele (Level of Evidence 2).
- Findings of defaecography could be used to predict the outcomes of sacral nerve stimulation and laparoscopic ventral rectopexy for the treatment of FI (Level of Evidence 3).
- Fluoroscopic defaecography seems more useful than MR defaecography for the management of FI because the former is superior to the latter in diagnosing rectal intussusception and rectocele (Level of Evidence 2).

Recommendations for Practice Related to Defaecography
- Perform defaecography for the diagnosis and management of FI by measuring perineal descent and anorectal angle (Grade of Recommendation C), evaluating involuntary leakage of the contrast material, (Grade of Recommendation C) as well as diagnosing rectal intussusception and rectocele (Grade of Recommendation B).
- Perform defaecography in patients with FI, when their symptoms cannot be explained by anorectal physiology and endoanal ultrasound with rectal intussusception and/or rectocele being suspected from symptoms and anorectal examinations (post-defaecatory passive FI) (Grade of Recommendation B).
- Perform defaecography in patients with FI, who have failed to maximum conservative therapies, and are possible candidates for laparoscopic ventral rectopexy (Grade of Recommendation B).
- Perform fluoroscopic defaecography rather than MR defaecography for the diagnosis of rectal intussusception and rectocele (Grade of Recommendation B).

Recommendations for Research on Defaecography
- Identify patients with rectal intussusception and/or rectocele, who would most benefit from ventral rectopexy by combining symptoms, clinical characteristics and defecographic findings.
- Establish the position for defaecography in the algorithm for the management of FI.

4. MAGNETIC RESONANCE IMAGING (MRI)

4.1. Introduction

MRI is a non-ionizing radiation technique which can provide high resolution images through the anal canal and pelvic floor. There are two kinds of MRI modalities that are used for the management of FI: one is static MRI, known as anal MRI, and the other is dynamic MRI, known as MRI defaecography (468). Anal MRI is used to evaluate the structures of anal sphincters and pelvic floor muscles, while MRI defaecography is used to diagnose dynamic pelvic floor disorders such as rectocele and rectal intussusception (See section above). This section focuses on the role of anal MRI for the management of FI.

Anal MRI provides detailed information of the anal sphincters and pelvic floor anatomy (478). It can be used to detect injuries of internal and external anal sphincters, which might be associated with FI. The spatial resolution of MRI, however, is less than that of endoanal ultrasonography (EAUS), and therefore, accuracy for detecting anal sphincter defects is reported to be slightly below that of EAUS (479-482). Moreover, experience with MRI techniques is less than EAUS because of its availability as well as paucity of dedicated radiologists in this field. Consequently, the role of MRI for the assessment of FI is limited in clinical practice, and it remains second line behind EAUS for the evaluation of anal sphincter integrity (483, 484).

Anal MRI is superior to EAUS for quantifying anal sphincters and pelvic floor muscles and delineating the presence of their atrophy (485). It is particularly useful in specialist situations where anatomy is complex or deranged, for example in anorectal malformations or following surgery (486). MRI is also more useful than EAUS in detecting pubovisceral muscle avulsions, which could be associated with FI after vaginal delivery (487). MRI is increasingly employed as a research tool to investigate the pathophysiology and mechanisms of defaecation (326).

4.2. Examination Methods of MRI

An expert consensus on MRI protocols was reported in 2017 by the pelvic floor-imaging working group of the European Society of Urogenital Radiology (ESUR) and the European Society of Gastrointestinal and Abdominal Radiology (ESGAR) (488). It was produced to standardize indications, patient preparation, sequences acquisition, interpretation and reporting of MRI for diagnosis and grading of pelvic floor disorders. A consensus-based terminology report was also published by the International Urogynecological Association (IUGA) and the International Continence Society (ICS) in 2017 to standardize terminology for female anorectal dysfunction (478). This joint report included terminology of MRI for anal sphincters and pelvic floor.

Static MRI provides detailed information of the anal sphincters and pelvic floor anatomy (478). Current state-of-the art MR imaging of the pelvic floor includes imaging at a magnetic field strength of 1.5 Tesla (T), using pelvic or phased-array coils and T2-weighted fast-spin echo (FSE) sequences. Based on T2-weighted FSE sequences, muscles including external anal sphincter (EAS) are relatively hypointense, ligaments and fascia hypointense, while fat and smooth muscle including internal anal sphincter (IAS) are hyperintense. MRI can be performed with endoluminal (endoanal or endovaginal) coils or surface phased-array coils placed external to the patient. The spatial resolution can be enhanced by using endoluminal coils. In combination with T2-weighted FSE sequences, endoluminal coils provide improved signal-to-noise ratio (SNR) and high-resolution images (489).

4.3. Normal Anal Sphincter Anatomy on MRI

Anal sphincter anatomy is best depicted on high resolution angled T2-weighted images which maximise the contrast between muscle and adjacent fat. It is possible to measure muscle volume and length on the resulting images which may have some clinical utility. For example, in a series of 100 healthy volunteers, Rociu *et al*. reported that age- and sex -related differences were demonstrable on endoanal MRI, and women had a significantly shorter EAS than men (490).

The normal IAS is formed by smooth muscle in direct continuation with the circular muscle of the distal rectum. The IAS demonstrates intermediate signal intensity on T1- and T2-weighted images. The EAS is comprised of skeletal muscle and demonstrates low signal on T2-weighted images. Tirumanisetty *et al*. demonstrated in their normal value study of 112 asymptomatic healthy women that 92% had normal appearing IAS and EAS, while 96% had a normal appearing puborectal muscle (491).

It should be noted that the inferior edge of the EAS may be open posteriorly and anteriorly, which should not be confused for a tear (468). The complex anatomy of the EAS has been elucidated by

MRI techniques including diffusion tensor imaging, fibre tracking and spin-tag MRI. Using these sequences, Mittal *et al*. demonstrated a purse-string morphology of the EAS on contraction, with decussation of muscle fibres within the perineal body to the contralateral transverse perineal and bulbospongiosus muscles (492). This understanding could potentially question the fundamental premise behind lateral episiotomy and overlapping sphincteroplasty, as both of these surgical techniques assume that the EAS is a circular muscle. The subcutaneous EAS often does not form a complete ring on axial sections, stating that the variational gaps at posterior or anterior commissures can be misinterpreted as sphincter defects (493),.

4.4. Anal Sphincter Defects on MRI

The ability of MRI to detect anal sphincter defects has been addressed by several studies. In general, those reporting higher accuracy have utilized an endoanal coil, although large scale comparisons with surface coils are lacking. An advantage of MRI is multiplanar image acquisition which facilitates evaluation of the sphincter complex in multiple orientations, improving diagnostic accuracy, although 3-dimensional (3D) EAUS can also produce multiplanar images. One pitfall of MRI evaluation of the anal sphincter complex is that variations in normal anatomy may be misdiagnosed as sphincter defects by the unwary.

The IAS is typically of higher signal than the EAS on T2 weighted images and defects manifest as either discontinuity or thinning, with replacement of the normal smooth muscle by fibrous tissue. IAS defects are often found in combination with EAS defects, especially in women presenting with incontinence following obstetric sphincter tear. Solitary IAS defects are more common in iatrogenic cases of incontinence, for example after surgery for anal fistula and anal fissure.

Akin to EAUS, EAS defects manifest as discontinuity in the normal intermediate signal muscle structure, often with associated low signal fibrosis. Secondary changes to the architecture of adjacent structures (for example, the longitudinal muscle and perianal fat) may provide supportive evidence of a sphincter tear. There is evidence that MRI is accurate in detecting EAS defects potentially suitable for anal sphincteroplasty in patients presenting with FI, and accuracy of 95% has been reported for EAS tears (494-502).

In a nested case control study of 68 women with FI and 68 matched controls, Bharucha *et al*. reported that IAS injury detected on endoanal MRI was an independent risk factor for incontinence. However, neither EAS nor puborectalis injury was itself an independent risk factor (503). A retrospective cohort study in 189 women with pelvic floor dysfunction found no correlation between pubovisceral muscle avulsions detected on MRI and symptoms of FI, although there was a correlation with symptoms of pelvic organ prolapse and an inverse correlation with symptoms of obstructed defaecation (487). A retrospective study in 119 women undergoing external phased array coil MRI and anal manometry found that a patulous anal canal (which cannot be identified with endoanal MRI) was associated with more severe anal injury as documented by reduced squeeze pressure increment (504).

4.5. Anal Sphincter Atrophy on MRI

MRI has higher accuracy in identifying EAS atrophy compared with EAUS (485, 505). The ability of MRI to accurately detect EAS atrophy has been demonstrated in a number of studies (494, 495, 497, 506). For example, in a study of 25 women undergoing surgical EAS repair, Briel *et al*. (497), compared pre-operative MRI evaluation of sphincter atrophy with histological analysis of full thickness muscle biopsies. Atrophy on MRI was defined as muscle thinning or fatty replacement. Against the histopathological reference, MRI achieved a sensitivity of 89% and specificity of 94% for sphincter atrophy. Importantly, the same group reported a clear association between EAS atrophy on MRI and significantly poorer outcome following EAS repair (506), emphasizing the clinical importance of this observation. The work also showed that atrophy was only be detected on MRI and not using EAUS. There is good evidence that the longer-term functional outcome following sphincteroplasty for obstetric-related EAS defects is inferior in those with neuropathy-associated EAS atrophy (485, 505-508).

In a retrospective cohort study of 158 women with pelvic floor symptoms undergoing external phased array coil MRI, Kessels *et al.* reported a correlation between severe EAS atrophy and FI, as well as a link between the severity of EAS atrophy and increasing age and body mass index (BMI). There was, however, no statistically significant correlation between the presence of sphincter defects and FI (509).

4.6. Post-Surgical Sphincter Evaluation on MRI

MRI has been found useful in assessing patients with defaecatory dysfunction after surgical correction of anorectal malformations, both in children (486, 510, 511) and adults (512). An increased anorectal angle, misdirection of the neorectum and peritoneal fat herniation between the neorectum and striated muscle complex are associated with an increased incidence of FI. MRI is superior to EAUS in demonstrating the amount and quality of any residual EAS.

Using clinical scoring and MRI, Gangopadhyay *et al*. compared three surgical procedures in 130 children after surgery for anorectal malformations. It was concluded that MRI was a valuable modality for postoperative structural analysis of patients with anorectal malformations and was also useful for predicting the long term functional outcome of FI (486).

New Evidence about MRI

An expert consensus on MRI protocols was reported by the pelvic floor-imaging working group of the European Society of Urogenital Radiology (ESUR) and the European Society of Gastrointestinal and Abdominal Radiology (ESGAR). It was produced to standardize indications, patient preparation, sequences acquisition, interpretation and reporting of MRI for diagnosis and grading of pelvic floor disorders.

A consensus-based terminology report was published by the International Urogynecological Association (IUGA) and the International Continence Society (ICS) to standardize terminology for female anorectal dysfunction. This joint report included terminology of MRI for anal sphincters and pelvic floor.

Summary of MRI

- MRI can be used to diagnose defects of internal and external anal sphincters as well as pubovisceral muscle avulsions, which might be associated with FI (Level of Evidence 3).
- MRI is accurate in detecting external anal sphincter defects potentially suitable for anal sphincteroplasty in patients presenting with FI (Level of Evidence 3).
- Endoanal MRI has higher accuracy than surface coil MRI for detecting anal sphincter injuries. Its spatial resolution, however, is still less than that of endoanal ultrasonography (EAUS), and therefore, accuracy for detecting anal sphincter defects is slightly below that of EAUS (Level of Evidence 3).
- MRI is superior to EAUS for assessing external anal sphincter atrophy, which may correlate with symptoms of FI and predicts

poorer outcome after anal sphincteroplasty (Level of Evidence 2).
- MRI is useful in assessing children and adult patients with defaecatory dysfunction after surgical correction of anorectal malformations (Level of Evidence 2).

Recommendations for Practice Related to MRI
- Perform MRI to diagnose anal sphincter defects which might be associated with FI, if endoanal ultrasonography (EAUS) is unavailable or its results are inconclusive (Grade of Recommendation C).
- Perform MRI to evaluate external anal sphincter atrophy, which might be associated with FI or before anal sphincteroplasty (Grade of Recommendation B).
- Perform MRI in patients with anorectal malformations and/or previous anal sphincter surgery, which might be associated with FI (Grade of Recommendation C).

Recommendations for Research on MRI
- Improve the spatial resolution of MRI, so that its diagnostic accuracy becomes comparative or superior to endoanal ultrasonography (EAUS) in detecting anal sphincter defects.
- Further evaluate the usefulness of MRI in diagnosing external anal sphincter atrophy for the management of FI, particularly as selection criteria for anal sphincteroplasty in patients with obstetric anal sphincter injuries.

5. TYPES OF NEUROPHYSIOLOGICAL TESTING FOR FI

5.1. Introduction

Neurophysiological testing in patients presenting with incontinence appears to be diminishing in practice because of improvements in clinical sphincter imaging and as a result of the understanding that some neurophysiological parameters have only minimal influence on decision-making (513). Despite the rise of sacral and tibial nerve neuromodulation in selective management of incontinent patients, there is no clear guideline for specific predictive neurophysiological testing (514, 515) relegating its specific use in complicated cases of incontinence secondary to particular neurological diseases and following spinal injury. A consensus paper suggested that neurophysiological testing should be performed in all incontinent patients who either have reduced anal pressure with no obvious explanation or who have a neurological

disease although this is not supported by any references (516).

The following are the typically described neurophysiological test modalities in FI:
- Electromyography (EMG)
- Pudendal terminal motor latency (PNTML)
- Sacral latency test (SLT)
- Somatosensory evoked potentials (seps) of pudendal nerve
- Motor evoked potentials (meps)
- Anorectal reflex assessment
- Autonomic nervous system (ANS) testing

Somatic motor testing assesses skeletal muscle motor innervation plus sensory innervation from cutaneous sites to the muscle spindles. This testing incorporates all forms of electromyography (EMG), PNTML studies, motor nerve conduction studies, and motor evoked potentials. Somatosensory testing includes somatosensory evoked potentials and sensory neurography. ANS testing assesses visceral afferent pathways at peripheral, spinal and supraspinal levels.

5.2. Electromyography

In the past the specific use of this EMG technology in FI was for the differentiation of patients with potential voluntary sphincter defects from those without sphincter defects thought to be reparable but who had an attendant presumptive neurological cause for their incontinence. Concentric needle electromyography (CN-EMG) is performed with single-use needles employed at multiple sites. Inherent differences exist at rest in sphincter musculature when compared with peripheral (non-sphincteric) musculature showing basal resting activity whereas non-sphincter musculature is electrically silent (517, 518). The technique can help identify neurogenic from myopathic causes of anal sphincter dysfunction (503). There is no correlation between severity of EMG findings and degree of incontinence (519). Denervation is diagnosed as a reduction in the number of continuously firing low-threshold motor unit potentials (MUPs). CN-EMG has disappeared with improved accurate sphincter imaging; however, it may have a specific place in those patients where ultrasonography and/or MR imaging is equivocal.

Single fibre EMG (SF-EMG) has a smaller recording surface with a pickup of activity from a smaller muscle volume than that recorded with CN-EMG, recording generally 1-3 single muscle fibres from the same MU. Single fibre (needle) EMG is not routinely performed due to the associated discomfort. Surface EMG has no value in assessing neurogenic aspects of sphincter function (but may be used as part of biofeedback therapy) (18).

5.3. Pudendal Nerve Conduction Testing

Pudendal nerve conduction testing measures the nerve conduction velocity in the pudendal nerve as latency time between direct stimulation of the pudendal nerve and external anal sphincter (EAS) contraction. There is a customised (Dantec Electronic Tonsbaaken 16-18 DK-2740 Skovlunde, Denmark) St. Mark's electrode that has been designed. Prolongation of the pudendal nerve terminal motor latency (PNTML) is common after vaginal delivery and with aging (520-522). The technique tends to underestimate the degree of pudendal neuropathy since the latency measured reflects the function of the most rapidly conducting nerve fibres (523). Unlike needle EMG, it does not show direct neurological damage.

It has been suggested that the delay in PNTML is associated with a worse overall prognosis of external anal sphincter repair for patients presenting with FI (507, 524) although there is little available evidence to suggest that PNTML measurement alters specific surgical decision-making or outcomes after surgery (525). In addition, the measurement is influenced by body habitus and clinician factors (526, 527). There is little available evidence that the presence or extent of a pudendal neuropathy correlates with objective incontinence (513), or with the specific response to biofeedback therapy with or without the presence of an external anal sphincter defect (528).

5.4. Sensory System Testing

Anorectal sensitivity plays a significant role in the defaecation process and in maintaining faecal continence. Variation in anorectal sensibility is also important in pain disorders and in irritable bow-

el syndrome. Basic sensory testing of light touch and pinprick and sensation of bladder filling is standard. The ano-cutaneous sensation of the perianal area and in the anal canal below the dentate line is conveyed by the efferent fibres of the pudendal nerve (S2-S4) (529).

5.5. Anal Mucosal Electrosensitivity

Anal mucosal electrosensitivity (MES) testing was originally described independently by

Roe *et al.* (530), and Sigel (531), using two electrodes with a constant square wave of current with variable intensity. It is unknown precisely which receptors are involved in this standardised and reproducible response (532). Incontinent patients invariably have a high MES whereas patients with anal sphincter defects, (with or without FI), show an increased MES with the highest values found in patients with a combined internal anal sphincter and external anal sphincter defect.

New Evidence about Neurophysiological Testing

Assessing Anorectal Reflexes

Assessment of the rectoanal inhibitory reflex is an accepted part of anorectal physiology testing. Absence of the reflex is suggestive of anorectal pathology, including previous anorectal resectional surgery, anal hypotonia, faecal loading or megarectum. The possibility of an aganglionosis needs to be considered (533).

Summary of Neurophysiological Testing

- Neurophysiological testing in patients with FI is diminishing in practice because of improvements in clinical sphincter imaging, and its contribution to making a diagnosis or selecting treatments is minimal (Level of Evidence 4).
- Basic sensory testing of light touch and pinprick, the rectoanal inhibitory reflex, and sensation of bladder filling is a standard part of the clinical assessment of FI (Level of Evidence 4).
- CN-EMG testing can be used to help distinguish neurogenic from myopathic causes of anal sphincter dysfunction (Level of Evidence 3).
- PNTML is not useful in the preoperative assessment of patients before sphincteroplasty or sacral nerve stimulation as it does not alter specific surgical decision-making or outcomes after surgery (Level of Evidence 4).

Recommendations for Practice Related to Neurophysiological Testing

- Specialised neurophysiological testing is not recommended for routine secondary assessment of patients with FI because it has limited value over other diagnostic tests (Grade of Recommendation C).
- Basic sensory testing of light touch, pinprick, and the rectoanal inhibitory reflex is recommended as part of initial and secondary clinical assessment of FI, especially in patients suspected to have Hirschsprung's disease (Grade of Recommendation C).
- PNTML is not recommended for preoperative assessment of patients before sphincteroplasty or sacral nerve stimulation (Grade of Recommendation C).
- EMG can be used to help identify neurogenic from myopathic causes of anal sphincter dysfunction (Grade of Recommendation B).
- CN-EMG may have a specific role when ultrasonography and/or MR imaging is equivocal (Grade Recommendation C).

Recommendations for Research on Neurophysiological Testing

- Assess reproducibility of testing of anorectal sensation on predicting outcome of surgical and conservative/medical treatment for FI in large patient samples.

VIII. QUALITATIVE RESEARCH ON THE EXPERIENCE OF FI AND QUALITY OF LIFE

Qualitative studies about an individual's experience of FI and its impact on quality were included for the first time in the 5th ICI (116). Qualitative studies provide an in-depth description of the patients' experience as they live with and manage their FI. These studies typically use small purposeful sample sizes that generate a large amount of text data to accomplish their aims. The sample sizes in the 5 new studies included in this review ranged from 3 to 102 individuals and used descriptive, narrative, and phenomenological qualitative methods to explore participants' experiences.

1. CRITERIA FOR EVALUATION

Given that qualitative research employs different methods than quantitative research, a framework for making decisions about the quality, levels of evidence, and limitations of these studies was developed for the 5th ICI review (116). This framework was informed by literature on quality and rigour in qualitative research and is included in this update and the criteria and scheme used by the ICI for quantitative research studies (534-543). This framework was used to critique studies, identify their strengths and limitations, and assign an evidence level.

1.1. Type of Study – The Qualitative Evidence Pyramid

1. Qualitative meta-synthesis
2. Interpretive designs including phenomenology, grounded theory, ethnography.
3. Descriptive qualitative designs using content analysis (including inductive and deductive content analysis approaches, analysis of focus group data, photovoice, participatory action research, single or multiple case studies).
4. Surveys with semi-structured open-ended questions.

1.2. Criteria for Evaluation of Qualitative Studies

a) There is a clear research purpose or questions appropriate for qualitative inquiry.
b) The purpose or questions are linked with a critical review of the literature and key studies are included identifying a gap or misunderstanding of the phenomenon.
c) There is a guiding frame of reference for the study that fits the phenomenon being studied.
d) There is congruence between the method and the research purpose.
e) The sampling plan is purposeful and is consistent with the purpose and method.
f) The sample size is appropriate for the purpose and sampling strategy.
g) Inclusion and exclusion criteria are described and appropriate for the purpose.
h) Data collection techniques and sources are appropriate for the purpose, method and sample.
i) The analysis plan is appropriate for the purpose and method.
j) Data are sufficiently analysed and interpreted and is reported in a way that the meaning is apparent. The interpretation or description is distinguishable from the original data collected.
k) The participants' voices are evident in and demonstrate the meaning of categorical, thematic or conceptual findings.
l) Concepts, categories and themes are well developed and linked to each other and to the data.
m) The results offer new insight into the phenomenon studied and transferable to similar contexts.
n) Reflexivity is addressed within the context of the study.
o) Evidence of an audit trail of how key decisions were made is clear. Strategies to achieve rigor are described.
p) Study specific limitations are summarized.
q) Ethical considerations are discussed.

1.3. Levels of Evidence for Qualitative Studies

- **Level 1:** A study meets the following Criteria for Evaluation of Qualitative Studies: a, d-f and h-m. These are typically the studies listed as type 1 and 2 in the Qualitative Evidence Pyramid.
- **Level 2**: A study meets the following Criteria for Evaluation of Qualitative Studies: a, d-f and h-m. Level 2 studies are ones listed as types 3-4 in the Qualitative Evidence Pyramid.
- **Level 3:** The Study does not meet the majority of the Criteria for Evaluation of Qualitative Studies.

1.4. Grades of Recommendation for Qualitative Studies

- **Grade A** recommendation: Excellent evidence leads practice recommendations. A Grade A recommendation is based on Level 1 studies.
- **Grade B.** Moderate evidence leading to possible practice recommendations (more evidence is needed). Grade B recommendation includes studies with evidence levels 1 and 2 studies of only level 2 studies.
- **Grade C**. Provide poor evidence from level 3 studies that does lead to practice recommendations.

2. BACKGROUND

The 5th and 6th editions of the ICI proposed a five-domain quality of life framework for people experiencing FI that was thematically derived from the findings from qualitative studies of people with FI (1, 116). The domains were 1) Living with FI related to relationships, 2) Living with FI related to time and planning, 3) Living with FI related to bodily symptoms, self-esteem, and body image, 4) Living with FI related to sexuality, and 5) Living with FI related to dietary issues.

2.1. Living with FI Related to Relationships

Both men and women report that FI poses a threat to their relationships (5, 6, 544-546). They suffered from social isolation and anxiety because of FI (5, 87, 136, 536, 537, 545, 547, 548). They reported discomfort about being in 'mixed company' and having a possible accident (5, 6). Women expressed concerns about entering new relationships due to fear and shame of having to disclose FI (87), and did not attend social events and made excuses unrelated to their incontinence (546). Individuals described trying to protect themselves from the unpredictability of their symptoms and kept up a facade to keep FI a secret from others (87, 540). They also reported that it was a sensitive topic to discuss with others and was strongly associated with the emotions of guilt and shame (546). Humour was used as a resource to avoid humiliation and embarrassment in dealing FI and relationships, even though feelings of shame and humiliation persisted (5, 6, 87, 536, 546). Individuals expressed concern about who to tell about their FI and when. Family, close trusted friends, or co-workers were told because the secret could not be completely concealed (5, 6, 545). Support from spouses was very important (5, 6, 545, 547). Adaptation to FI was attributed to loving, empathic, unconditional support from significant others (549).

Study participants reported that relationships with health care providers were unhelpful in providing advice and that misinformation or no information was commonly given (5, 6, 87, 537, 550). Women reported feeling embarrassed, humiliated, and marginalized when their FI was minimized or trivialized by rude or blaming health care providers (6, 87, 546, 547). After years of dealing with FI men and women reported that their interactions with health care providers had become confident, assertive and control-seeking in decision-making (551).

2.2. Living with FI Related to Time and Planning

Participants reported that they spend a significant amount of time planning for and worrying about accidents (5, 6, 546). "Being prepared" was a common theme. Planning and management strategies to avoid an accident included: morning bathroom rituals, changing the location of their workstation (relative to the bathroom), altering eating habits (foods and timing), taking a fibre supplement, or using anti-diarrhoeal products (5, 6, 87, 537, 545, 546, 550). Women reported the frequency of stool leakage was unpredictable and because of this they needed to be vigilant and prepared for the unexpected (6, 87). Many reported packing 'kits' of absorbent products, cleansing supplies and extra clothing as a routine part of planning to leave their home (6, 545). Space was experienced as a measure of risk exposure of FI and personal space shrank inward or expanded related to perceived comfort or lack of perceived social safety (5, 6, 536, 537, 542, 544, 545, 548, 550). Women and men experienced heightened anxiety about FI symptoms and the risk of accidents in public spaces (6, 537, 542, 545, 550). Travel was limited to familiar spaces and significant planning was required to prevent an accident (5, 6, 536, 546, 547, 550). Seeking out the location and availability of a bathroom was a major consideration in all dimensions of space outside the home (5, 6, 87, 536, 537, 542, 545, 550, 552). Work life presented complicated situations for both men and women and limited some people's ability to engage in productive work outside the home (5, 6, 548, 550, 552). Women reported postponing business meetings because of FI (6). FI symp-

toms were reported as common reason for early retirement for both men and women (5, 6, 548).

2.3. Living with FI Related to Bodily Symptoms, Self-Esteem, and Body Image

Feelings of shame and embarrassment related to FI were noted across all studies. Men and women with FI felt stigmatized and stigmatized themselves (5, 6, 545-547, 550). They reported altered body image, low self-esteem, guilt, and distress (5, 6, 87, 536, 546), and that their emotional life and self-confidence was undermined because of embarrassment (5, 6, 536, 545-547). Other negative feelings associated with living with FI included anger, frustration, injustice, guilt, shame, disappointment, hopelessness, despair and sadness (546). Poor public knowledge of FI created feelings of stigma in persons with IBD and FI (550). Additional chronic illnesses with worsening bowel control affected one's whole self-concept (551). Key concerns were the unpredictability about the type, timing and magnitude of FI events (542, 550). Some women reported the need for psychological consultations because of feeling insufficient, incompetent, or vulnerable (87, 547). Bothersome, embarrassing, or distressing bodily sensations associated with the FI included: sensations in the intestines, itching, burning, cramping, feelings of incomplete bowel movements, and odour associated with flatus and or leaked faeces. Other distressing symptoms discussed included: leaking stool without defaecation sensations, and false abrupt and urgent sensations usually indicative of defaecation (5, 6, 537, 542, 546, 550). Skin excoriation at the rectum was reported due to frequent bowel movements, soling and associated cleansing (536, 542). Urgency to have a BM and associated fear and the unpredictable nature of FI were the most troubling bodily symptoms for persons with IBD and FI (550).

To deal with FI women used a personalised approach to adapt as "life has to go on". Women were hopeful and optimistic that they would get better. They believed their incontinence would be easier to accept if they had an explanation for their symptoms (546). Men and women adapted in the presence of obstacles, downgrading aspirations and "making the best of it" (re-evaluating control) (551). Not talking about the problem and denying the FI were coping mechanisms used to protect from threat to self-esteem and prevent public embarrassment (547).

The essential theme in the phenomenological study of men managing FI was 'secret resignation': men came to expect the consequences of FI as normal (5). The essential theme in the phenomenological study of women managing FI was 'controlling the body out of control' and a similar subtheme in the Dibley and Norton study (550), of 'loss of control'. Women tried to control all aspects of their life in relationship to the incontinence and avoiding accidents (5, 536, 546, 550, 551). Women were attentive to their body image and dressed carefully to conceal pads and wore dark clothing to hide stains if an accident should happen (6, 87, 544, 550). Men and women wore only small disposable pads that were not obvious through their clothing. Large diaper-like pads were avoided because of their perceived visibility beneath clothing (5, 6, 87).

Major goals of people experiencing FI were to have fewer dietary restrictions, less faecal leakage especially during exercise, improved public toilet accessibility, more confidence in controlling FI symptoms and associated odour, and a normal daily routine (538). A sense of mastery and new self-confidence were achieved by some after years of successfully dealing with the symptoms of FI (549, 551). After 10 or more years of living with FI, men and women found comorbidity and aging posed further challenges to adaptation. By using trial and error, adaptation was ongoing (549).

2.4. Living with FI Related to Sexuality

Although asked about sexuality and intimacy, women were reticent to discuss their sexuality or the effect of their symptoms on their sexual functioning (6, 87). Among those who did, some felt there were no changes in their sexual drive (546, 547), while others reported a range of psychosocial issues including lack of sexual arousal or desire to abstinence (87, 537, 544, 546). Women reported that they arranged timing of sex to meet their needs and the needs of their husbands in relation to the symptoms of FI (547). Choice of clothing was seen as outward expression of sexuality and FI and UI restricted clothing to wearing patterned materials to avoid people detecting an accident (544). Men and women reported continually washing themselves to avoid smelling (544). Participants reported that health care professionals did not discuss sexuality even after surgeries that affected sexual functioning (544, 548).

2.5. Living with FI Related to Dietary Issues

Men and women discussed fasting or not eating for a number of hours or days as strategies to deal with FI symptoms when outside the home (5, 6, 87, 547, 550, 553). Alternating the timing of meals to avoid an accident was a common management strategy (5, 6, 536, 545, 550). Sweets, alcohol, onions, rich and spicy foods, caffeine, fruits, greasy, fat, fried foods, and dairy products were noted to affect FI and restricted (547, 553, 554). Limiting portion or meal size was another reported strategy to limit FI (6, 536). Gas-producing foods such as, pea soup, onions, cabbage, cauliflower, and dairy products were avoided as a treatment for flatus (5, 6, 536). Increasing dietary fibre and taking fibre supplements along with digestive enzymes and yogurt were noted as treatments for FI (6). Some women reported eating foods they enjoyed at home and then dealing with the consequences of FI symptoms (5, 6, 536). Some women reported using protracted voluntary constipation for up to one month as a management technique for leakage (537). Women reported a lack of available therapeutic guidance regarding dietary modifications and adopted recommendations from other gastrointestinal disorders such as IBS and lactose intolerance or approached dietary modification by trial and error (6).

New Evidence about Qualitative Research on Quality of Life Associated with FI

Five new qualitative studies were included in this review (Table 15-7). A descriptive study with a sample of 39 community-dwelling women who had experienced FI (FI) during the prior 3 months (unrelated to diarrhoea) and were not currently undergoing treatment sought to describe barriers to seeking care for FI (555). The goal was to inform the development and revision of an instrument to assess barriers to care-seeking. Data were collected during focus groups and 10 individual cognitive interviews. Twelve barriers to seeking treatment for FI were identified: lack of knowledge about the condition; lack of knowledge about treatment options; fear of the evaluation process, including the possibility that it would identify an unwanted diagnosis, and treatment; normal thinking related to FI (attributing it to aging or childbirth); avoidance/denial, hoping the symptoms would resolve on their own; life impact of the incontinence being minimal overall or in relation to other competing medical issues; embarrassment/shame; self-blame about the cause of incontinence; sigma related to talking about FI; isolation (both literal and emotional); provider barriers including interpersonal relationships, gender and previous negative experiences with providers; and access limitations including financial, transportation, need to take time off work, and the need to see a specialist. Three overarching themes were identified for the 12 barriers, with most barriers mapping onto more than one theme. The themes were the internalized self in relation to FI, perceptions about FI and its treatment, and interaction with the health care system. The study was of good

quality, although reflexivity and procedures to ensure rigour were not discussed.

A descriptive qualitative study used three focus groups of older women to explore the association between diet and FI symptoms and dietary strategies and modifications used to manage incontinence with the goal of using the information to inform the development of an age-appropriate, culturally competent, and socially acceptable dietary modification plans (134). The 21 participants were 65 years age or older, had FI at least monthly during the prior 3 months that was bothersome enough to desire treatment, independently managed their diet, and did not have a diagnosis or colorectal cancer of inflammatory bowel disease. All participants were aware that diet played a role in their FI.

Themes about the relationship between diet and FI were discovery of the relationship between FI and diet (often a lengthy process); dietary triggers for FI including foods and food groups (triggers varied widely and most women identified more than one trigger): methods of food preparation (included fried, greasy, spicy, rich and hot foods); and amount and frequency of food intake. Themes related to dietary modifications used to manage FI included modifications in the intake of specific foods or food groups, food preparation methods, and the timing and amount of food. Finally, themes related to suggestions for dietary modifications for FI management included the importance of health care provider input (given that shame may deter women from discussing dietary habits, providers should be more proactive in discussing diet), a balanced approach (weighing the benefits of dietary modification against the enjoyment of the foods given up), and sharing of individual experiences. The study was of good quality although there was limited discussion of procedures to ensure rigour and reflexivity was not discussed.

In a descriptive study with six individuals with FI and seven health care providers (3 surgeons, 2 physiotherapists, and 3 nurses), the investigators sought to determine what constituted success in managing FI from the perspectives of both patients and health care providers and to identify barriers and promoters of participating in treatment programs for FI (108). Barriers to care included themes of education (patient knowledge and helplessness and provider helplessness) and access (lack of treatment options, access to care, health care costs, inconvenience of care, patient compliance and patient expenses). Promotor themes that encouraged patients to seek treatment for the FI were its negative impact of quality of life, personal hygiene, activities and productivity; its psychological burden; motivation to participate in new treatments; positive expectations related to treatment; and satisfaction with available treatment options.

Patients varied in their definition of successfully managing FI including having greater control of bowel function, more confidence in relation to control and a reduction in the need to participate in FI hygiene behaviours. Among clinicians, definitions of success also varied with nurses identifying it as overall patient happiness or any improvement in bowel function, physiotherapists emphasizing functional outcomes, and surgeons defining success in terms of what the patient considered a successful treatment. The study was of good quality although there was no mention of reflexivity, participant voices were not heard for some themes and study limitations were only briefly discussed.

Another study using a phenomenological method explored the experience of having AI during the early postnatal period (7). Three women who had experienced FI following vaginal delivery and were less that 12 months postnatal participated in the study. Data were collected during individual face-to-face interviews with each woman. For these women, the essential structure of their lived experience was comprised of six key constituents: the changed bodily self, becoming familiar with the postnatal body, emotional engagement, putting the baby first, a sense of hope, and an evolving sense of self. Their experiences with FI involved coming to terms with unexpected changes in their body that sometimes could not be controlled or predicted and interfered with their new maternal role and relationships with others and caused anxiety and uncertainty. Symptoms could evoke embarrassment or fear of embarrassment especially in public settings and there was reluctance to disclose incontinence. All three women reported putting their baby's needs before their own. They described becoming familiar with their new body and their maternal role and were more or less hopeful about the possibility of recovering normal bowel function. The study was of good quality although there was no mention that data collection was based on data saturation or of an audit trail.

The final study used a narrative method to describe the emotional, social, and psychological consequences of FI following obstetric injury to the anal sphincter and to develop a 'word picture' describing the consequences of FI and the pathways to coping and recovery. The sample included 81 women referred to the first author for assessment as part of a potential negligence claim. Fourteen of these women later participated in face-to-face interviews. Data collected from the interviews as well as reviewing the written consultation records (which included quotations describing the consequences of the injuries as well as coping and recovery processes) were used to construct the 'word picture' which was reviewed and refined by a focus group (n=14 women; eight were part of the previously described sample) and a postal questionnaire group (n=25; 10 were part of the previously described sample).

During the interviews women described the following themes related to FI: feeling unclean; hiding my FI; fear of incontinence during sexual intercourse; feeling isolated, guilty or embarrassed; loss of dignity; failure as a mother and feeling inadequate as a mother; loss of confidence; no one to talk to about the incontinence; employment concerns; lack of understanding within the family; shock, stress, marriage fears, disfigurement, and feeling like a failure; and anger, pain, denial, disbelief, and feeling low. The frequency with which each was reported varied and is summarized in Table 15-7. The most common strategies used to cope with FI were repetitively washing to feel clean and planning daily activities and being aware of and having access to toilet facilities. Some women reported that focusing on daily tasks or returning to work helped them cope with their FI. Women also identified factors related to recovery and healing with the baby being critical to recovery. Other factors related to recovery and healing were sharing with and support from others and moving from anger to forgiveness and despair to being positive. The study was of good quality although there were some limitations related to the evaluation criteria. The background literature was not well developed, inclusion and exclusion criteria were not described, there was no mention of reflexivity and limited procedures to ensure rigour were described.

For the most part, the findings of studies included in this edition were consistent with the themes identified in the 5th and 6th consultations of the ICI (1, 116). Based on evidence from the new studies included in this addition, however, the theme related to relationships was expanded to include roles and an addition sixth theme was identified – facilitators and promoters of seeking treatment.

Summary of Qualitative Research on Quality of Life Associated with FI

Living with FI Related to Relationships and Roles

- Concern about experiencing FI is a threat to relationships (Level of Evidence 2), particularly new relationships (Level of Evidence 2), and participation in social events, particularly in mixed company (Level of Evidence 1).
- FI evokes feelings of embarrassment, shame and guilt and individuals express concern about who to tell about their incontinence and when. Family members, close trusted friends and co-workers are often told because the individual feels they cannot completely conceal their FI (Level of Evidence 2).
- Experiencing FI following childbirth can interfere with women's adaption to their new role as a mother (Level of Evidence 2). While women report that incontinence contributes to feelings of inadequacy as a mother, the baby was also identified as a factor in recovery and healing (Level of Evidence 2).
- Over time, women reported becoming more comfortable with their new body and maternal role and were more hopeful about the possibility of normal bowel function (Level of Evidence 2).
- Health care providers are perceived as unhelpful in providing advice with study participants reporting that misinformation or no information is commonly given (Level of Evidence 2).

Living with FI Related to Time and Planning

- Study participants reported spending a significant amount of time planning for and worrying about possible accidents (Level of Evidence 2). They used a variety of management strategies to avoid potential incontinent episodes and be prepared for unexpected accidents (Level of Evidence 2).
- Concerns about FI affect both travel and work life (Level of Evidence 2).
- While some women reported concerns related to work outside their homes, for those who returned to employment, work was also identified as a coping mechanism (Level of Evidence 2).

Living with FI Related to Bodily Symptoms, Self-Esteem and Body Image

- Feelings of shame and embarrassment related to FI were reported by participants across all studies (Level of Evidence 2).
- Men and women with FI felt stigmatized and stigmatized themselves (Level of Evidence 2).
- Men and women reported altered body image, low self-esteem, guilt, and distress and that their emotional life and self-confidence was undermined because of embarrassment (Level of Evidence 2).
- Low levels of public knowledge about FI contributed to feelings of stigma (Level of Evidence 1).
- Individuals with FI report a variety of bodily sensations and distressing symptoms associated with incontinence (Level of Evidence 2).
- Both men and women reported repetitively washing to feel clean and avoid smelling (Level of Evidence 2).
- Some individuals develop a sense of mastery and self-confidence after years of successfully managing their symptoms (Level of Evidence 2).
- Women with post-natal FI identified moving from anger to forgiveness and despair to positivity as factors related to recovery and healing (Level of Evidence 2).
- Women with postnatal FI coped by repetitively washing to feel clean (Level of Evidence 2).
- Aging and new comorbidities posted additional challenges to adapting to FI (Level of Evidence 2).

Living with FI Related to Sexuality

- Women were reluctant to discuss sexuality or the effect of FI symptoms on sexual functioning even when asked about sexuality and intimacy (Level of Evidence 2). Among those who did, some reported that there were no changes in their sexual drive while others reported a range of psychosocial issues including lack of sexual arousal or desire to abstinence (Level of Evidence 2).
- Study participants reported that health care professionals did not discuss sexuality (Level of Evidence 2).
- Women with postnatal FI reported fear of incontinence during sexual intercourse (Level of Evidence 2).

Living with FI Related to Dietary Issues

- Study participants reported using a variety of dietary alterations as strategies to deal with FI symptoms (Level of Evidence 2).
- Older women reported that shame deterred them from discussing dietary habits with health care providers (Level of Evidence 2).

Living with FI Related to Barriers and Prompters of Seeking Treatment

- New studies included in this review explored barriers and facilitators of treatment-seeking behaviour among participants with FI. Barriers identified included lack of knowledge about FI and its treatment, fear about testing and treatment; attributing FI to aging, inheritance or childbirth; and feelings of embarrassment, shame, self-blame and stigma. Health system barriers to seeking treatment included provider sex, previous negative experiences with health care providers and access-related factors including cost and needing to take time off from work for evaluation and treatment (Level of Evidence 2).
- Factors identified as promoting treatment seeking were motivation to participate in new treatments and positive expectations about the benefits of treatment (Level of Evidence 2). The life

impact of FI could serve as either a barrier or promotor to seeking treatment (Level of Evidence 2).
- Women reported that lack of knowledge about FI and its evaluation and treatment as well as fear about testing and treatment were barriers to seeking care (Level of Evidence 2).
- Attributing FI to aging, inheritance, or childbirth were identified as barriers to seeking treatment among women (Level of Evidence 2).
- The life impact of FI could serve as a barrier (if episodic, if other health issues were seen as more important) or facilitator of seeking treatment (if symptoms interfered with life) (Level of Evidence 2).
- Women identified embarrassment, shame, self-blame, and stigma as barriers to seeking care for FI (Level of Evidence 2).
- Women also identified provider and health care system barriers to seeking treatment for FI: Provider sex, a prior negative experience with a provider, access to health care including treatment-related costs, and needing to take time off work (Level of Evidence 2).
- Motivation to participate in new treatments, satisfaction with current treatments, and positive expectations about the benefits of treatments for FI were identified as promoting treatment-seeking behaviour (Level of Evidence 2).
- Clients with IBS and FI noted the services they would want to manage FI included access to bathrooms in both public and employment spaces (Level of Evidence 2).

Recommendations for Practice Related to Quality of Life Associated with FI
- Clinicians should actively acknowledge the problem of FI compassionately and initiate the assessment and discussion of FI symptoms as stigma, embarrassment and sensitivity associated with FI may impede communication and provision of therapeutic advice (Grade of Recommendation B).
- Clinicians need to recognize and eliminate dismissive or blaming responses as they can impair future care-seeking and contribute to patient distress and under-reporting of FI (Grade of Recommendation B).
- Providers should consider the facilitation of gender sensitive support groups to share practical knowledge of FI symptom management (Grade of Recommendation B).
- Health care providers should be aware of clinical interventions to improve symptoms (Grade of Recommendation B).
- Health care providers should inform pregnant women about the risk of anal sphincter injury during vaginal delivery and facilitate early assessment, support, and treatment of women who develop FI post-delivery (Grade of Recommendation B).
- Health care providers should support post natal women affected by FI with regard to their maternal role (Grade of Recommendation B).
- Health care providers should identify a condition-specific 'buddy', support group, or online forum for women with postnatal FI to share knowledge and provide support (Grade of Recommendation B).
- Providers should share practical management strategies, such as preparing cleansing kits and locating public restrooms, etc., with clients with FI (Grade of Recommendation A).
- Providers should promote self-efficacy by coaching clients on how to plan for and prevent unpredictable accidents and teaching strategies to go out confidently (such as, education on products, packing a change of clothes, disposable wipes, etc.) (Grade of Recommendation A).
- Providers should acknowledge and support the common feelings of shame and embarrassment by facilitating self-management (Grade of Recommendation B).
- Health care providers should raise awareness with clients and the general public that FI is not something to be tolerated and that it responds to conservative treatment (Grade of Recommendation B).
- Clinicians should educate patients regarding conservative symptom management: causes of FI, dietary modifications including fibre supplements, behavioural strategies such as pelvic floor exercises and biofeedback, anti-motility medications, use of absorbent products and ways to reduce odour and flatus (Grade of Recommendation A).
- Clinicians should consider sharing positive coping strategies identified by participants with other people managing the symptoms of FI (Grade of Recommendation B).
- Clinicians should consider patient's goals when developing a management plan for FI (Grade of Recommendation B).
- Clinicians should request completion of a daily stool diary when accurate information of FI severity is important (Grade of Recommendation A).
- Health care providers should consider referral to psychologists to manage the emotional impact of FI on self-efficacy, self-esteem and mood, as indicated and appropriate (Grade of Recommendation B).
- People with FI should be referred to, or informed of, other services for continence (Grade of Recommendation A).
- Providers should ask directly about the impact of FI on patients' sexuality (Grade of Recommendation B).
- Providers should ensure a comfortable, stigma-free climate in order to elucidate the impact of FI on sexuality and teach practical strategies (Grade of Recommendation B).
- Providers should enquire directly about dietary restrictions because some individuals may be reluctant to discuss these and not all strategies employed by people with FI are helpful or evidence-based (Grade of Recommendation B).
- Providers should teach successful dietary strategies, including: timing of food intake, restricting food amounts to minimize leakage, avoiding aggravating foods, increasing water intake, and increasing the consumption of yoghurt, high fibre foods or a fibre supplement (Grade of Recommendation B).
- Providers should ask specifically about FI, recognizing that individuals with FI may not report it (Grade of Recommendation A).
- Providers should educate patients about treatment options for FI (Grade of Recommendation B).

Recommendations for Qualitative Research on Quality of Life Associated with FI

The following topics are recommended for further research in this area

- Implementation and evaluation of gender sensitive support groups to facilitate sharing of practical management strategies for symptom management.
- Investigation of role-modelling effectiveness in adapting to FI.
- Investigation into living with FI long-term
- Investigation of interventions that promote enhanced self-efficacy, self-management, and increase incontinence health literacy.
- Evaluation of effect of public and work-based education campaigns on normalizing elimination and raising awareness that incontinence is a treatable condition.
- Determination of how goal setting and tailoring interventions for FI is effective in promoting adherence to a management plan
- Investigation of the use of humour as a therapeutic coping strategy for dealing with the symptoms of FI.
- Further exploration of the phenomenon of secret resignation as a method of coping by men and effective attitudes in treating these attitudes to assist them with improved communication with health care professionals and health care seeking
- Clinical trials about the effect of dietary strategies on FI
- Investigation of appropriate and effective interventions to educate and support men and women in adopting practices for managing FI and associated odour and urgency symptoms
- Investigation of the experience of having and managing FI in presence of other multiple chronic conditions and when the outcome of pregnancy is not delivery of a healthy baby
- Develop and test interventions that minimize stool leakage during intercourse.
- Investigate whether barriers to treatment seeking can be minimized by dissemination of information about FI and its treatment
- Exploration of attitudes and treatment goals of health professionals treating FI to identify barriers to effective treatment

Table 15-7. Qualitative Studies about FI

Authors, Reference, Country	Study Purpose/ Research Questions	Qualitative Design	Sample and Patient Type/ Diagnosis	Data Collection	Findings
Roe & May (544) UK	Explore the impact of faecal and urinary incontinence on sexuality and identify interventions for the management of incontinence on sexuality	Descriptive	27 adults Various causes of faecal incontinence	Semi-structured interviews and field notes	Themes: clothing and appearance; intimacy and caring; management techniques and relationships; life trajectory
Chevavanayagam & Norton (556) UK	Describe issues affecting quality of life of women with faecal incontinence	Descriptive	13 women Various causes of faecal incontinence unsuccessfully treated	Structured open-ended questions	Issues with toileting, psychological and emotional effects, timing of meals and proximity of toilets, skin excoriation and constant cleaning, difficulties while in public places such as shopping, maintaining an attractive appearance and wearing clothes that conceal pads and possible accidents, reduced exercise, issues with employment, restricted travel, limited socialization
Rozmovits & Ziebland (548) UK	Understand aspects of distress in colorectal cancer and explore the impact of the illness on identity and self-understanding	Descriptive	39 adults with loss of bowel control with and without colostomy or ileostomy Colorectal cancer	Narrative interviews	Loss of professional identity: temporal and special boundness Loss of ability to socialize: Considerable impact on travel, eating away from home and engaging in leisure pursuits Learning to manage a stoma: loss of dignity, privacy and independence, disruption of sexual identity

Authors, Reference, Country	Study Purpose/ Research Questions	Qualitative Design	Sample and Patient Type/ Diagnosis	Data Collection	Findings
Collings & Norton (545) UK	Discover psychosexual and psycho-social aspects of living with faecal incontinence to inform practice	Descriptive	20 women Various causes of faecal incontinence	Semi-structured interviews	Women with FI have ongoing stress and face potential humiliation. Strategies used for management include: fasting; pads; using own transportation; knowing the location of toilets. Faecal incontinence affects: skin care; shopping; eating; travel; appearance; employment; and socializing. Sex is not always affected but there may be fear and shame that deter single women from entering a new relationship.
Hansen et al. (136) USA	Investigate the meaning of food as a strategy for treating FI	Phenomenol-ogy	10 women living in the commu-nity with various causes of faecal incontinence	In-depth unstructured interviews	4 categories of diet strategies: restricting intake of food that worsen FI; avoiding gas-pro-ducing foods; limiting portion or meal size; and using diet and fluids as treatments Themes: restricting diet and eating patterns; eating and dealing with the consequences; treating faecal incontinence with food and fluids; lack of therapeutic guidance for diet modifications
Wilson & McColl (557) UK	Explore the quality of life, management strategies, reasons for and barriers of seeking help by participants experiencing faecal incontinence	Grounded theory	22 adults living in community with various causes of faecal incontinence	In-depth guided interviews	Five themes: impact of FI on self; response to faecal incontinence including adaptation or maladaptation; interactions with sig-nificant others; positive/negative life direction; interaction with health professionals

Authors, Reference, Country	Study Purpose/ Research Questions	Qualitative Design	Sample and Patient Type/ Diagnosis	Data Collection	Findings
Peden-McAlpine et al. (6) USA	Understand the experience of women with faecal incontinence and how they manage the problem on a daily basis	Phenomenology	10 women living in the community with various causes of faecal incontinence	In-depth unstructured Interviews	Lived space: comfort at home;limited travel outside the home; social isolation; availability of a bathroom a priority; anxiety about public accidents; productive work outside the home problematic Lived time: progression of symptoms over time; planning to prevent accidents; frequency of leakage and defaecation; urgency Lived relationality: faecal incontinence a threat to social acceptability and relationships; careful about disclosure of problem; humiliation and embarrassment at problem; caregiver responses rude and blaming Lived corporeality: management of symptoms aimed at regaining bodily functions; self-esteem suffered; attentive to body image Controlling the body out of control was essential theme.
Coterill et al. (87) UK	Identify question items for a tool assessing symptoms and quality of life of individuals with faecal incontinence	Descriptive	Qualitative interviews with 31 patients with Inflammatory bowel disease with FI Opinions from 7 clinical experts	Interviews with patients Comments by clinical experts	Assessment areas defined by clinical experts: type, amount and frequency of FI; ability to control flatus and stool; straining to evacuate;incomplete evacuation; ability to discriminate between flatus and stool; passive and urgent episodes of faecal incontinence; sensation during faecal incontinence episodes; ‘normal’ bowel pattern for the individual Free text comments ranking; toilet location; social life; hygiene/odour issues; coping strategies; fear, physical activities; embarrassment; bowel unpredictability Interview analysis key issues: unpredictability; coping strategies; and importance of sexual matters

Authors, Reference, Country	Study Purpose/ Research Questions	Qualitative Design	Sample and Patient Type/ Diagnosis	Data Collection	Findings
Johnsen et al. (554) Sweden	Describe problematic aspects of faecal incontinence to the experience of adults with Spina Bifida	Descriptive	11 adults with spina bifida and bowel problems	Semi-structured open-ended interviews	13 specific problem issues were identified in 4 broad categories: subjects spent a lot of time controlling their defaecation; problems communicating with nurses and physicians; involuntary faecal leakage contributed to social isolation; they did not feel secure in relationships; leisure time was determined by access to toilets; sense of helplessness and worry about smell, gaining control, accidents; sense of impurity, being socially unacceptable; poor self-image; decisions about bowel control were troubling (colostomy or voluntary constipation); and changing patterns
Norton & Chelvanayagam (558) UK	Describe the impact bowel dysfunction has on the lives of people with MS and to identify interventions that MS Society Members find helpful that may warrant further investigation	Survey with open-ended question	155 adults with multiple sclerosis	Free-text section on questionnaire	Faecal incontinence had a more profound effect on quality of life than constipation. Bowel dysfunction and bowel management had the greatest negative impact on quality of life, as much as difficulty with mobility.
Rasmussen & Ringsberg (547) Sweden	Elucidate how women experience what it is like to live with faecal incontinence due to childbirth complication and how they cope with that situation	Grounded theory	9 women with anal sphincter rupture during childbirth	Unstructured interviews	To have faecal incontinence due to a child birth complication is like being in an everlasting fight. To live with and cope with faecal incontinence is like having to fight to be like others, a fight against attitudes and having a constant striving for confirmation.
Manthey et al.(30) USA	Examine the management goals of individuals with faecal incontinence living in the community if total reduction of faecal incontinence would not be possible	Descriptive	189 community dwelling adults with various causes of faecal incontinence	Semi-structured interviews	Patients have numerous goals if cure is not possible. Having fewer leaks was most popular goal. One-third of patients can identify their own goals. Differences between men and women: men are more interested in not leaking stool at night and decreas ing the amount of stool leaked. Women rate having less urgency and decreasing size/amounts of pads of higher importance. Younger participants are more interested in elimination of leakage of stool during sex and lessening worry.

Authors, Reference, Country	Study Purpose/ Research Questions	Qualitative Design	Sample and Patient Type/ Diagnosis	Data Collection	Findings
Peden-McAlpine et al. (5) USA	Describe the life experience of men managing faecal incontinence	Phenom-enol-ogy	11 men living independently, managing frequently occurring faecal incontinence for 1 year minimum	Interviews	Essential theme: Secret Resignation -- Men accept FI as normal, limit activities outside the home, associate FI with aging, and accept the changes in their body image. Did not generally employ self-care strategies or use product
Dibley & Norton (550) UK	Understand the experiences and concerns of people with IBD and faecal incontinence To understand factors that influence help-seeking and needs or desires for continence services	Mixed methods Reflexivity, rigor, and study limitations not described by authors. New insights for persons with IBD and faecal incontinence regarding urgency and need for quick public access to toliets	28 adults with IBD Diagnosis; 583 questionnaire responses	Free-text responses to survey Interviews	7 themes: FI has intense negative emotional and psychological impact; feelings of stigma; limited life activities; 5 predominant symptoms; practical coping mechanisms; access to toilet facilities; and fear of faecal incontinence
Norton & Dibley (552) UK	Understand the experiences and concerns of people with IBD and faecal incontinence Understand factors that influence help-seeking and needs or desires for continence services	Mixed methods	Adults with IBD Diagnosis 617 questionnaire responses	Free-text responses to survey	Minority sought help for faecal incontinence because: thought nothing could be done, did not know who to ask, did not know of specialist services or thought it was too insignificant a problem. Desired services included public and social issues (e.g., employer awareness, access to toilets) and health services to cope with emotional aspect, better designed products and well-informed and sympathetic specialists

Authors, Reference, Country	Study Purpose/ Research Questions	Qualitative Design	Sample and Patient Type/ Diagnosis	Data Collection	Findings
Wilson (551) UK	Determine changes that had taken place since first study Focused on adaptation and establishing the factors for adaptation	Descriptive	5 men and 6 women with faecal incontinence of various causes	In-depth guided interviews based on topic guides directed by the initial study findings Emerging topics were explored where relevant.	The major theme identified is the quest for control. Sub-themes include: other chronic conditions: additional adversity or providing perspective (control in context), adaptation in the presence of obstacles: downgrading aspirations and making the best of it (re-evaluating control), Meaningful support: significant others (sharing control), Interaction with health professionals: from passive recipient to expert patient (taking over control); Interactions with others with FI: from advice seeker role model (inspiring control), Interaction: the generalized other (outwardly in control).
Olsson & Bereto (546) Sweden	Identify and describe the lived experience of persons living with FI and show how it affects daily life	Interpretive Phenomenol-ogy	5 women with faecal incontinence regardless of cause or severity	Unstructured interviews	Four themes: self-affirmation; guilt and shame; limitations in life; personal approach Leaked faeces, associated odour and worry about these problems occurring continue to be concerns and sources of guilt and shame
Wilson (549) UK	Report on a 10 year follow up study exam-ining the challenges associated with living with faecal incontinence and different ways of managing the condition, including the importance of social support.	Grounded Theory	3 men and 6 women with various causes of faecal incontinence	Semi-structured guided interviews	The core category was impact and response to FI. Sub-categories included: interaction with the generalized other; interaction with significant others; interaction with insiders The follow up study after 10 years of living with faecal incontinence posed challenges to adaptation. Adaptation was ongoing and faecal incontinence was not always the dominant issue. New self-management strategies were identified.
Brown et al. 2017 (555) US	To describe barriers to care seeking for FI	Descriptive	39 Community dwelling women who experienced FI unrelated to acute diarrhoea during the prior 3 months and were not currently receiving treatment (they may or may not have sought care in the past)	Six focus group (4-8 women/ group) and 10 in-dividual cognitive interviews	12 barriers to seeking care were identified that encompassed three overarching themes. The themes were: the internalized self in relation to FI, perceptions about FI, and interactions with the health care system. The 12 barriers were: (1) lack of knowledge about FI, (2) lack of knowledge about testing/ treatment, (3) fear of testing/ treatment, (4) normative think-ing, (5) avoidance/denial. (6) life impact, (7) embarrassment/ shame, (8) self-blame, (9) stigma, (10) isolation, (11) provider barriers, and (12) access limitations.

Authors, Reference, Country	Study Purpose/ Research Questions	Qualitative Design	Sample and Patient Type/ Diagnosis	Data Collection	Findings
Andy et al. 2020 (134) US	To identify dietary modifications used by older women to manage FI	Descriptive	21 women age 65 years and older with FI at least monthly over the prior 3 months that was bothersome enough to seek treatment and who controlled their own diet intake and who did not have a diagnosis of colorectal or anal cancer or inflammatory bowel disease Recruited from urogynaecology and geriatric practices.	Focus groups of 3 to 7 women	Themes identified were: discovery of the relationship between FI and diet; dietary triggers for FI including foods and food groups, methods of food preparation, and amount and frequency of food intake; dietary modifications used to manage FI which included specific foods or food groups, preparation methods, and the timing and amount of food; and suggestions for dietary modifications for FI management which included the importance of health care provider input, of a balanced approach, and sharing of individual experiences.
Helewa 2017 (108) Canada	To identify success from the perspective of patients and health care providers and barriers to promoters that could impact the success and sustainability of a percutaneous tibial nerve stimulation program	Descriptive	6 patients who failed conservative treatment for FI (cause not specified) and were interested in additional treatment; recruited from a colorectal surgery clinic	Patients: interview Clinicians: group interviews with one surgeon interviewed individually	Three broad categories of themes were identified: barriers to care, promoters of care and successful definition of FI management. Barriers to care included themes of education (patient knowledge and helplessness and provider helplessness) and access (lack of treatment options, access to care, health care costs, inconvenience of care, patient compliance and patient expenses). Promoter themes that encouraged patients to seek treatment for FI were its negative impact on quality of life, personal hygiene, and activities and productivity; its psychological burden; motivation to participate in new treatments; positive expectations related to treatment; and satisfaction with available treatments. Definitions of success varied among clinicians with nurses identifying overall patient happiness or any improvement in bowel function, physiotherapists emphasizing functional outcomes, and surgeons defining success in terms of what the patient considered a successful treatment. Patients varied in their definitions of success including greater control of bowel function, more confidence in relation to control and reduced needs to participate in ongoing FI hygiene behaviours.

Authors, Reference, Country	Study Purpose/ Research Questions	Qualitative Design	Sample and Patient Type/ Diagnosis	Data Collection	Findings
Hutchens et al. 2020 (7) UK	To describe the lived experience of having FI during the early postnatal period	Interpretive Phenomenology	3 women with FI following vaginal delivery and were within 12 months post-natal regardless of the frequency or resolution of incontinence	Individual interviews	Experiences with FI involved coming to terms with unexpected changes in their body that sometimes cannot be controlled or predicted. This interfered with their new role as mother and relationships with others and caused anxiety and uncertainty. Symptoms could evoke embarrassment or fear of embarrassment especially in public settings and there was reluctance to disclose the incontinence. All three women reported that their baby's needs before their own. The women described becoming familiar with their new body and their maternal role and were more or less hopeful about the possibility of recovering normal bowel function.

Authors, Reference, Country	Study Purpose/ Research Questions	Qualitative Design	Sample and Patient Type/ Diagnosis	Data Collection	Findings
Keighley et al. 2016 (559) UK	To describe the emotional, social and psychological consequences of FI after obstetric injury to the anal sphincter and to construct a 'word picture' to describe the consequences of FI and the pathway toward coping and recovery	Narrative	Women with FI following obstetric anal sphincter injury Three samples: (1) 81 women with FI referred for assessment as part of a potential negligence claim (2) 14 women from the first sample who completed a series of face-to-face interviews (3) a focus group of 14 women (6 from sample 1, 2 from sample 2 and 6 who were not part of either previous sample); and (4) 25 mothers with FI consisting of 15 new women and 10 from the case study sample. Data from samples 1 and 2 were used to develop the preliminary 'word picture' which was reviewed and refines by samples 3 and 4	Review of written documentation from legal consultations (sample 1) and face-to-face follow-up interviews with the 14 women in sample 2 Women is samples 3 and 4 reviewed and revised the 'word picture' developed from data collected from samples 1 and 2	Themes described during the face-to-face interviews and the frequency that they were reported: • Feeling unclean (n=14) • hiding my condition (n=13), • fear of incontinence during sexual intercourse (n=12) • feeling isolated, guilty and embarrassed n=9 for each) • loss of dignity (n=7) • failure as a mother (n=6) and feeling inadequate as a mother (n=4) • loss of confidence (n=5) • no one to talk to about condition (n=4) • employment concerns (n=3) • lack of understanding within family (n=3) • shock, stress, marriage fears, disfigurement, feeling like a failure (n=2 for each)anger, pain, denial, disbelief, feeling low (n=once each) Coping strategies described: • repetitively washing to feel clean • plan day and being aware of and having access to toilet facilities • focusing on daily tasks • returning to work Factors related to recovery and healing • the baby • having a plan • sharing • moving from anger to forgiveness and despair to being positive • support from others

ALGORITHM: SURGERY FOR FAECAL INCONTINENCE **1706**

REFERENCES **1709**

I. INTRODUCTION

Treatment for faecal incontinence is based upon a number of considerations, including symptom severity, particular pathophysiological findings (e.g. structural integrity of the anal sphincter) and, for surgery, whether non-surgical measures have already failed.

As a starting point, non-surgical approaches are applicable to most patients with incontinence. These treatments, including biofeedback, pelvic floor muscle therapy, percutaneous tibial nerve stimulation, may be delivered in surgical clinics and are discussed in detail in Chapter 15. This chapter addresses treatments that are generally considered to require surgical intervention and which vary in their magnitude from minimally invasive to reconstructive surgery.

Historically, the most widely accepted surgical therapy for faecal incontinence has been overlapping sphincteroplasty, respecting the long-held functional primacy of anal sphincter integrity above other factors and the evident link between incontinence and direct sphincter damage during childbirth. This approach has changed, not least as the contribution of anal sphincter injuries is now better understood (particularly those that are not grossly evident on basic inspection), and may be less important than more subtle changes in anorectal sensorimotor function that occur with age, late pregnancy, childbirth, and other conditions.

Although sphincteroplasty is well established, paradoxically, the evidence to support its use is less robust than that supporting newer treatment options. Sphincteroplasty is useful only in cases in which there is an anatomical anal sphincter defect. Sphincteroplasty provides satisfactory results in most patients, however the results deteriorate significantly with time.

Several operations were developed to treat patients whose native sphincter was either intact but weak, or not amenable to repair. Parks conceived the postanal repair to accentuate the anorectal angle in patients with incontinence due to pelvic neuropathy. Muscle transposition procedures using either gluteus maximus or gracilis were devised to create a new sphincter (neosphincter), the latter being augmented by electrical stimulation of the neosphincter (dynamic gracilloplasty). Both failed to gain popularity outside a few pioneering centres and are rarely performed today. An artificial anal sphincter was devised as a salvage procedure for patients who had failed or were not candidates for standard therapy. A simplified magnetic bead artificial sphincter was also developed for this purpose. All have fallen from grace mainly as a consequence of surgical complications, poor long-term outcomes (or both).

Over the past 25 years, sacral neuromodulation (SNM) has become the first line surgical approach for most patients with intact or minimally disrupted anal sphincters in whom non-surgical measures have failed. A wealth of data, albeit almost all observational, attest to the general success of SNM in reducing or curing symptoms in the long-term for more than 50% patients. Such success comes with very little surgical risk but not inconsiderable direct costs. Data are awaited to address effect size in well-powered multicentre randomised trials and detailed mechanistic studies may help future selection of patients.

There has been considerable interest in the development of other minimally invasive approaches to faecal incontinence for patients with less severe symptoms. These include the use of injectable biomaterials, radiofrequency energy treatment, and pelvic sling procedures. The use of autologous muscle cells to augment residual anal sphincter function is also gaining traction, as in other areas of regenerative medicine.

Several important caveats apply to the interpretation of the results of surgery for faecal incontinence as reported in the literature. First, most reports contain only observational data, and the majority of these are uncontrolled case series. Prospective high-quality cohort studies are uncommon and often have significant issues of bias such as attrition over time; randomised controlled studies are rare, and those reported usually include insufficient numbers of patients to claim statistical power for their observations.

Secondly, there has been no standardisation of core outcomes for faecal incontinence with little sense of what defines a “successful” outcome beyond arbitrary suggestions e.g. 50% reduction in incontinence episodes. On this basis a critical review of existing outcome measures is included in this chapter.

Finally, the quality of data reported is variable, though this has generally improved in more recent studies. Chart review has been supplanted by patient questionnaires and interviews by independent data auditors. Daily continence diaries, a more stringent form of data collection, have become increasingly used (although not routine) and are now being digitalised to improve compliance. A recent systematic review has highlighted many of their limitations[1]. Notwithstanding, clinical guidelines published by the American College of Gastroenterology[2], Rome committee[3] and the American Society of Colon and Rectal Surgeons[4] provide a framework under which to consider the evidence available to support clinical decision-making regarding surgical treatments for faecal incontinence.

1. SCOPE AND REPORTING

In contemporary surgical management of faecal incontinence the surgeon has relatively few options at his/her disposal. Many procedures are now only of historical interest because they are recognised to be of limited value or, in the case of some devices, have been withdrawn from the market. While, previous iterations of this chapter have covered such procedures in considerable detail[5], this chapter has been considerably modernised. **Table 1** provides an overview of present and past surgical approaches (termed contemporary and historic for want of better descriptors) and these have been separated in the ensuing text for reader clarity. Procedures falling under the historic category have been given appropriate brevity and readers wishing to explore these interventions in more detail should refer to previous editions of the Consultation..

2. SEARCH METHODS

A PubMed search was conducted to identify studies published on the use of surgery for faecal incontinence. Keywords used were faecal (fecal) incontinence and surgery. Full text copies of studies deemed to be potentially relevant were obtained. Priority was given to systematic reviews, randomised controlled trials, and controlled clinical trials; if those were unavailable or inadequate, observational designs were considered including cohort and case-control studies. In several instances, the search was limited to poor quality observational data such as case series. Reviewers were not blinded to names of studies’ authors, institutions or publications. In view of the nature of the guideline, priority was given to the reports with large number of patients and longer follow-up periods. Particular emphasis was placed on those reporting functional outcomes including quality of life after surgery.

Table 1. Scope and reporting: contemporary and historical surgical approaches for faecal incontinence

Contemporary procedures	**Year**	**Comments**
Sphincter repair (primary)	Unknown	Repair at time of injury is optimal and is performed worldwide by obstetricians and colorectal surgeons
Anal sphincteroplasty	1923 - date	End-to-end (Lockhart Mummary); overlapping (Blaisdell 1940)
Sacral neuromodulation	1994 - date	Most commonly performed surgical procedure for faecal incontinence
Injectable biomaterials	1993 - date	Variety of agents and sites of injection
Posterior anal (puborectal) sling	1974 - date	Several slings trialled over time
Temperature-controlled RF energy	1999 - date	Reducing popularity: no published reports since 2015
Autologous cell therapies	2010 - date	Under evalauation; several ongoing clinical trials
Stoma	2000	Still recommended for end-stage faecal incontinence
Historic procedures	**Year**	**Comments**
Post-anal repair	1975-1990s	Largely abandoned due to poor results
Non-stimulated gracilis neosphincter	1952-2000s	Complexity, cost and high levels of morbidity including major perineal wound and donor site complications, as well as new onset evacuation problems, have limited current use to a very small number of patients
Electrically-stimulated gracilis neosphincter	1988-2000s	
Artificial bowel sphincter	1987-2010	Withdrawn due to infection and explantation rates as well as for commercial reasons
Magnetic anal sphincter	2012-2018	Withdrawn for commercial reasons
Pudendal neuromodulation	2010 – 2015	Several promising reports in selected patient groups not followed by commercial investment

RF = radio-frequency

Non-English language papers were noted but excluded from the review unless they contained an English language abstract providing sufficient information.

II. SURGERY FOR ADULT FAECAL INCONTINENCE

1. CONTEMPORARY PROCEDURES

1.1. Sphincter Repair

Anal sphincter repair is the term used to describe primary repair of the disrupted anal sphincter following direct trauma. The most common indication is following childbirth, and repair in this situation is usually performed by the attending obstetrician. Colorectal surgeons are more commonly involved in primary repair of injury that is the result of blunt or penetrating trauma [6]. Occasionally, the anal sphincter is damaged during anorectal surgery for other anal pathology, particularly surgery for anal fistula[7].

In Western obstetric practice, the majority of women, up to 79%, experience some form of perineal laceration at the time of vaginal delivery [8]. The obstetric injury of the perineum is classified as a *first degree* tear if confined to vaginal epithelium and perineal skin, *second degree* if the perineal muscles are torn, third degree if the anal sphincter muscles (external: EAS; internal: IAS) are torn, (3a: less than 50% EAS torn; 3b: more than 50% EAS torn; 3c: both EAS and IAS torn) or *fourth degree* if both EAS and IAS and rectal or anal mucosa are torn [9]. Third- and fourth-degree tears are collectively termed “OASIS” (obstetric anal sphincter injuries) since they involve anal sphincter mechanisms. The incidence of overt OASIS is low, with a population-based cohort study reporting 3.3% for third-degree tear and 1.1% for fourth-degree tear [10]. However, they affect quality of life (QOL) with 29% of women with OASIS reporting affected QOL due to anal incontinence after OASIS [11]. When prospectively looked for with endoanal ultrasound, the actual incidence of OASIS is higher[12, 13]. A meta-analysis of 717 vaginal deliveries found an incidence of new anal sphincter defects of 27% in primiparous and 9% in multiparous women using 2 dimensional-endoanal ultrasonography (2D-EAUS)[14]. 3D-EAUS detected anal sphincter defects in 45% of 56 primiparous women, although 30% of them were asymptomatic[15]. On the other hand, the detection of over OASIS can be improved by careful examination by experienced specialists. Andrews et al [16] demonstrated that the identification of overt OASIS increased from 11% by an accoucheur to 25% (P<0.01) when women were re-examined by an experienced doctor. **LEVEL OF EVIDENCE 2.**

Women with undiagnosed OASIS have higher rates of anal and urinary incontinence, more anal sphincter defects of greater size on endoanal ultrasound, shorter perineal body length, and more reconstructive surgeries compared to women with diagnosed and repaired OASIS [17]. In a meta-analysis of 103 studies involving 16,110 women who delivered vaginally Sideris *et al* reported that OASIS were diagnosed on ultrasound in 26%, with 19% experiencing anal incontinence. In women without clinical suspicion of OASIS (n = 3,688), sphincter defects were observed in 13% and anal incontinence experienced by 14%. Following primary repair of OASIS, 55% of 7,549 women had a persistent sphincter defect, with 38% experiencing anal incontinence [18]. **LEVEL OF EVIDENCE 2.**

A systemic review of 43 studies including 716,031 parous women reported that definite risk factors for OASIS included instrumental vaginal delivery (Risk Ratio (RR):3.4, 95% Confidence Interval (CI): 2.2 - 5.2), midline episiotomy (RR 2.9, CI:1.8 - 4.7) and a persistent occiput posterior position (RR: 2.7, CI: 2.1 - 3.6). Mediolateral epi-

siotomy did not increase its risk but was also not protective against perineal laceration (RR:1.6, CI: 0.95 - 2.5) [19]. A prolonged second stage of labour, higher neonatal birthweight and shoulder dystocia were also reported as possible risk factors [10,19]. **LEVEL OF EVIDENCE 1.**

A systematic review in 2005 [20] and a Cochrane review in 2017 [21] both concluded that routine episiotomy to reduce perineal tear is unjustified, and that a selective episiotomy policy reduces the incidence of OASIS in women where no instrumental delivery is intended. It is unknown whether routine episiotomy is useful to reduce perineal tear in women who expect instrumental delivery [21], even though two studies demonstrated that mediolateral episiotomy reduced the risk of OASIS during operative vaginal delivery[22,23]. If there is need for episiotomy, mediolateral episiotomy is recommended because of the association of midline episiotomy with increased risk of injury to the anal sphincter complex.[9]. **LEVEL OF EVIDENCE 2.**

Primary repair of an obstetric tear is correctly termed "anal sphincter repair" and is frequently performed by the obstetrician immediately after delivery, most commonly in the delivery room under local or epidural anaesthetic. However, guidelines issued by the RCOG (Royal College of Obstetricians and Gynaecologists) in the UK and by the ACOG (American College of Obstetricians and Gynaecologists) [9] in the US recommend that all such repairs should be treated as surgical procedures with adequate exposure, lighting and anaesthesia in an operating theatre or suitably equipped delivery suite. By tradition, the technique of repair has been a direct oppositional repair of the severed EAS. However, an overlapping technique, as commonly used in secondary sphincteroplasty by colorectal surgeons, has been recommended as it obliges identification and adequate mobilization of the severed ends of the EAS [24]. The IAS, if damaged, is difficult to identify separately and is usually repaired en-block with the anal canal mucosa in a 3c or 4th degree tear. However, Mahoney *et al.* [25] have shown that persistence of an IAS defect is adversely associated with continence outcome following repair of a 3rd or 4th degree tear, while Roos *et al.* [26] found that women with major tears (grade 3c or 4) were significantly more likely to have ultrasound evidence of a persisting IAS or combined IAS and EAS defect following obstetric repair; these women were more likely to have poor functional outcomes. Separate repair of the IAS is recommended when the sphincter can be separately identified using a direct appositional technique[27, 28,9]. **LEVEL OF EVIDENCE 2**.

There have been six randomised clinical trials[24, 29-33], a Cochrane review[34], and a further systematic review[35] that have compared the effectiveness of primary overlapping repair versus end-to-end repair following OASIS. The results of trials are conflicting, with four finding no difference between the two procedures, one trial showing the superiority of overlap repair and one finding the end-to-end repair to be superior. The Cochrane review of the six RCTs including 588 women showed a statistically significant lower incidence of faecal urgency and lower anal incontinence score in the overlap group. The overlap technique was also associated with a statistically significant lower risk of symptomatic deterioration of anal incontinence over 12 months. At 36 months follow-up, however, there was no difference in flatus or faecal incontinence between the two procedures. The Cochrane review concluded that more evidence is needed to establish optimum technique of repair. Norderval *et al.* [36] have shown that continence outcomes in women with OASIS were improved if the entire length of the EAS was repaired, in addition to separate repair of the IAS, if a co-existing injury was found. The guideline from the ACOG states that end-to-end or overlap repair are both acceptable for full-thickness external anal sphincter injury [9]. **LEVEL OF EVIDENCE 2**.

As colorectal surgeons are, in general, quite familiar with the anatomy of the anal canal, it has been suggested that primary anal sphincter repair might be best performed by a colorectal surgeon rather than an obstetrician. Nordenstam *et al.* [37] concluded, in a single institution study of 165 women, that technique and expertise affect the outcome of primary repair and that, if needed, the repair could be safely delayed until such expertise was available. In a similar study, Soerensen *et al.* [38] found no adverse outcome with delayed primary repair. Co-operation between obstetric and colorectal surgical colleagues can result in much improved outcomes[39]. On the other hand, the ACOG guideline states that repairing and caring for perineal lacerations are part of the obstetrician–gynaecologist's training and clinical expertise [9]. It was reported that a structured hands-on training programme for obstetric trainees improved the clinical outcomes of repairs for OASIS[40]. Instructional videos demonstrating repair techniques for fourth-degree laceration have also demonstrated the effectiveness, especially for postgraduate year 1 trainees [41]. **LEVEL OF EVIDENCE: 2.**

There have been two randomised trials of post-operative management of the bowel after primary anal sphincter repair. These have shown benefit in use of a laxative rather than a constipating regimen but no advantage to the addition of a stool bulking agent[42, 43]. **LEVEL OF EVIDENCE:2**

Some alteration in faecal continence occurs in approximately 13 - 17% of women following primiparous vaginal delivery, even in the absence of a recognised sphincter tear [12, 44, 45]. The prevalence is greater if faecal urgency is included as a symptom [13]. MacArthur *et al.* [46] found flatus incontinence in 27% of 7,879 women surveyed 12 weeks after delivery. Fenner *et al*. [47] found that women who had sustained third- and fourth-degree tears were more likely to have faecal incontinence than women without anal sphincter injury 6 months following delivery. This was more pronounced in women with a history of 4th degree tear. Women with 4th degree tear in the first delivery have a higher risk of long-term anal and faecal incontinence than women with 3rd degree tear [48]. Samarasekera *et al* [49] found long-term effects on anal continence and QOL following postpartum anal sphincter injury. Oom *et al.* [50] suggested that concomitant injury to the pelvic floor may be an associated determinant of outcome, in addition to adequacy of sphincter repair. Following repair of obstetric anal sphincter injury, patients should be referred for pelvic floor physiotherapy[51, 52] **LEVEL OF EVIDENCE: 2**

Management of subsequent labour following a previous anal sphincter tear must take account of obstetric risk factors, symptoms of incontinence and patient preferences. Harkin *et al.* [53] found an approximately 5-fold increase in the incidence of recurrent sphincter tear compared to the incidence of first sphincter injury during second labour. In a meta-analysis of 8 studies including 99,042 women, Jha *et al.* [54] reported that risk factors for recurrent OASIS in women who had suffered OASIS in their previous delivery included instrumental delivery with forceps (OR 3.1, 95%CI: 2.4–4.0) or ventouse (vacuum) delivery (OR 2.4, 95%CI: 1.8–3.3), previous fourth-degree tear (OR 1.7, 95%CI: 1.2–2.3), birth weight ≥4 kg (OR 2.3, 95%CI: 2.1–2.5) and maternal age ≥35 years (OR 1.2, 95%CI: 1.0–1.4). Caesarean delivery before the onset of the second stage of labour was found to be protective[55]. However, Nelson *et al.* [56] found that pregnancy rather than delivery was more important in predicting post-partum continence. Abramowitz *et al.* [57] have confirmed in a RCT that subsequent vaginal delivery is reasonable in asymptomatic women after a previously repaired third degree tear. **LEVEL OF EVIDENCE: 3.**

Regarding the subjective satisfaction about subsequent vaginal delivery after OASIS incurred at the previous delivery, Edwards *et al.* [58] reported that among 50 women who had experienced OASIS at their previous delivery, 41 (82%) chose a subsequent vaginal delivery after counselling. Of the 50 women, including 9 who chose caesarean delivery, 27 (54%) had no regret regarding their decision about subsequent delivery, while 18 (36%) and 5 (10%) had mild and moderate/severe regret, respectively. The regret was significantly associated with older age and prevalence of faecal incontinence after the previous delivery with OASIS.

A number of studies have examined long-term outcomes after repair of 3rd- or 4th-degree tears and all have shown an increasing prevalence of continence disorders in association with greater age. These findings parallel those in the general population of parous women who have not had a recognized tear[44, 59, 60]. Fornell *et al.* [61, 62] found that subjective and objective anal function after anal sphincter injury deteriorated with time and subsequent deliveries. A persistent defect in the IAS was also found to be an important determinant, an observation supported by Mahony *et al.* [25]. In a meta-analysis of 103 studies involving 16,110 women, Sideris *et al*. [18] reported that following primary repair of OASIS, 55% of 7549 women had persistent sphincter defect with 31% and 9 % experiencing flatus and faecal incontinence, respectively. **LEVEL OF EVIDENCE: 3**

In a study of women 10, 20 and 30 years following delivery Eogan *et al.* [63] found that onset of menopause was the most significant determent of symptoms, whereas Mous *et al.* [64] found that the incidence of faecal incontinence increased with age irrespective of menopausal status. There is some evidence that hormone replacement therapy may be of value in women who develop faecal incontinence in post menopause[62]. **LEVEL OF EVIDENCE: 3**

Summary:

- Careful examination and training are recommended to improve the detection of overt OASIS (obstetric anal sphincter injuries).

Grade of Recommendation: C

- Endoanal ultrasonography is recommended to detect occult OASIS, undiagnosed at the time of vaginal delivery.

Grade of Recommendation: C

- Primary anal sphincter repair should be treated as a surgical procedure and undertaken by an experienced operator under optimal conditions. If necessary, co-operation between obstetric and colorectal colleagues is recommended.

Grade of Recommendation: B

- A structured hands-on training programme as well as instructional videos for the repair techniques of OASIS are recommended to improve clinical outcomes.

Grade of Recommendation: C

- Primary anal sphincter repair can be performed either by end-to-end or overlapping repair.

Grade of Recommendation: B

- Separate IAS repair should be considered when divided.

Grade of Recommendation: B

- Following repair of OASIS, patients should be referred for pelvic floor physiotherapy.

Grade of Recommendation: C

- Following obstetric injury, management of subsequent deliveries should take account of patient symptoms and preferences as well as obstetric factors.

Grade of Recommendation: C

- Subsequent vaginal delivery is recommended in asymptomatic women after a previously repaired OASIS.

Grade of Recommendation: C

1.2. Sphincteroplasty

The term “anal sphincteroplasty” is used to describe secondary or delayed reconstruction of the anal sphincter injury, which has either been asymptomatic at first or was not recognised at the time of injury. Anal sphincteroplasty is also offered when the outcome of acute primary sphincter repair has been unsatisfactory. Anal sphincteroplasty is usually delayed for a minimum duration of three months after the initial injury. Anterior overlapping sphincteroplasty is the most common type of reconstruction performed because of the association with obstetric injury. In this situation, the anal sphincter muscles and perineal body are separated, leaving a horseshoe type configuration to the anal sphincter mechanism with a large defect in the anterior quadrant. Occasionally, the defect is such that the anal and vaginal mucosae have healed to form a cloacal defect. Anal sphincter defects related to previous anal fistula surgery or direct trauma are usually less complex and are not associated with a deficient perineum unless there has been an avulsion injury with significant tissue loss.

1.2.1. Indications

The decision to perform anal sphincteroplasty is based on an assessment of symptoms, anorectal function, particularly the EAS contractile function, and the anatomical extent of the sphincter defect[4, 22, 65]. When the repair is considered decades after delivery, other causes of faecal continence are first excluded e.g. inflammatory bowel disease, colorectal cancer and neurological disorders. Patients with background IBS are more likely to be symptomatic than those with a more predictable bowel habit and equivalent anal sphincter defects[66]. Other caveats are covered below.

In assessing symptoms, obtaining a consistent measure of severity of incontinence and its impact on quality of life should be considered. This can be accomplished using several validated scores. The three most commonly applied are the Cleveland Clinic Florida Fecal Incontinence Score (CCFIS)[67], the Fecal Incontinence Severity Index (FISI) [68] and the St Mark’s Incontinence Score [69]. A quality-of-life instrument, such as Fecal Incontinence Quality of Life Scale[70], may also aid a fuller understanding of outcomes, although some of the questions on this scale are rather specific to the development population. **LEVEL OF EVIDENCE: 4**

Anorectal function can be evaluated objectively using different modalities, including anorectal manometry, rectal sensation, rectal compliance and pelvic floor electrophysiology including, but not limited to, pudendal nerve terminal motor latency (PNTML)[71]. Pre-operative physiological testing is helpful in the overall management of patients with faecal incontinence. However, the value of

anal manometry and pelvic floor electrophysiological assessment as prognostic indicators for outcome following sphincteroplasty is controversial, [72]. There are no established parameters that reliably predict outcome following sphincteroplasty[73, 74].

The anatomical extent of the sphincter defect can be evaluated with either anal ultrasonography or anal MRI. Multiple ultrasound modalities can be used, including transanal transvaginal or transperineal. **LEVEL OF EVIDENCE: 3**. Results of manometry, ultrasound or any other objective measurements should be applied with recognition that these examinations are often inadequate in determining the presence and/or severity of the condition[75, 76]. **LEVEL OF EVIDENCE: 4**

For symptomatic patients with >90 degrees of anal sphincter defect, anal sphincteroplasty may be appropriate. However, this requires that the defect is believed to be the main cause (pathophysiologically) of incontinence. The finding of a sphincter defect on ultrasound, decades after an injury, may simply be a residual marker of an injury that of itself is contributing little to the current problem compared with other risk factors such as ageing, obesity, general pelvic floor laxity and neuropathy. Repair of an atrophic, denervated muscle will have no benefit (akin to anywhere else in the body where tightening of striated muscles is not perfomed). Decision making in this regard is not straight-forward and is hamperedby limitations of diagnostic tests of structure and function that measure what is measurable rather than what may be most relevant to the minute-to-minute preservation of continence. Decision making is easier if there is an obvious clinical defect leading to a visible gutter, where restoration of structural integrity is intuitive. Rectal evacuation disorders should also be excluded, since these may be worsened by tightening the barrier. For all patients, a trial of non-surgical measures should usually have failed before surgery is considered[22, 65].

Preoperatively, patients should be counselled that post-operative wound healing difficulties are common. Nevertheless, the majority of well-selected patients can expect significant improvement in continence after the procedure with a mean of 66% reporting excellent or good results in the short-term[65]. There are concerns that long-term outcomes are unsatisfactory, decreasing to between 30-80% improvement at 80 months and to 6% at 120 months [77] [see below].

Concomitant repair of a cloacal defect or vaginal fistula should be undertaken [78],[79]. There is no evidence that a defunctioning colostomy or ileostomy improves outcome [80], although some surgeons employ this in certain scenarios such as significant cloacal defects or redo repairs.

1.2.2. Technique

Anal sphincteroplasty can be performed in the lithotomy position or the prone jack-knife position. Full bowel preparation is not mandatory, although most would give at least a cleansing enema pre-operatively. The conventional incision is an inverted 'V' that may be closed as an inverted 'Y' as described by Parks and McPartlin[81]. If anterior levatorplasty or rectocele repair is contemplated, a posterior fourchette incision with the patient in the lithotomy position may have advantages[82]. The external anal sphincter is usually repaired using an overlapping technique without separate identification and repair of the IAS [22]. However, there are two studies that reported good long-term outcomes of sphincteroplasty with separate suturing of the IAS and EAS[73],[83]. **LEVEL OF EVIDENCE: 3** There has been one small randomised trial of direct versus overlapping sphincteroplasty which showed similar outcomes [84]. To prevent dehiscence and subsequent failure, the two divided ends of the external sphincters must have an adequate blood supply and the reconstructive suture cannot be under excessive tension. Occasionally the EAS defect is not full thickness and overlapping repair in such circumstances would require division of the residual intact fibres to facilitate overlap. Oberwalder et al. [85] have, in a small series of patients, found that, in such cases, imbrication of the EAS is associated with outcomes similar to formal overlapping sphincteroplasty. **LEVEL OF EVIDENCE: 3**

A limited levatorplasty can be added to lengthen the anal canal and to help support the external anal sphincter repair. Great care should be taken not to narrow the vagina excessively, which can cause dyspareunia. Women should be counselled accordingly. **LEVEL OF EVIDENCE: 4**

Other adjuncts to sphincteroplasty have been assessed. Khafagy *et al.* [86] developed an overlapping anal sphincteroplasty with the injection of bone marrow aspirate concentrate. Although the combination therapy improved the anatomical and functional results, compared with the sphincteroplasty alone, only 20 patients received the injection. Larger studies are needed. Mesh interposition, although reported is no longer recommeneded for concerns around infection and erosion. **LEVEL OF EVIDENCE: 4**

1.2.3. Outcomes

The results of anal sphincteroplasty in recent series reporting more than 50 patients are given in Table 2. Dividing them into 12 studies of short-term (< 60 months) and 11 studies of long-term (≥ 60 months) follow-up, the proportion of patients who achieved good or excellent continence after sphincteroplasty was 62% on average from the 12 studies of short-term follow-up, whilst the proportion of those who maintained the excellent or good continence after sphincteroplasty was 38% on average from the 11 studies of long-term follow-up, assuming "<30%" as "30%" in the study by Lehto *et al.* [87].

Complications from sphincteroplasty include wound infection, wound dehiscence, and urinary tract infection. A US national cohort[88] using 30-day complications recorded in registry data provided figures of 5.1%, 2.1% and 1.0% respectively for these three complications. Other large single-centre series cite higher rates. In the study by Oom *et al.* [50], 39 (23%) of patients had a postoperative complication including wound infection in 35 patients resulting in an abscess in 21 patients and a fistula in 15 patients (all required further surgical treatment). Stool impaction can be a cause of complete wound breakdown and steps should be taken to mitigate against this. Complete breakdown may require stoma formation and pateints should be informed of this risk and asked to give informed consent accordingly consented.

Initial success of sphincteroplasty is related to whether the anal sphincter defect is corrected[89, 90]. Early failure is usually associated with a persisting defect identified using endoanal ultrasound[91]. This may be amenable to a redo sphincteroplasty[90, 92, 93]. There is, however, increasing evidence that continence outcomes deteriorate with long-term follow-up (above) particularly after secondary sphincteroplasty [94], [95].Evidence regardingthe effect of age at time of operation on long-term function is conflicting [96, 97]. The long-term effects of aging and menopause coupled with atrophy of the sphincters may be relevant[22, 87, 98]. **LEVEL OF EVIDENCE: 3**

1.2.4. Sphincteroplasty and sacral neuromodulation [see also SECTION II.1.3.5]

Patients with unsatisfactory clinical outcomes following sphincteroplasty may be considered, if sufficiently symptomatic, for adjunctive sacral neuromodulation (SNM)[99]. Ratto *et al.* reported that SNM

was as effective as sphincteroplasty for the treatment of faecal incontinence due to sphincter lesions [100], and in a systematic review has also demonstrated that SNM is effective for faecal incontinence associated with an anal sphincter lesion [101]. Rodrigues *et al.* [102] reported even better outcomes of SNM than sphincteroplasty for the treatment of faecal incontinence in patients with a sphincter defect. Consequently, SNM has tended to be favoured over sphincteroplasty for faecal incontinence in patients with a sphincter defect because of the complication profile and poor long-term outcomes after sphincteroplasty . By examining the surgical interventions for faecal incontinence performed at five specialist centres in Europe and one in the US between 2000 and 2013, Ong *et al.* [103] reported a changing paradigm of SNM and sphincteroplasty for faecal incontinence, showing that 95.3% of the index operations were sphincteroplasty in 2000, while in 2013 82.6% were SNM. This might be the reason why no studies of sphincteroplasty with 50 or over patients were published between 2013 and 2018, as is shown in Table 2. However, Oom *et al.*[50] concluded in a long-term study (median: 111 months) of 120 patients that anterior sphincteroplasty resulted in acceptable to excellent outcomes in 60% of patients, emphasising the ongoing important role of sphincteroplasty as a surgical treatment for faecal incontinence. Altomare *et al.* [104] also asserted that these data did not support the replacement of sphincteroplasty with SNM in patients with faecal incontinence secondary to sphincter defects. Even in the era of SNM, sphincteroplasty still deserves a place in the treatment of faecal incontinence associated with a sphincter defect, not only by improving symptoms of faecal incontinence but also by correcting the anatomical deformity due to perineal lacerations. The choice of the surgical procedure, should be made after full discussion with patients, depending on their preference and the status of their perineal deformity.

Summary:

- Clinically overt and symptomatic cloacal defects should be surgically repaired.

Grade of Recommendation: D

- The decision to perform anal sphincteroplasty in patients without an overt cloacal defect is based on an assessment of symptoms, anorectal contractile functions, and the anatomical extent of the sphincter defect as determined by EAUS and clinical examination.

Grade of Recommendation: C

- For symptomatic patients with a < 90° anal sphincter defect, conservative therapies are recommended as first line treatments.

Grade of Recommendation: D

- For symptomatic patients with a > 90° anal sphincter defect, anal sphincteroplasty is an option after conservative therapies fail.

Grade of Recommendation: C

- An overlapping repair is recommended over end-to-end repair.

Grade of Recommendation: C

- After anal sphincteroplasty, long-term follow-up is recommended as outcomes deteriorate with time.

Grade of Recommendation: B

- In symptomatic patients with unsatisfactory clinical outcomes following sphincteroplasty, sacral neuromodulation (SNM) can be recommended.

Grade of Recommendation: B

- The choice of sphincteroplasty or SNM for the treatment of faecal incontinence associated with an anal sphincter defect is to be made after full discussion with patients, depending on their preference and the status of their perineal deformity.

Grade of Recommendation: C

1.3. Sacral Neuromodulation

SNMSacral nerve stimulation (SNM)was first applied for the treatment of faecal incontinence in patients with functional deficits of the anal sphincter but no morphologic defect in 1994 by Matzel *et al.* [123]. . The concept of recruiting residual function of an inadequate anorectal continence organ by electrostimulation of its peripheral nerve supply, i.e. the sacral spinal nerves, was adapted from the field of urology in the early 1990s[124], where it has been used since 1981[125]. The rationale for applying SNM to faecal incontinence was based on both clinical observations and anatomical considerations (from the former, the beneficial effect on bowel habits and anorectal continence function and increased anorectal angulation and anal canal closure pressure seen in urological patients; from the latter, the demonstration by dissection of a dual peripheral nerve supply of the striated pelvic floor muscles that govern these functions[124], with the sacral spinal nerves being the most distal common location of this dual nerve supply). It was hypothesised that stimulating the sacral spinal nerves could both enhance physiological function and improve the symptoms of faecal incontinence.

1.3.1. Technique

SNM has become a minimally invasive technique with low morbidity. The surgical technique can be divided into two stages. As no other predictors of SNM outcome exist at present, patients are uniformly selected for operative implantation of a permanent neurostimulation device on the basis of clinical improvement during test stimulation. This first stage, percutaneous nerve evaluation (PNE), is used to confirm a satisfactory neural response and then to evaluate the clinical effect of stimulation before implantation of a permanent device. Trial stimulation is performed for 1 – 3 weeks, a period sufficient to demonstrate its therapeutic effect: commonly considered as a decrease in the frequency of incontinence episodes (documented by bowel-habit diary) by at least 50% (and reversibility after discontinuation of stimulation if temporary electrodes are removed after the trial stimulation). Two technical options are used for PNE: a temporary, percutaneously placed, unipolar test stimulation wire (or multiple wires) that are removed at the end of this phase; or operative placement of a quadripolar lead, the so-called “foramen electrode,” close to a target nerve, usually the S3 root, less frequently that of S4. The latter approach is termed the first stage of the so called ‘two-staged’ implant[126]. This electrode can stay in place and be used for permanent stimulation if the trial is effective.

A minimally invasive technique places this foramen electrode with a modified anchoring device, the so-called “tined lead,” through a trochar. This foramen electrode implant technique has been optimized by a). introducing the regular use of a softer, curved stylet to guide the electrode placement[127] and b). standardizing the surgical steps with the key elements of the use of the curved stylet, radiological imaging and marking to define the optimal entry of the electrode

Summary:
Anal sphincteroplasty should be considered in symptomatic patients with a defined defect in the external anal sphincter. Overlapping EAS repair is usually performed. Results of sphincteroplasty appear to deteriorate with time. Redo sphincter repair may be feasible in patients with a poor continence outcome. Grade of Recommendation: C

into the sacral foramen and its progression through the foramen. Exact placement of the electrode is monitored by a combination of a typical appearance in imaging/fluoroscopy and achieving specific motor/sensory responses with stimulation[128]. The aim of the modified electrode placement technique is to ensure close electrode proximity to the target nerve providing a higher likelihood for optimal effect with less energy consumption (better battery longevity), more programming options with more electrode contacts close to the nerve and reduced likelihood of side-effects. This lead placement using a novel standardized flouroscopy-guided technique has been recently validated by an anatomical study demonstrating that this implantation technique enables a close contact between electrode and nerve[129]. Preliminary data indicate that with electromyographic recordings the placement of the electrode can be guided to achieve better pelvic floor muscle response to stimulation[130]. EMG-guided electrode placement confirms the upper medial quadrant of the foramen as the optimal entry point for electrode placement [131].

The therapeutic outcome for permanent SNM appears to be best when both sensory/anal motor and toe flexion responses are achieved during test stimulation[132], although threshold for motor reaction of the pelvic floor/anal sphincter during acute testing should be lower than for a potential concomitant reaction of the ipsilateral toes/forefoot[128]. For screening, both types of leads are connected to an external pulse generator, the tined lead with a percutaneous extension cable.

If the screening test is successful, the second stage is implantation of the neurostimulator. Patients with a temporary lead and a successful test require simultaneous implantation of the pulse generator and the quadripolar tined lead. Those with a tined lead foramen electrode already in place for screening will undergo removal of the percutaneous extension before placement of the pulse generator.

Bilateral placement of foramen electrodes remains the exception,

based either on improved outcome of bilateral stimulation during the screening phase[133] or on conceptual considerations[134]. A study exploring the benefit of bilateral over unilateral SNM had to be discontinued prematurely after an interim analysis of 20 patients demonstrated no additional benefit in symptom score, quality-of-life score, or findings on anorectal manometry[135].

The pulse generator is placed subcutaneously, usually in the gluteal area or under certain circumstances in the abdominal wall. It is activated and stimulation parameters are set early after surgery by telemetry; it can be deactivated by the patient with a small, handheld device commonly referred to as a "patient programmer." The patient programmer also offers the ability to vary among four preset stimulation protocols.

Recently, rechargeable and conditional magnetic resonance imaging (MRI)-safe devices have been introduced in both Europe and USA. Preliminary data indicate that the clinical effectiveness of this system appears to be similar to that of the current recharge-free device[136]. The advantages of full-body MRI-safe devices are obvious: up to 23% of SNM explantations in urology are currently due to the need for MRI[137]. Certain groups of patients, requiring regular MRI examinations for disease monitoring (such as multiple sclerosis), surveillance (such as LARS syndrome after rectal resection for cancer) or those with chronic spinal disease may benefit for the availability of MRI safe device.

Issues related to the recharging of pulse generators, device size, device longevity, treatment compliance, disease awareness and patient preference will determine patient decision making and acceptance[138].

1.3.2. Patient selection and contraindications

Over the years, the indications for SNM have gradually expanded and a variety of causes of faecal incontinence are now successfully treated with SNM. During the initial SNM experience, only patients presenting with deficient function but no morphologic defect of the striated anal sphincter and levator ani were eligible[123, 139, 140]. However, because of the high predictive value of a positive test stimulation, a more pragmatic, trial-and-error approach to patient selection evolved. Patients are now selected for SNM based upon PNE results rather than conceptual considerations of the potential mechanism of action. Test stimulation is indicated, not by an underlying pathophysiological condition, but by the existence of an anal sphincter with reduced or absent voluntary squeeze function with or without a sphincter defect. An intact nerve-muscle connection is preferably present and may be confirmed by intact anocutaneous reflex activity or by muscular response to pudendal stimulation with the St. Mark's electrode[141]. **LEVEL OF EVIDENCE: 3**

The two-stage technique offers an opportunity to test treatment efficacy before proceeding to permanent implantation, and a positive test stimulation is the only reliable method for selecting patients who will likely benefit from permanent therapeutic stimulation. Various studies have attempted to identify potential preoperative predictors that can be used to identify the ideal patient for SNM therapy. In a study by Gourcerol *et al.*[142], older age was the only variable related to success of temporary stimulation. This was confirmed in a study by Govaert *et al.*[143] but contradicted in a study by Maeda *et al.*[144] where increasing age was an independent risk factor for treatment failure. Several other studies could not confirm that patient age had any predictive value[145-147].

In another cohort analysis, the need for repeated temporary procedures was associated with failure during the screening in univariate and multivariate analysis[145]. This was confirmed by Govaert *et al.*[143]. A low threshold to obtain motor response during temporary lead placement was revealed to be associated with improved outcome only in univariate, but not in multivariate, analysis. In 244 patients undergoing test stimulation with a success rate of 78.3%, Maeda *et al.* [144] determined that low amplitude of the sensory threshold during PNE and lead placement anterior to the sacral cortex were positive predictors of PNE outcome. No other demographic, physiological or morphological variable (motor response threshold) was a negative predictive factor. Evidence of anal sphincter injury related to a greater risk of failure of SNM will be addressed in a separate paragraph in this chapter. Briefly, the results are variable but the overall conclusion is that a morphologically intact sphincter is not mandatory for successful SNM[99, 143, 148, 149].

In a cohort of 200 patients from 6 centres with permanent SNM [146] only loose stool consistency, a history of diarrhoea management by medical treatment, and low stimulation intensity were associated with improved medium-term outcome. Multivariate regression analysis confirmed that stool consistency and stimulation intensity were independent predictive factors of success or failure of SNM.

The prognostic value of preoperative anorectal physiology testing is controversial. In a cohort of 45 consecutive patients, temporary stimulation was successful in 32 (71%). At a median follow-up of 33 months, the neurostimulator remained in place in 25 (55%) and active in 23 (51%). No statistically significant differences were found in characteristics, including anorectal physiological workup, of the 32 patients who underwent implantation and the 13 who did not or in those 23 with a functioning stimulator[150]. In another study including 60 patients preoperative anal resting and squeeze pressures, rectoanal inhibitory reflex, minimum sensory threshold, and pudendal nerve terminal motor latency did not correlate to patient outcome following treatment with SNM[151].

The vast majority of studies exploring predictive factors for a successful outcome of SNM were not able to detect convincing correlations. In a single centre study, at 3-year follow-up with 33 (of 66) patients with a ≥ 30% improvement in Cleveland Clinic Incontinence score (CCIS), Roy *et al.* were unable to demonstrate any predictive factor of success, based on preoperative and postoperative assessment[147]. In a study from four European centres of 228 patients with chronic SNM, Altomare *et al.* could find no determinant of success at follow-up of ≥ 60 months[152]. Factors investigated included: demographics, technique, symptom severity and cause (age, sex, PNE vs. tined lead test, implant side, implant site, sphincter lesion, extension of sphincter lesion, incontinence type and baseline episodes of incontinence, CCIS, and St. Mark's incontinence score). Factors associated with a significantly lower failure rate over the long term included a reduction of six incontinence episodes per week and eight Cleveland Clinic and St. Mark's score points during test stimulation[152].

In a retrospective analysis of prospectively obtained data from 84 patients, Prapasrivorakul *et al.*[153] found less success at one-year follow-up in patients with a coexisting high-grade internal rectal prolapse (HIRP Oxford Grade III and IV) when compared with those without HIRP (FISI 37 to 23; $p < 0.01$ vs. 38 to 34 $p= 0.16$). In a univariate analysis, concomitant rectocele, enterocele and HIRP were found to be associated predictors of outcome of permanent SNM; in multivariate analysis only HIRP was predictive[153]. In a recent study including defecography preoperatively, the only predictive factor for a favourable outcome of SNM was an increased anorectal angle at rest. The presence of intussusception was not a predictive factor of success or failure[154].

In general, results from numerous studies on predictive factors are inconclusive and none of the variables usually considered in preoperative evaluation are of any help in selecting the appropriate patient for chronic SNM. **LEVEL OF EVIDENCE: 3**

Contraindications to SNM include abnormalities of the sacrum preventing adequate electrode placement (such as spina bifida), skin disease at the area of implantation, trauma sequelae with micturition disorders or low bladder capacity, pregnancy, bleeding complications, psychological instability, limited cognitive function that interferes with the operation of the neurostimulation device. A case series has shown the relative safety of the use of SNM in the presence of a cardiac pacemaker when monitored intraoperatively. If the distance between the devices is greater than eight inches, interference is unlikely[155, 156]. **LEVEL OF EVIDENCE: 4**

1.3.3. Mechanism of action

The mechanism of action of SNM remains uncertain. Electrode positioning is guided by clinical observation of motor striated pelvic floor musculature response to stimulation of the sacral spinal nerves. For two decades it has been postulated that the clinically observed inward bellows response indicative for a contraction of the pelvic floor musculature to sacral spinal nerves stimulation is correlated to oligosynaptic and polysynaptic reflex responses mediated by afferent input to the spinal cord[157, 158]. Recent findings challenge this idea: recordings of intramuscular needle EMG of the anal sphincter and intravaginal surface EMG with latencies measurements indicate that the inward bellows movement observed by stimulating the sacral spinal nerves is not reflex mediated, but a direct efferent stimulation resulting in pelvic floor contraction. In addition to the direct motor response, oligosynaptic reflex and polysynaptic reflex responses can occur[130].

Clinical outcome has been seen to correlate with results of anorectal physiology studies, but the effect of chronic stimulation varies greatly among published reports[141, 159]. Data monitoring colorectal and anal function are in part contradictory and inconclusive and sometimes irreproducible. The effect appears to be somatomotor[160-166], somatosensory[160, 167, 168], autonomic nervous system-based[160, 162, 166], and mediated by somatovisceral reflexes[169, 170]. The effects do not appear to be limited to the continence organ *per se*, but also to the central nervous system: corticoanal excitability in patients with faecal incontinence was found to be reduced with SNM[171]; in successfully treated patients cerebral somatosensory evoked potential (SEP) latencies were higher at baseline than in the normal population, whereas they were normal in patients with SNM failure. Success was also associated with a fall of the SEP latency to the normal range after one month of SNM at 40 Hz[172]. SNM induces changes in anal representation on the primary somatosensory cortex[173]. The effect on the CNS induced by SNM changes during its course: at its initiation, changes are seen in the contralateral frontal cortex, reflecting focus attention; subsequent changes are found in the ipsilateral caudate nucleus, an area related to learning[174]. Qualitative changes in anal, rectal and colonic motility - i.e., reduction of spontaneous rectal motility complexes[175, 176], spontaneous anal sphincter relaxation[175], reduction in antegrade transport from the ascending colon[177] or no change[178], and increased retrograde transport from the descending colon at defecation[177, 178], increase rectal perception thresholds[160, 167, 168] and improved pelvic floor contraction during SNM[168]. The findings on rectal capacity with SNM have been inconsistent: unaltered [168, 179, 180] or increased [175, 181]. No changes in gastric retention, gastric emptying, small bowel transit or colonic passage have been seen with scintigraphic measurements during SNM[182].

A review indicates that physiological functions outside the anorectum are influenced by stimulation of afferent nerve fibres via the sacral spinal nerves[159] although gating effects on corticoanal and spinobulbar pathways are almost certainly important as in the bladder[183]. The mechanism of action is most likely multifactorial and dependent on the underlying condition. **LEVEL OF EVIDENCE: 4**

1.3.4. Outcomes

The results of permanent SNM after pragmatic, trial-and-error, patient selection are shown in **Tables 3-5**. Most studies have included patients with heterogeneous pathophysiology, and they vary with regard to design and patient number, but there is general agreement regarding the test stimulation for selection for permanent implant. Quantitative measures are used to describe the clinical benefit, such as change in CCIS, days with incontinence episodes or absolute numbers of incontinence episodes per period of observation, ability to postpone defaecation (in minutes), percentage of improvement, and quality of life. Even though published reports differ with regard to patient population, a general pattern of outcome can be observed: when compared with baseline status, the clinical outcome is significantly improved. Outcome reporting increasingly includes both PP and ITT analyses.

In a first multicentre prospective trial of SNM adherent to the initial, confined spectrum of indications, Matzel *et al.*[139] reported 37 patients, 34 of whom underwent a permanent implant. Not only was the frequency of incontinence episodes and the CCIS score improved significantly, so was the ability to postpone defaecation. These effects were attained immediately. Since then, multiple case series and retrospective reports have been published, but the number of randomised controlled trials is small.

The US pivotal cohort study by Wexner *et al.* [184] confirmed the efficacy of SNM in reducing symptoms of faecal incontinence: of 112 patients with permanent SNM followed for a mean of 28 months (2-69), 83% experienced a ≥50% improvement, including 41% who gained complete continence (at 12 months). Mellgren *et al.* [185] reported on the same cohort after a mean follow-up of 3.1 years (0.2 – 6.1 years). With a complete or partial data set available in 64% of the patients, a ≥ 50% reduction of incontinence episodes was seen in 86% of these, with 40% achieving perfect continence. Symptom improvement resulted in improved quality of life, which was stable over follow-up. If a “last observation carried forward analysis” is performed, the 50% reduction of symptoms at 3 years is a 78% success rate; in a ‘modified worst-case analysis’ with all missing data classified as failure--the success rate at 3 years is 59%. Again, this same cohort was reported upon at follow-up ranging from five years (63% of patients) to more than eight years: faecal incontinence episodes per week decreased from 9.1 (mean at baseline) to 1.7 at 5 years; 89% reported a ≥ 50% improvement of incontinence (36% complete continence). After 5 years, therapy was active in 81% of the patients[185].

In a systematic review including 61 publications from 2001 to 2012, Thin *et al.*[186] found higher median rates of ≥50% improvement in incontinence episodes/week when patients’ data were analysed “per protocol” (PP) (i.e., implantation after a successful test period) than when the denominator for analysis was PNE (i.e., comparable to “intention-to-treat” [ITT] principles): short-term (median 12 months) 79% (69-83%) vs. 63% (33-66%); medium-term (25 months) 80% (65-88%) vs. 58% (51-81%); long-term (56 months) 84% (75-100%) vs. 54% (50-58%). In the ITT analysis only two studies comprising 86 patients were long-term. Perfect continence was likewise greater in the “per protocol” analysis than in the ITT: short-term 42% (21-68%) vs. 36% (8-68%); medium-term 44% (5-74%) vs. 32% (4-

72%); long-term 35% (4-52%) vs. 20% (2-48%). The CCISs were also significantly improved and remained stable over follow-up.

A summary of the published long-term outcome of SNM up to 2015 included 12 studies with a median follow-up of 85 months in 745 patients[152]. As in the report of Thin et al. [186], improvement (≥ 50% reduction in incontinence episodes) was greater on PP than on ITT analysis: median 78% (21–96%) vs. 50% (42–89%). Full continence was also greater: median 36% (4–52%) vs. 20% (2–48%).

In a meta-analysis of publications from 2000-2008, comprising 790 patients, 28 studies compared incontinence episodes per week before and with SNM, and 14 studies compared incontinence scores. Both outcome criteria were significantlyimproved. Another nine studies documented the ability to postpone defaecation, and this criterion also was significantly improved[187]. **LEVEL OF EVIDENCE: 2**

Whereas cohort studies and observation studies are numerous, only a limited number of randomised controlled trials of SNM for faecal incontinence could be included in a Cochrane review from 2015: four crossover trials and two parallel group trials[188]. In a randomised controlled trial of patients with severe faecal incontinence, Tjandra *et al.*[189] compared the effect of SNM at 12 months with that of supervised optimal medical therapy comprising pelvic floor exercises, bulking agents, and dietary manipulation. In 53 patients, permanent SNM was significantly better than conservative treatment in 60 patients: CCIS 1.2 vs. 14.1; incontinence episodes/week 3.1 vs 9.4; days with incontinence/week 1 vs. 9.4 (mean difference −5.20, 95% confidence interval [CI] −9.15 to −1.25 at 3 months; MD −6.30, 95% CI −10.34 to −2.26 at 12 months); lifestyle 3.31 vs. 2.31; coping/behaviour 2.68 vs. 1.86; depression/self-perception 3.25 vs. 2.64; embarrassment 2.76 vs. 1.78.

In a parallel group trial with 6 months' follow-up carried out by Thin *et al*., patients were allocated to receive either SNM or percutaneous tibial nerve stimulation (PTNS)[190]. Participants (N = 15) who underwent permanent SNM had had a two-week test stimulation period demonstrating at least a 50% reduction in faecal incontinence. Compared with the PTNS group, they experienced fewer episodes of faecal incontinence (MD −3.00, 95% CI −6.61 to 0.61 at 3 months; MD −3.20, 95% CI −7.14 to 0.74 at 12 months). Mean (±SD) faecal incontinence episodes per week at baseline and 3 and 6 months of follow-up with chronic stimulation were: 11.4 (12.0), 4.0 (4.0) and 4.9 (6.9), respectively, for SNM compared with 10.6 (11.2), 5.8 (6.9) and 6.3 (6.9) for PTNS. Mean (±SD) CCIS values at baseline and 3 and 6 months were: 16.2 (3.0), 11.1 (5.2) and 10.4 (5.6) for SNM versus 15.1 (2.7), 11.7 (4.4) and 12.1 (5.2) for PTNS.

Leroi *et al* [214] reported a double-blind, crossover multicentre study in 34 patients. The indication to progress from temporary to permanent SNM (N = 27) was based on at least a 50% reduction in the number of episodes of incontinence or faecal urgency per week, or both. After implantation each participant underwent a 1-3 month phase with the stimulator turned on to determine the most effective stimulation parameters. At the end of this post-implantation period, patients were randomised in a double-blind manner to on- or off-stimulation for a 2-month period, with reversal of the activation mode after 1 month. Of these, 24 of the 27 (89%) patients completed the 2-month trial. A significant decrease in median frequency of

faecal incontinence episodes was noted during the on-stimulation period. No significant difference was observed between on- and off-stimulation for frequency of urgency episodes, delay in postponing defaecation, or median number of bowel movements per week (10.2 and 11.1 for on and off, respectively). There was a trend towards greater improvement in the CCIS during on-stimulation (8.5 vs 10.5 [ns]). All 24 patients felt they had improved during the off period. In 19 participants who preferred the on period and five who preferred the off-period outcomes were reported separately: For the group of 19, the median (range) episodes of faecal incontinence per week fell from 1.7 (0-9) during the off period to 0.7 (0-5) during the on period; for the group of five, however, the median (range) rose from 1.7 (0-11) during the off period to 3.7 (0-11) during the on period.

In the crossover trial by Kahlke *et al* [215], 16 of 31 patients who had had SNM for a median of 26.8 months agreed to be randomised in a crossover design to two three-week periods each of stimulation on and off. After six weeks, the patients--still blinded to the stimulator status-- chose which stimulation period they preferred. The mode of stimulation corresponding to the selected period was then continued for 3 months (final period). All patients (N=14 of 16) selected the on mode. They experienced significantly fewer episodes of faecal incontinence per week (1 [SD 1.7]) compared with the off period (8.4 [8.7]). The CCIS was significantly higher ($P < 0.05$) during the off period (14.6 [SD 4.6]) compared with the on period (8.7 [SD 3.6]). The overall number of bowel movements per week declined significantly ($P < 0.05$) in the crossover on period (10.9 [SD 4.1]) compared with the off period (18.2 [SD 8.7]). During the final 3-month period incontinence episodes per week remained low 0.3 (SD 0.5), CCIS was 6.4 (SD 3.3), and the number of bowel movements per week was 9.4 (SD 2.6). **LEVEL OF EVIDENCE: 3**

A large proportion of patients experience altered bowel habit and faecal incontinence following anterior resection of the rectum. This has been increasingly investigated during the last decade and

named low anterior resection syndrome (LARS) Several studies investigating the efficacy of SNM have been published but with few patients included in each study (n=1 to 12). Huang *et al.* published the most recent review and a meta-analysis including ten studies with a total of 75 patients being implanted. There was a wide heterogeneity in the inclusion criteria and the outcome measures. All studies used CCIS to evaluate response while only three studies used the LARS score. The conclusion was that SNM may be beneficial for symptom control, however the current evidence is limited, and general recommendations cannot be made until larger multicentre studies have provided more evidence[216]. The largest series of patients was published in 2000, with 25 patients included. There was a significant reduction of both the Wexner and the LARS score after one year of treatment and a positive correlation between the clinical changes and overall satisfaction. Patients with very low anastomosis and previous radiotherapy had a less successful outcome of SNM[217]. **LEVEL OF EVIDENCE 3**

The efficacy and safety of SNM for faecal incontinence following pelvic radiotherapy have been reported in three studies[218-220]. Maeda retrospectively reviewed the outcome of 13 patients who had undergone a PNE test following pelvic radiotherapy 6,5 years previously. Seven patients went on to chronic stimulation and the frequency of incontinence episodes improved from 24(4-56) to 4 (3-6). Another study reported that the efficacy of SNM in eleven patients treated with oncological multimodal treatment for pelvic malignancies persisted at 24 months follow-up. Mege compared 19 patients with faecal incontinence after pelvic radiotherapy to 38 matched patients with faecal incontinence related to other conditions and the success rate of SNM was similar in the two groups [220]. **LEVEL OF EVIDENCE 3**

1.3.5. SNM for Patients with Anal Sphincter Lesions

An increasing body of evidence indicates that SNM may also be a treatment option for patients with sphincter defects, either unrepaired or after attempted anatomical reconstruction. This was partly addressed in section II.1.2.4. The presence of an internal anal sphincter defect on endoanal sonography is reportedly unrelated to the success of permanent SNM[145]. Since the first report that three of five patients with ultrasound evidence of sphincter disruption measuring 25–33% of the circumference benefited from chronic SNM[221], several studies have been published[148, 149, 200, 221-225]. The origins and morphologic findings regarding the extent of the sphincter gap differ in these studies but lesions up to 180° have been treated. It appears that outcome is not dependent on the radial extent[149, 221]. A significant improvement in clinical function, measured either as frequency of incontinence episodes or CCIS, has been seen in a substantial number of patients in all studies[102, 148, 151, 222, 223, 225, 226]. Follow-up is still limited. **LEVEL OF EVIDENCE: 3**

Melenhorst *et al.*[148] showed that the primary use of SNM in patients with a sphincter gap 17-33% of the circumference appeared to re-

sult in an outcome similar to its use after failed sphincter repair. In another study, SNM in 6 of 8 patients with faecal incontinence related to obstetric full-thickness anal sphincter lesions of >30-150º resulted in improved frequency of incontinence episodes (from 5.5 to 1.5 per week)[224], improved ability to postpone bowel emptying, and improved ASCRS quality-of-life scores at a median follow-up of 26.5 months[221]. No correlation between improvement and the radial extent of the sphincter defect was seen. In patients with internal and external sphincter disruption related to Crohn's disease SNM was beneficial in one study[222].

In 2012, a review of SNM for faecal incontinence associated with anal sphincter lesions identified ten publications (nine retrospective; one prospective) from 1995-2011 comprising 119 patients, of whom 106 (89%) had a definitive implant after PNE testing[227]. A lesion of the external and/or internal anal sphincter was confirmed on endoanal ultrasound. Outcome reporting was not uniform. Follow-up ranged from 4.5 to 48 months. The weighted average number of weekly incontinent episodes decreased from 12.1 to 2.3, the weighted average CCIS decreased from 16.5 to 3.8, and the ability to defer defaecation, when evaluated, increased significantly. Quality of life improved significantly in almost all studies.

In the one prospective investigation, a comparative cohort study[149], the effect of permanent SNM was reported in 53 patients with either an intact external anal sphincter (N=32, 37.5% after sphincter repair) or an external anal sphincter lesion (N=21, 81% after prior sphincter repair) of <90° (N=11) or 90-120° (N=10). Improvement in symptoms and quality of life was achieved, and outcome after 12 months was not significantly different between groups. **LEVEL OF EVIDENCE: 3**

In a single-blinded randomized controlled trial at two hospital units Rydningen *et al*. demonstrated that SNM is superior to injection therapy with Permacol in faecal incontinence following OASIS. The difference in reduction of the St Mark's score was 8.9 (95% CI: 6.1-11.7, P < 0.0001) between the two groups: St Mark's score between baseline and 6 months was reduced by 11.2 (SD 5.3) in the SNM group (n:30) vs. 2.3 (SD 5.0) in the Permacol® group (N: 28). The differences in the four scales of FIQL (lifestyle, coping, depression, embarrassment) were 0.90 (95% CI: 0.50-1.30, P < 0.001), 1.05 (0.62-1.47, P < 0.001), 0.52 (95% CI: 0.16-0.87, P = 0.005) and 0.95 (95% CI: 0.50-1.40, P < 0.001), respectively, in favour of SNM[228]. The findings of another study confirm the positive outcome of SNM PNE testing in patients with OASIS demonstrating a reduction in weekly FI episodes of 94.5%, from a median (interquartile range) of 4.8 (2.0–11.0) to 0.5 (0–2.0) (P < 0.001)[229].

A recent retrospective study including 475 patients treated during 2000-2013 indicated that the increase in the number of SNM procedures during 2000-2013 was not proportional to the change in the number of patients with sphincter injuries, suggesting that SNM has become the operation of choice for FI regardless of the underlying sphincter profile[103]. Increase in utilization and popularity of SNM is also reflected by a population-based cohort study (prospectively obtained data including 621 patients treated for FI between 2011 and 2014 in the state of New York) by a decline in numbers of sphincteroplasties performed after the approval of SNM in 2011[230].

1.3.6. SNM for specific FI aetiologies

The therapeutic potential of SNM has also been demonstrated in some, mostly small, case series and individual case reports of patients with distinct pathological conditions or well defined anorectal pathophysiology: e.g. muscular dystrophy[231]; proctocolectomy with ileoanal J-Pouch reconstruction for colitis[232]; neurological dysfunction including spinal disc prolapse[233]; rectal prolapse repair[234, 235]; rectal resection for cancer[236] with or without neoadjuvant chemoradiation[134, 237-239]; after proctectomy with colorectal or coloanal anastomosis for rectal cancer ± neoadjuvant radiochemotherapy[240]; after neoadjuvant and adjuvant chemoradiation / radiotherapy for endometrial and anorectal cancer[218, 219, 241]; after unilateral traumatic pudendal neuropathy[242]; in spina bifida[243]; in congenital faecal incontinence[244] including from anorectal malformations[245] and incontinence related to external anal sphincter atrophy[246]. **LEVEL OF EVIDENCE: 4**

1.3.7. Quality of Life

Outcome assessment has also evolved, and aspects of quality of life have been added to the evaluation (CCIS, SF-36 and Fecal Incontinence Quality of Life [FIQL] Score). The therapeutic impact of SNM is most evident when a disease-specific quality-of-life instrument, the ASCRS FIQL scale, is applied.

In the first study to apply this instrument, the multicentre clinical trial by Matzel *el al.*[139], ASCRS FIQL was significantly increased in all 4 scales; SF-36 scores improved in 7 of 8 scales, the greatest being social functioning and mental health, but only the former reached statistical significance. A similar result was published by Leroi *et al.* [214] with the French version of the ASCRS QOL (FIQL): at the final follow-up visit, improvements in lifestyle, coping behaviour, depression, and self-perception and embarrassment were significant. Hetzer *et al.* [247] demonstrated a significant improvement of the median Gastrointestinal Quality of Life Index score with permanent SNM from a baseline of 96 (range 47–128) to 107 (range: 36–128) at 6 months' post-implantation.

In many studies on outcome, quality-of-life evaluation is a secondary endpoint[99, 133, 139, 140, 160, 189, 192, 214, 233, 234, 236, 238, 248, 249]. When used, improved quality of life is consistently related to symptom relief and remains stable with longer follow-up[99, 194, 196, 247, 250]. Indeed, long-term data with a follow-up of at least 5 years indicate a significant improvement of all four scales of the FIQL score[250, 251].

In a meta-analysis[187] of 34 studies with 790 patients, SF-36 score data were analysed from 7 studies with 98 to 102 patients and ASCRS FIQL data from 9 studies comprising 199 patients: SF-36 outcome was significantly increased in all categories (physical functioning, social functioning, role physical, role emotional, mental health, vitality, general health) with one exception (bodily pain). FIQL outcome was significantly increased in all categories (lifestyle, coping/behaviour, depression/self-perception, embarrassment).

In a two-centre study of patients with permanent SNM for a median of 46 months (range: 11-122), 108 of 127 patients responded to questionnaires regarding bowel habits and quality of life. Using a non-validated score, 75.8% reported satisfaction, which in most was related to clinical improvement. However, at last follow-up 11 of 23 patients who had failed to achieve a 50% reduction in incontinence episodes reported satisfaction, and 6 of these had more incontinence episodes than at baseline[195].

Four of the randomised controlled trials discussed above, when relating quality of life to clinical efficacy of SNM, have used varying instruments: SF-12, ASCRS FIQL[189]; SF-36[252]; the French version of the ASCRS FIQL[214]; and ASCRS FIQL, SF-36 and EQ-5D[190]. Improvement was found in all, except for EQ-5D with chronic SNM. **LEVEL OF EVIDENCE: 2**

1.3.8. Cost benefit

Permanent SNM is expensive; however, its cost-effectiveness has been demonstrated in several European nations. Hetzer *et al.* [253] compared the costs of SNM with those of conservative treatment, anterior sphincteroplasty, dynamic graciloplasty, and stoma creation in 34 consecutive patients. The 5-year cumulative cost for SNM was €19,333, compared with €35,965 for a stoma (with annual costs of €5,339) and €34,953 for dynamic graciloplasty (annual costs €1,659). The equivalent cost for conservative treatment was €3,895, and the overall median real cost for an anterior sphincteroplasty was €5,327. Muñoz-Duyos *et al.* [254] analysed the direct medical costs of SNM in a series of 47 patients undergoing 57 PNEs and the consequent 29 patients with a permanent unilateral implant for a median follow-up of 34.7 (2.3-81.2) months. The cost totalled €371,434, including €317,791 for the devices. In patients without anal sphincter damage SNM provided 0.34 incontinence-free life-years and entailed additional costs of €1,054, which generates a cost-effectiveness ratio of €16,181 per quality-adjusted life-year (QALY). The nationally accepted threshold is around €30,000/QALY. The economic impact of the introduction of SNM would be to add 0.07-0.1% to the care of these patients (2008 data).

In a decision-analysis model based on prospectively collected data in 70 patients undergoing test stimulation and implantation of the permanent SNM device, incontinence episodes/week were reduced from 6 at baseline to 0.5. Dudding *et al.*[193], based on direct medical and non-medical costs, found an incremental cost-effectiveness ratio (ICER) for SNM of £25,070 per QALY gained. It cost £1,038 per year to achieve a median reduction of 238 incontinence episodes, equal to £3.61 per reduced episode. The ICER of £25,070 per QALY was within the UK nationally accepted £30,000 per QALY threshold.

In a similarly designed study based on published reports and expert opinion, Indinnimeo *et al.* [255] found that the ICER was €28,285 per QALY gained in patients with a structurally deficient anal sphincter and €30,662 per QALY in patients with an intact anal sphincter. Both were below the relevant national threshold of €40,000 per QALY gained. Budget-impact analysis demonstrated that the implementation of SNM would have an estimated impact of 0.56% over a 5-year period on the budget allocated for faecal incontinence treatment.

In a French study, clinical outcome and cost-effectiveness analyses were performed in parallel with a prospective, multicentre cohort study that included 369 consecutive patients with urge urinary and/or faecal incontinence with a follow-up of 24 months[256]. Cost-effectiveness outcomes were expressed as incremental costs per 50% of improved severity scores (incremental cost-effectiveness ratio). Based on a national health perspective the average cost of SNM for faecal incontinence was €6,581 more for the first 2 years when compared with alternative treatments (95% confidence interval, €2,077- €11,084; P = 0.006) when an improvement of more than 50% in the continence severity score was used as the criterion of effectiveness. The incremental cost-effectiveness ratio for SNM was €94,204 and €185,160 at 24 months of follow-up for urinary and faecal incontinence respectively. These findings were above the generally accepted range of cost effectiveness, but SNM was considered to offer marked health benefits for patients with faecal incontinence (measured by the severity score).

In a retrospective study of a national (> 90% of implants performed in New Zealand) cohort of 100 out of 110 patient with a permanent SNM device treated between 2008 and 2019 Varghese et al[213] described the efficacy of SNM and reported a reintervention rate of 41.5%. SNM therapy was considered expensive, costing >NZ$30,000 for implantation, increasing to >NZ$46,000 depending on number and kind of required re-interventions.

SNM requires maintenance, which comes with costs. In a structured, prospectively performed post implant follow-up program of 85 patients with permanent implant having regular visits at 3 months, 6 months, yearly thereafter for therapy monitoring and adjustments and further visit because of the need of device adjustments based on symptom changes McMullin *et al*. [257]. demonstrated at a median follow up after permanent implantation of 24 months (range: 3–108) that 27 % of the patients had an unsatisfactory outcome. The follow-up cost for these patients constituted 48.7% of the £75,702 total follow- up cost. **LEVEL OF EVIDENCE 3**.

1.3.9. Safety

SNM is a relatively safe procedure however, adverse effects are commonly reported. Painful or uncomfortable stimulation, leg cramp, superficial wound infection at the site of the implant and loss of efficacy are usually resolved with medication or reprogramming[258]. Some adverse events such as severe pain at the IPG site, lead migration or fracture, deep wound infection and battery depletion require surgical revision or explantation, The incidence of surgical revision of SNM varies in different publications and ranges from 16% to 39%, and younger age (<55 years) is the only risk factor that has been identified and associated with an increased frequency of device revision and explantation[259, 260].

In an FDA study with strict monitoring of adverse events, 334 were reported in 99 patients at three-year follow-up; 67% occurred in the first year, and most required no or minimal intervention at the time. The adverse events included pain at the implant site (28%), paresthesiae (15%), change in the sensation of stimulation (12%), implant site infection (10%), urinary incontinence (6%), diarrhoea (6%), and extremity pain (6%). Half of the infections required surgical intervention with removal of the device in 5 of 6 patients[250]. More recent data of the same patient cohort report a 39% need for device revision, replacement, or removal. With 5 years' follow-up, 26.3% of patients had a revision, replacement, or removal of the device for reasons other than battery depletion [261]. Significant differences between those who exited because of a lack of efficacy before five years and those who remained in the study were found in two areas: average percentage of improvement at test stimulation (90% vs. 80%, p=0.007) and the percentage of patients completely continent during the test stimulation (47% vs 7%; p=0.004).

Major complications are rare: one case report of a life-threatening haemorrhage after elective tined lead electrode removal has been published[262].

A review of 48 cohort studies (45 for faecal incontinence and 3 for constipation) documented the postoperative events in the 1,661 patients with test stimulation and 1,600 patients with a permanent SNM implant[263]: the review found that the incidence of suboptimal outcome was 12.1%, pain 13%, and infection 3.9%. The most common problem during test stimulation was lead dislodgement (5.3%). Systematic literature review suggests a possible underreporting of suboptimal outcome and adverse events. In one single study, the rate of adverse events reached up to 85.2% in patients with a median follow-up of 11 months: loss or lack of efficacy and pain or discomfort accounted for 88.5% of these [264]. In a review with 45 studies including 1,953 patients the pooled rate of infection was 5.1% (4.1-6.4) without significant heterogeneity between trials [265]. In a recent multicentre study with the objective to estimate incidence of infection after placement of an IPG and to identify risk factors associated

with SNM explantation, 38 cases of infection required IPG explant in a cohort of 1,930 IPG implants (1.97%). A deep pacemaker pocket (>3cm) and postoperative haematoma were factors significantly associated with infection requiring IPG explant. The most common infectious organism identified was methicillin-resistant *Staphylococcus aureus*. There was no difference in risk of infection based on choice of prophylactic antibiotics at implant[266].

In their summary of studies with long-term follow-up (70-118 months), Altomare *et al.* reported minor complications in 79 patients (PP, 29%; ITT, 19.4%), of which 64 (PP, 23.5%; ITT, 15.7%) were device related. The most common was pain at the subcutaneous site (23 patients) prompting device removal in 12 patients and replacement in seven. Removal and repositioning for dislocation or battery depletion was necessary in another 17 patients[152].

In general, the most common intervention described in the literature is repositioning of the pacemaker due to pain or migration. In a recent study the incidence of IPG site pain as a function of the site of IPG implantation was studied in patients with permanently implanted nerve stimulation systems. A total of 424 patients participated in the survey of which 80 patients (19%) had a sacral nerve stimulator. Overall, 31% of patients reported pain at IPG site (31,4% reporting moderate to severe pain, 7.6% reporting severe pain). Older age was inversely associated to IPG-related pain and the anatomical location of the IPG placement did not affect the incidence or severity of IPG site pain. However, patients with pre-implant chronic pain disorder had a higher frequency and severity of IPG site pain[267].

LEVEL OF EVIDENCE: 2

Summary:
Sacral nerve stimulation is an effective treatment in patients with severe incontinence unresponsive to conservative treatment. It may be effective as a first-line treatment in patients with an anal sphincter defect. The therapeutic benefits are sustained in the medium- to long-term. The mechanism of action is not entirely certain however effects on sensory afferents appear most probable. SNM has an effect on the peripheral and central nervous system. SNM is a relatively safe procedure, however adverse events are common and surgical revision required in up to one third of the implanted patients. **Grade of Recommendation: B**

1.4. Injectable Biomaterials

There have been several developments in the field of injection of bulk-enhancing agents into the anal canal to treat faecal incontinence (FI) since the last review. These include the use of new materials and injection techniques. Only two of these have been randomized comparisons of two or more interventions[228, 268] The remainder have been case series, one of which compared data with those from a previous series[269].

The ideal agent for injection should be biocompatible, non-allergenic, non-immunogenic, easy to inject, and should not migrate within the tissues. No agent currently has all these properties. Agents that have a diameter of 80µm are felt to be less prone to migration, but agents with a larger particle size require a larger bore needle to inject, which put them at a higher risk for leakage from the injection site.

Injectable agents for FI were first used in 1993 when Shafik treated 11 patients with injections of polytetrafluoroethylene paste into the anal submucosa[270]. Since that time there has been a steady arrival of new materials, usually after initial enthusiasm in the treatment of urinary incontinence. Most of these agents are only in use for a few years before a newer agent takes their place.

1.4.1. Types of injectable biomaterials

The following biomaterials have been used in the treatment of faecal incontinence:

- Polytetrafluoroethylene paste (Teflon)
- Autologous fat
- Glutaraldehyde cross-linked synthetic bovine dermal collagen (Contigen)
- Polydimethylsilozane elastomer silicone biomaterial (PTQ, Macroplastique)
- Microballoons with biocompatible hydrogel
- Carbon-coated zirconium oxide beads (Durasphere)
- Calcium Hydroxylaptatite Ceramic Microspheres (Coaptite)
- Dextranomer-hyaluronic acid copolymer, NASHA/Dx (Zuidex, Solesta)
- Ethylene Vinyl Alcohol EVOH
- Polyacrylonitrile cylinder (Gatekeeper)
- Polyacrylate-polyalcohol (Exantia)
- Polyacrylamide gel (Bulkamid)
- Cross-linked porcine dermal collagen (permacol)
- Polyacrylonitrile cylinder (Sphinkeeper)

1.4.2. Observational data

The multitude of case series providing outcomes for injectable biomaterials in FI are shown in **Table 6** and will not be discussed in detail here. Of 29 case series, 16 included fewer than 20 patients and none included more than 100. There was no standard methody of inclusion, injection technique or assessment. There was also wide variation in both the length of follow-up and outcome measures used. None of the case series are of high quality. Most of the studies report a modest improvement in measure of incontinence utilized. Those that measured longitudinal outcomes generally showed deterioration over time. None of the earliest biomaterials, Polytetrafluoroethylene paste (Teflon), Autologous fat, Glutaraldehyde cross-linked synthetic bovine dermal collagen (Contigen), Polydimethylsilozane elastomer silicone biomaterial (PTQ, Macroplastique), Microballoons with biocompatible hydrogel, Carbon-coated zirconium oxide beads (Durasphere), Calcium Hydroxylaptatite Ceramic Microspheres (Coaptite) are still in use for the treatment of faecal incontinence.

A recent addition to the long list of trialled materials is the polyacrylonitrile (Gatekeeper™) device. This is a shape-memory hydrophilic material that enlarges to seven times its initial diameter of 1.2 mm once in contact with human tissue. It can be manufactured into thin rods, which are injected into the intersphincteric space. An initial single-centre report showed a sustained improvement in incontinence and quality of life scores over a mean follow-up of 33 months[271]. A larger multicentre observational study reported the outcome of this device. At 12 months' follow-up, 30/54 (56%) patients achieved a greater than 75% improvement in incontinent symptoms, and 7 (13%) achieved continence. The implant extruded in three patients [272]. This technique was developed further into the SphinKeeper. Instead of using six rods, ten are placed in intersphincteric space. A combined series from St Mark's and the Royal London Hospitals in 2020 reported on 27 patients. All had passive FI. In 30% the delivery device jammed and not all of the implants were delivered. Post-operative endoanal ultrasonography showed that a median of 7 implants (0-10) were seen in each patient, with a median of 5 (0-10) postioned in the optimal intersphincteric position. Despite this, the St Mark's FI score improved by a median of 6 points and 14 patients (52%) achieved a greater than 50% improvement in symptoms. This success rate did not appear to be

related to implant position[273].

1.4.3. Randomised Controlled Trials

There have now been eight randomised trials of bulking agents for FI (Table 7), but only three of them compared an injectable biomaterial to a control/placebo. None demonstrated a clear over placebo or non-operative management.

In the first, 44 patients were randomised to receive transdermal injections of polydimethylsilozane elastomer silicone biomaterial (PTQ) or saline into the intersphincteric space[299] . Three 2.5ml injections were performed using local anaesthesia. Patients, but not investigators, were blinded to the treatment. There was no difference in percentage of patients in the two groups who had a treatment success, defined as having a CCF-FIS score <8 or the decrease in CCF-FIS scores post-treatment. The saline group tolerated treatment better and had fewer adverse effects overall. Thus, the study concluded that the use of PTQ should not be recommended.

The second is the largest study published to date, a randomized,

double-blinded sham-controlled trial of 206 patients randomised in a 2:1 fashion to receive NASHA Dx (Solesta) or placebo saline injection[300]. The patients and the evaluating investigators were blinded to the treatment. More patients in the treatment group had 50% or greater reduction in number of incontinence episodes (52% versus 31% of controls; p=0.009), but the change in CCF-FIS did not differ after treatment between groups (14 to 2.5 in the treatment group vs. 13 to 1.7 in placebo group). The FIQL was only significantly improved compared to placebo for the coping and behaviour subscale. Both groups had high retreatment rates: 82% of patients in the Solesta group received reinjection of product and 87% of patients in the control group had repeat sham injection. The Solesta group had significantly more adverse events, including proctalgia, rectal bleeding, pruritus, diarrhoea, constipation, fever, and two serious complications of rectal abscess and prostatic abscess. The control group had more injection site bleeding. [300]

Although the final RCT compared Solesta to biofeedback rather than placebo, it does represent a study that compares a surgical procedure with injectable biomaterial with a non-operative control. This was a large and well-designed randomised controlled trial from Norway, 126 patients were randomised to either Solesta or biofeedback training[301]. Patients were followed up to 24 months. There was no difference in improvement in St Mark's Incontinence Score between these groups at any of the follow-up times. Solesta was not superior to biofeedback retraining.

1.4.4. Randomised Comparison Trials

There have been five randomised studies comparing different surgical options. One compared SNM to Permacol, one Permacol to polyacrylamide gel (Bulkamid), two compared PTQ to Durasphere, and another compared different doses of Bulkamid.

In the trial by Rydningen *et al.,* Permacol was compared with SNM in 58 women with FI.[228] The reduction in the St Mark's score between baseline and 6 months was 11.2 (SD 5.3) in the SNM group vs 2.3 (SD 5.0) in the Permacol group (P < 0.0001). SNM also had a significantly greater improvement in all four domains of the FIQL (p<0.005). There was no difference in adverse effects. There was a clear advantage to SNM over Permacol injection

A pilot study conducted in 2008 examined two other products, cross-linked porcine dermal collagen (Permacol), and polyacrylamide hydrogel (Bulkamid) [302]. Ten patients with passive FI to liquid or solid stool who had failed conventional treatments were prospectively randomised to receive either of the two products. There was a modest reduction of the St Mark's incontinence score at 6 weeks for both groups, but this decrease was sustained at 6 months only for the Bulkamid group. This pilot study lacked power to determine if these two treatments for FI differed significantly.

Two trials compared the safety and efficacy of PTQ and Durasphere[303] [304]. In the trial by Tjandra *et al.* the sample size was calculated to detect a 50% reduction in the CCFIS post injection. [285] Thus, 40 patients with FI (mean CCFIS 11.45) were randomised to receive either PTQ or Durasphere. Both groups were similar in

Table 7. Randomised trials of Injectable biomaterials

Author Year	Agent	Patient no.	Injection technique	No. sites	Volume	Outcome	P value < 0.05
Siproudhis[299] 2007	Polydimethylsilozane elastomer silicone biomaterial (PTQ)	22	Intrasphincteric	3	2.5ml	No difference in CCF-FIS: 13.8 to 11.7 PMDS, 14.6 to 11.4 placebo	No

	Permacol	28	Transanal	3	2.5ml	StMIS reduced by 2.3	
Altman[261] 2016	Polyacrylamide gel (Bulkamid)	10	Transanal SM	4	4ml	CCF-FIS reduced by 1.8	No
		10	Transanal SM	3	4ml	CCF-FIS reduced by 2.4	
		10	Transanal SM	3	6ml	CCF-FIS reduced by 3.1	
Maeda[302] 2008	Permacol	5	Transsphincteric	3	9ml	StMIS 15 to 12.5	No
	Polyacrylamide hydrogel (Bulkamid)	5	Transsphincteric	3	15ml	StMIS 15 to 12.5	
Tjandra[303] 2008	Polydimethylsiloxane particles (PTQ)	20	Intrasphincteric	4	2.5ml	CCF-FIS 11.5 to 3.8, FIQL and SF-12	Yes
	Pyrolytic carbon coated beads (Durasphere)	20	SM	4	2.5ml	complications, CCF-FIS 11.5 to 7.0 FIQL, SF-12 not improved	
Morris[304] 2013	Polydimethylsiloxane particles (PTQ)	17	Intersphincteric	3-4	2.5ml	Wexner score compared to baseline was reduced by 4.3 (P<0.001), 4.2 (P<0.001), and 1.1 (P=0.24) 6 weeks, 6 and 12 months.	No difference between groups
	Pyrolytic carbon coated beads (Durasphere)	18	SM	4	2.5ml	Improvements in the Durasphere arm for the same time periods were 5.3 (P=0.003), 4.1 (P=0.002), and 1.8 (P=0.19).	

Key: StMIS St Marks Score; SNM Sacral neuromodulation; CCF-FIS Cleveland Clinic Florida Faecal Incontinence Score; SM submucosal; FIQL Faecal incontinence Quality-of-Life score; SF-12 Short Form Health Survey Quali-ty of Life score; NA Not applicable.

terms of age, medical history, FI severity and quality of life scores as well as anorectal manometry results. Although the Durasphere group had a greater reduction in CCFIS at 2 weeks (11.45 to 8.25 vs. 11.45 to 10.9), the PTQ group had a greater reduction in CCF-FIS at 6 weeks, 6 months and 12 months (4.6,2.95 and 3.8 vs. 7.65, 6.2 and 7) and had no complications. The Durasphere group had several complications including anal pain (5%), mucosal erosion (10%), arthritis and skin rashes (5%). Furthermore, the PTQ group demonstrated significant improvements in general and faecal-incontinence-specific quality-of-life scores that were not seen in the Durasphere group. Thus, the conclusion was that PTQ was safer and more effective than Durasphere for the treatment of FI. [285] The second trial, by Morris *et al.*, was of a similar size but and demonstrated an improvement in both groups at 6 weeks and 6 and 12 months. This trial did not identify any difference between the two techniques. [304]

Altman *et al.* randomly employed different injection strategies for Bulkamid in three groups of 10 patients with CCF-FIS >10 using 3 or 4 sites of injection and either 4 or 6 mls of Bulkamid[268]. At 12 months follow-up there was a significant but modest improvement of mean CCF-FIS from 14.7 to 12.4 but no difference between the different injection groups was detected. This study was clearly underpowered to allow any statistical inference.

These trials indicated that PTQ performed better than Durasphere in terms of both safety and efficacy,[303] Solesta, was not superior to biofeedback training[301], SNM was superior to Permacol[228] and in an RCT the dose of polyacrylamide gel did not alter its efficacy[268]

1.4.5. Conclusion

In summary, randomised controlled trials have failed to show any appreciable benefit to the use of injectable biomaterials for faecal incontinence. Furthermore, uncontrolled studies are mostly small, poor quality case series that in general show short-term efficacy. As of November 2020, only one bulking agent, NASHA DX (Solesta), had been approved by the FDA for treating faecal incontinence.

Two systematic reviews[305, 306] and a recently updated Cochrane review[307] have published the data for all injectable agents for faecal incontinence. Due to the poor methodology and small sample sizes of most of these studies, none of these reviews could establish adequate evidence to support the efficacy of any of these agents Randomised controlled trials have not demonstrated clear efficacy in any of these agents against non-operative treatment or placebo. The evidence base for managing FI with injectable biomaterials is of poor quality and their use cannot be recommended at this time. **LEVEL OF EVIDENCE: 2.**

Summary:
The role of injectable biomaterials in treatment of faecal incontinence is not established. The optimum bulking agent and site of injection remain uncertain. Use is not recommended **Grade of Recommendation: C.**

1.5. Puborectal sling

The puborectal sling operation was first reported by O'Rourke in 1974 [308]. In this procedure, an artificial sling is routed behind the anorectal junction and its two ends are fixed to the pubic bone, pulling the anorectal junction up forward with some tension. Similar to the postanal repair, the rationale of this operation is the restoration of the anorectal angle normally maintained by puborectal muscle.

No systematic reviews, randomised controlled trials, non-randomised cohort studies or case control studies have been reported regarding puborectal sling operation for faecal incontinence, while one prospective comparative study (level 2) [309], three prospective case series of good quality (level 3) [265, 310, 311] and three retrospective case series of low quality (level 4)[308, 309, 312] were identified.

O'Rourke[308] reported using Dacron® mesh for the treatment of 3 patients with full rectal prolapse as well as 4 patients with mucosal partial rectal prolapse and faecal incontinence. Of the 4 patients with faecal incontinence and partial prolapse, 3 were reported to have "benefited considerably" from the procedure although a formal evaluation was not performed, and the follow-up period was not documented. O'Rourke and Egerton [312] also reviewed 24 patients in whom the sling operation was performed using a strip of rolled Mersilene® mesh. This procedure, however, was performed mainly for the treatment of rectal prolapse, while it was conducted because of faecal incontinence alone only in two out of the 24 patients, and the outcomes regarding the continence were not formally evaluated.

Shafik [309] reported another sling operation called puborectoplasty utilising a Teflon™ sling for faecal incontinence. Of 31 patients who had been incontinent to solid stool and underwent this procedure, "good results" were achieved in 26 patients (84%) after a follow-up period of between 2 - 4 years: 20 became continent to solid and liquid stool as well as flatus; 6 to solid and liquid stool but not to flatus; 4 to solid stool only; and only one remained incontinent to solid stool.

Shafik and Shafik[309] conducted a prospective comparative study comparing two fascia lata slings (double loop) in 22 patients and one fascia lata sling (single loop) in 22 patients for the treatment of faecal incontinence. After 12 months follow-up, "good results" were achieved in 14 (64%) and 8 (36%) by the double loop and the single loop, respectively

Yamana et al.[310] performed the perineal puborectalis sling operation in 8 patients with passive faecal incontinence using a polyester mesh sling. A rectal ulcer developed in one patient, requiring sling removal. In the 6-month evaluation of the remaining 7 patients, all reported some extent of improvement of their faecal incontinence. Both the Fecal Incontinence Severity Index and the Cleveland Clinic Florida Fecal Incontinence Score (CCIS) significantly improved from 27 to 9 and from 13 to 5, respectively. Moreover, all parameters in the Fecal Incontinence Quality of Life Scale (FIQL) significantly improved: lifestyle from 2.1 to 3.6; coping/behaviour from 1.5 to 3.4; depression/self-perception from 2.3 to 3.7; and embarrassment from 2 to 3.6.

The transobturator posterior anal sling (TOPAS™) is the first puborectal sling, aimed to be commercially available for the treatment of faecal incontinence in women. It is comprised of a knitted, Type 1 polypropylene monofilament mesh, which is covered by removable insertion sheaths, and two insertion needles. It is implanted through a transobturator approach via two small incisions in both thighs and buttocks. The implanted mesh is self-fixating and permanent with tissue in-growth providing additional support to the anorectum.

In a preliminary prospective multicentre study, 29 women were implanted with the TOPAS™ system[311]. Fifteen patients (52%) achieved treatment success, which was defined as a reduction of 50% or more in the number of faecal incontinence episodes compared with baseline, and 33% reported complete continence. The mean faecal incontinence episodes per 14 days significantly decreased from 6.9 at baseline to 3.5 at 24 months of follow-up. The CCIS and FIQL for all 4 domains were significantly improved during the overall follow-up period compared with baseline. A total of 12 patients (41%) experienced 19 procedure- and/or device-related adverse events, but there were no device-related erosions, extrusions or revisions.

In a larger multicentre FDA controlled study, 152 women were implanted with the TOPAS™ system [26493933] At 12 months of follow-up, 69% of the patients achieved treatment success, which was defined as a reduction of 50% or more in the number of faecal incontinence episodes compared with baseline, and 19% reported complete continence. The median number of faecal incontinence episodes per week significantly decreased from 9 at baseline to 2.5 at 12 months. The CCIS and FIQL for all 4 domains were significantly improved from baseline to 12 months. A total of 66 patients (43%) experienced 104 procedure- and/or device-related adverse events, but most of them were short in duration and 97% were managed without therapy or with nonsurgical interventions. There were no treatment-related deaths, erosions, extrusions, or device revisions. **LEVEL OF EVIDENCE: 3**

The puborectal sling operation, particularly with TOPAS™ system, appears promising because it is a simple procedure and yielded reasonably good results with a low rate of serious complications so far. More prospective studies of longer follow-up are warranted; these must closely evaluate complications such as sling infection, erosion and rectal ulcer requiring sling removal. Furthermore, owing to legitimate concens regarding the use of pelvic mesh, it is essential that any patient considered for this procedure should be discussed at a multidisciplinary team meeting (MDM), should be subject to enhanced informed conset processes and be part of a

registry.

Summary:
The efficacy of the puborectal sling remains unproven. It may be of value in selected patients but this must be balanced against potential risk of mesh-related complications. **Grade of Recommendation: C**

1.6. Radiofrequency energy treatment

The administration of radiofrequency energy for the treatment of FI was first used in Mexico in 1997 [313]T. It is commercialized as the SECCA® procedure and received clearance from the Food and Drug Administration (FDA) of the USA in 2002. Suggested mechanisms of action include tissue-tightening effects with collagen contraction, focal wound healing, remodelling, and tissue compliance reduction.

The procedure is generally performed using local anaesthesia and conscious sedation in an outpatient setting. The SECCA® System is made up of a sterile, single-use hand-piece and a reusable RF generator. The hand-piece consists of a clear plastic anoscope with 4 retractable needle electrodes, which are deployed into the internal anal sphincter. The generator delivers low power (465 kHz, 2–5 W), temperature controlled (65°C and 85°C) energy at each needle electrode for 60 seconds. During the treatment, the mucosa is constantly irrigated by chilled water at the base of each needle to avoid burning.

RF energy is delivered at five different insertion levels each at 0.5 cm beginning at the dentate line upwards. When all 5 levels have been treated within a quadrant, the handpiece is rotated through 90° and treatment starts in the next quadrant[314]. This results in a total of 20 radiofrequency deliveries with 80 separate treatment sites. The whole procedure takes approximately 45-60 minutes.

Published studies include only one randomised controlled trial [315] 11 prospective uncontrolled studies and 1 retrospective review of medical records. Results are summarized in **Table 8**.

All studies reported radiofrequency to be an easy, safe, and well-tolerated procedure. Reported complications were mild and rare, including pain, delayed bleeding and mucosal ulceration.

The very favourable results reported by the pioneers of this technique[313, 317] have not been confirmed by later studies. Even though reports were generally positive (significant reduction of fecal incontinence score), most series did not demonstrate a 50% improvement in scores and FI often persisted at levels that were clinically

Table 8. Studies investigating the efficacy of the SECCA procedure

Study	N	FU	Outcome measures	Definition clinical response	FI score	FIQL score	Clinical response

unsatisfactory. Morever, Takahashi *et al.* recently published their results of a 15-year follow-up[326] in which the therapeutic effects were not maintained. No study has been able to demonstrate changes in anorectal structure or function. Finally, the only randomized sham-controlled trial (n = 40)[315] showed only a minimal improvement in FI score compared with sham, with a negligible clinical impact, leading the authors to conclude that SECCA should not be recommended for patients with FI.

Summary:
Temperature controlled radiofrequency energy may transiently improve continence in patients with mild to moderate symptoms, but long-term results are disappointing. A single controlled trial showed no benefit. **Grade of Recommendation: C**

1.7. Autologous Cell Therapies

Despite the development of various devices to augment or replace the anal sphincter, there is an inherent feeling that the most ideal solution would be a biocompatible regeneration of tissue and restoration of its function.

Cell therapy appears to be a potential solution for restoring cells, tissues and even organs whose function is impaired following events as trauma, degenerative disease, or aging. Many skeletal muscle diseases are now receiving attention and the anal sphincter is no exception. FI is now the subject of several preclinical and clinical studies. 'Cell therapy' in this context usually corresponds to the use of freshly isolated or culture-expanded cells for local or systemic injection. In contrast, 'tissue engineering' usually corresponds to the use of scaffolds alone, or in combination with cells and/or trophics factors. To date, only cell therapy has been used in clinical studies, however, the successful creation and implantation of intrinsically innervated anal sphincter constructs have been reported in rats and rabbits[327, 328].

To date, data are available for 118 patients with FI receiving cells in 7 studies **[Table 9].** These comprised four observational studies (two with the same patient cohort), one case-control study and three randomised controlled trials. The majority of published cell therapy clinical studies have used autologous myoblasts (usually termed *autologous muscle-derived cells*: AMDC) injected into the EAS under ultrasound guidance. The first study of AMDC in humans was published in 2010 by Frudinger *et al.* [329]. This observational study included ten women with FI from obstetric trauma with non-operated anterior lesions that were refractory to conservative treatment. The authors took a striated muscle biopsy (approximately 1 cm^3) from the pectoralis muscle. In the laboratory, the muscle was digested and myogenic cells were isolated and cultured. After a mean cultivation time of 39 days, cells were harvested and pelleted in a concentration of ~20 million cells/ml medium with 10% autologous serum. Twelve to fourteen AMDC injections of 0.5 ml were performed under ultrasonic guidance in a semi-circular array, including EAS divided ends and the intervening scar. In order to optimise cell integration, patients received electrical stimulation via

Table 9. Studies of autologous cells for faecal incontinence

an anal plug 15 min per day for 10 weeks prior to injection and for 28 days post-surgery. At one-year follow-up, there were marked reductions in Cleveland Clinic Incontinence score (mean 14 points) and incontinence episodes per week (mean 8 episodes). Overall quality of life was also significantly increased. However, there were no important changes in ultrasonography and anal pressures were unchanged. No adverse events appeared during follow-up. The authors concluded that the treatment is feasible, safe, well-tolerated, and improved symptoms of anal incontinence due to obstetric anal sphincter trauma.

Five-year follow-up of all ten patients was published in 2015[330] with maintenance of all outcomes and no later adverse events. Moreover, there was a rise in resting and squeeze pressures with the 5-year value significantly higher than at baseline, suggesting an increase of muscle strength with time.

The same year, Romaniszyn *et al*. [332] published a further prospective study of ten patients undergoing AMDC therapy. Muscular biopsy was obtained from the quadriceps. After an average of 5.5 ± 0.8 weeks of *in vitro* culture, a total of $3x10^8$ cells were injected around the entire circumference of the EAS. In patients with an EAS defect, the volume of the suspension was divided into three 1-ml portions: 1 ml was injected on both sides of the muscle scar, one was applied on the remaining circumference of external sphincter muscle ring, and the last portion was injected directly into the scar. Follow-up was available for nine patients. At 18 weeks, six patients (66.7 %) reported subjective improvement with significant increase of squeeze anal pressures and high-pressure zone length on manometry (five very significantly (55.6%)). Electromyographic (EMG) examination showed a significant increase in signal amplitude in all patients. At 12 months, two of the six patients with good results at 18 weeks reported deterioration of continence, with deterioration of manometric and EMG parameters. Nevertheless, mean values were still significantly improved compared to pre-implantation. The remaining four patients (44.4%) persisted with satisfactory results.

A phase II, randomised, double-blind, placebo-controlled trial of AMDC was published in 2018 [334]. Twelve patients received intrasphincteric injections of cells and 12 received placebo. At 6 months, median Cleveland Clinic Incontinence score significantly decreased from baseline in both the therapeutic (9 vs. 15, P = 0.02) and placebo (10 vs. 15, P = 0.01) groups with differences failing to meet the primary endpoint. However, at 12 months, median score continued to reduce in the AMDC group (6.5 vs. 15, P = 0.006), while this effect was lost in the sham injection arm (14 vs. 15, P = 0.35), with a higher response rate observed in the treated group (58% vs 8%, P = 0.03). After delayed frozen AMDC in the placebo group, the response rate was 60% (6/10) at 12 months. Despite these good clinical results, no physiological changes (sonography, MRI or electrophysiological tests) were observed.

More recently, Frudinger *et al*. [331] reported data for 39 patients who received cryo-preserved AMDC for FI due to EAS damage and/or atrophy, including 5 males. Twelve injections (79.4 ± 22.5 × 10^6 AMDC) were extended in a circular array directly into the EAS and all patients performed anal canal electrical stimulation for 4 weeks post-implantation. After 12 months, frequency of weekly incontinence episodes (primary outcome) and FI QoL improved significantly. In 80.6% of males and 78.4% of females, the FI frequency decreased by at least 50%; Cleveland Clinic Incontinence Scores and severity of FI complaints also decreased significantly, independent of sex and aetiology of FI. Anorectal manometry showed a significant change in the functional length of the anal canal (high-pressure zone length), with an increase of 11 mm (95% CI 7-15mm) while the other structural and functional variables remained unchanged. **LEVEL OF EVIDENCE 3**.

Other types of adult stem cell used clinically as a treatment for FI are mesenchymal (bone-marrow- or adipose-derived) stem cells. Three studies have reported their application to reinforce anal sphincter repair. In 2017, a case-control study from Khafagy *et al.* [86] reported results from 20 patients with EAS defect who underwent overlapping anal sphincter repair and autologous Bone Marrow Aspirate Concentrate (BMAC) injection. These were compared to a historical control group of patients managed with sphincter repair alone. At the end of follow-up, group with BMAC injection had significantly lower mean postoperative Cleveland Clinic Incontinence Scores (5.4 ±7.6 Vs 10.6 ± 7.4; p= 0.03). Both groups demonstrated a significant decrease in the size of the residual EAS defect; however, there was no significant difference between groups regarding the extent of the postoperative EAS defect except in patients with smaller preoperative defect (equal to or less than one-third of the anal circumference). The same year, Sarveazad *et al.* published a double-blind randomised trial using allogenic adipose tissue-derived stem cells (ASCs) injected after sphincteroplasty[333]. Nine patients received ASCs injected into each end of the muscle and 9 received placebo in the same manner. After two months, both groups improved equally in symptom scores. However, EMG activity and muscle area (the ratio of the area occupied by the muscle to the total lesion area in echography) were significantly higher in the ASC group (P = 0.002). The authors concluded that injection of ASC during sphincter repair may cause replacement of fibrous tissue with muscle. However, the exact mechanism of action remains unclear. **LEVEL OF EVIDENCE 3**

Most recently, a Spanish randomized, multicentre, triple-blinded, placebo-controlled pilot study[335] reported the use of autologous ASC obtained from surgically excised adipose tissue. Sixteen patients with a sphincter defect not exceeding 100 degrees were included. ASC or placebo (4 ml Ringer's lactate excipient) were injected into the muscular ends of the sphincter defect under endoanal echography guidance. Infusion procedures were successful in all the patients, but 48 weeks after surgery, there were no significant differences in any of the assessed clinical, manometric or ultrasonographic parameters. Other major studies are ongoing e.g. EU-funded AMELIE RCT of microsphere anchored AMDC and others are scheduled to report soon (Cook Myosite study of AMDC).

Currently, the place of cell therapy in the treatment algorithm of faecal incontinence remains to be determined. Safety seems to be assured and encouraging results have been published. However, it is difficult to draw any firm conclusions from the published data because of heterogeneity concerning the type of cells used, the method and the assessment used. Further studies in both animal models and clinical settings are needed before CS therapy for FI can be ready for ordinary clinical use.

Summary:
Current experience of cell therapy is limited and varies in outcome. Given the complexity of the therapy, it remains experimental and should only be offered as part of a well-designed research study. **Grade of Recommendation: C**

1.8. Colostomy

A permanent colostomy is usually formed as a last resort for severe FI when all other interventions have failed. Because colostomy is generally regarded as a failure of treatment, its effectiveness, perioperative complications, and impact on the quality of life have never been properly evaluated except for patients with functional bowel

disorder after spinal cord injury[336, 337]. Colostomy can be a successful management strategy for the population with severe faecal incontinence that restores dignity and allows patients to regain social function. No randomised controlled trials or high quality cohort studies have been reported for colostomy for faecal incontinence; only one systematic review with high levels of heterogeneity (level 4)[338], one poor-quality case-control study (level 4)[339] and two case series (level 4)[340, 341] were identified.

Colquhoun *et al.* [339] conducted a cross-sectional postal survey, comparing quality of life between 71 patients with FI and 39 with a colostomy created for rectal cancer, complicated colonic diverticular disease or FI. Analysis of the Short Form 36 General Quality of Life Assessment revealed significantly higher social function score in the colostomy group than in the FI group (0 vs. -0.6, p=0.022). Age- and sex-adjusted regression analysis of the Faecal Incontinence Quality of Life score revealed significantly higher scores in the coping (2.7 vs. 2.0, p=0.005), embarrassment (2.7 vs. 2.2, p=0.014), and lifestyle scales (3.2 vs. 2.7, p=0.14) in the colostomy group compared to the faecal incontinence group. The authors concluded that a colostomy was a viable option for patients suffering from severe faecal incontinence and offered a definitive cure with improved quality of life.

Tan *et al.* [338] performed a systematic review, using prior published data to compare the cost-effectiveness between end stoma (ES), artificial anal sphincter (AAS) and dynamic graciloplasty (DG). Quality-adjusted life years (QALYs) and incremental cost-effectiveness ratio (ICER) were compared between the three interventions by obtaining probability estimates for patients with FI from the reviewed study data (these being supplemented by expert opinion). The end stoma was the most cost-effective therapy at 5 years, with a QALY gain of 3.45 for GB£16,280 and an ICER of GB£4,719 / QALY, compared to AAS (4.38 for GB£23,569; GB£5,387 /QALY) and DG (4.00 for GB£25,035; GB£6,257/QALY). After 10 years, AAS became the most cost-effective surgical intervention, with a QALY gain of 8.384 for GB£32,397 and an ICER of GB£3,864/ QALY, compared to ES (6.9 for GB£27,910; GB£4,046 /QALY) and DG (7.678 for GB£35,165; GB£4,580 /QALY). Any inference from the results of this study is limited by uncertainty around modelled probability estimates (these themselves being derived from poor quality studies).

Norton *et al.* [340] examined patients' view of a colostomy by conducting a questionnaire study of patients who had a colostomy created to manage their FI. Sixty-nine people (58 women) responded. When patients were asked to rate their "ability to live with their stoma now" on a scale of 0-10, the median score was 8 (range 0 – 10). The majority (83%) felt that the stoma, within the past month, restricted their life "a little" or "not at all". Eighty-four percent answered that they would "probably" or "definitely" choose to have the stoma again. When they were asked the question "compared to when you were incontinent, how much change has having a stoma made to your overall quality of life?" on the scale of -5 (much worse) to +5 (much better), the median rating was +4.5 (range -5 to +5). The authors concluded that health care professionals should discuss the option of a stoma with incontinent patients because of the overwhelmingly positive outcomes.

An end sigmoid colostomy without proctectomy is usually recommended as the procedure of choice for patients who elect colostomy for the management of their refractory FI. Creating such a colostomy, however, does not always solve all the problems of patients. Catena *et al.* [341] reported a retrospective chart review of 44 patients (35 women) who underwent elective end sigmoid colostomy for FI of various etiologies. After colostomy formation, 19 patients (43%) were asymptomatic, while the other 25 experienced such problems with their rectal stump as diversion colitis and mucus leakage. Of the 25 patients, 12 (27% of the total) who underwent a secondary proctectomy due to the rectal stump problems sufficient to warrant the operation, histological examination revealed diversion colitis in 6. Age was the main factor associated with progression to proctectomy with younger patients being more likely to require rectal excision.

Summary:
Formation of an end colostomy should be considered as a reasonable treatment option for patients with refractory faecal incontinence who are unsuitable for or have failed other treatment modalities and who able to accept the associated alteration in body image. **Grade of Recommendation: C**

2. HISTORIC PROCEDURES

2.1. Postanal Repair

Postanal repair was first reported by Sir Alan Parks in 1975 [342]. This procedure was designed to increase the length of the anal canal, restore the anorectal angle, and re-create the flap valve mechanism, which at the time was thought essential for maintaining faecal continence. Success rates rates dropped with follow up to 15% from the initial reports of 83%, further affected by the definition of the success, the length of follow-up, and possibly the cause of incontinence. Published studies regarding postanal repair include four systematic reviews of randomised controlled trials[343-346], two randomised controlled trials[347, 348], two non-randomised cohort studies[349, 350], 8 case series of good quality[89, 351-357] and 11 case series of poor quality (not referenced). Subsequent observational studies with a median follow-up of more than 5 years revealed that continence deteriorated with time. Despite 60-80% of patients reporting persisting symptomatic improvement, only one-third were actually continent to liquid or solid stool [353, 355-358]. Even in the most recent study reporting the long-term outcome of postanal repair [359], only 26% reported none to minimal incontinence with the Cleveland Clinic Florida Fecal Incontinence score being between 0 and 5, while 79% improved symptomatically with a mean follow-up of 9.1 years.

These reports of increasingly poor outcomes have significantly diminished the popularity of this procedure. Since 2012, no new studies regarding the role of postanal repair for the treatment of faecal incontinence, other than one systematic review have been reported [346], with surgeons focusing on newer surgical options.

Summary:
Postanal repair should no longer be offered routinely to patients with faecal incontinence (due to the advent of newer treatments). **Grade of Recommendation: D.**

2.2. Non-Stimulated Muscle Transposition

Several muscle transposition procedures have been described for the treatment of faecal incontinence since the early 20th century when gluteus maximus muscles, transposed in a variety of configurations, were first used to create a neosphincter[360]. Small case series have subsequently described variable success rates [361-365]. A single randomised comparison to total pelvic floor repair in women with post-obstetric incontinence showed similar, variable results[366].

In 1952, Pickrell *et al.* [367] described the use of transposed gracilis muscle to create a neosphincter for incontinent children with neurological and congenital anomalies. Several subsequent series in

children and adults showed variable results that generally deteriorated over time[368-370]. While still used as treatment for recto- and ano-vaginal fistula[371], both gracilis and gluteus transpositions are no longer used to treat incontinence due to early complications such as wound breakdown followed by poor muscle function (see below) and problems of constipation.

Summary:
Unstimulated muscle transpositions should no longer be routinely offered for patients with faecal incontinence. **Grade of Recommendation: D**

2.3. Stimulated Muscle Transposition

Even after successful gracilis muscle transposition, functional outcomes are limited by two physiological factors. First, patients are unable to consciously maintain tonic contraction of their neosphincters over long periods of time. Furthermore, even if patient volition were not a problem, the gracilis muscle is poorly suited to tonic contraction. While the external anal sphincter comprises predominantly slow-twitch, fatigue-resistant type I fibres, the gracilis muscle comprises predominantly type II, fast-twitch fibres that are rapidly fatiguable [372]. Graded electrical stimulation transforms type II into type I muscle fibres, and the use of an implantable electrical pulse generator has been shown to convert transposed gracilis to a muscle with predominantly type I fibres[366]. The gracilis muscle is well suited to electrical stimulation due to the relatively constant proximal location of its neurovascular bundle, which is easily identified at surgery[373].

Successful electrical stimulation of a transposed gracilis muscle [popularly termed either *dynamic graciloplasty* or *electrically stimulation gracilis neoshincter*] was first reported in 1988 [365], and thence in 1990 in a case series of 6 patients of whom 5 had closure of a defunctioning stoma with improvement in continence [374]. Subsequent larger case series (with up to 200 patients) are shown in table 10. No randomised trial has ever been conducted and most case series come from a small group of enthusiastic centres (with some overlap of patients at different publication time points).

However, some multicentre data are available. Madoff *et al*. [375] studied 139 patients from 12 US centres, 128 of whom had gracilis wraps and 11 gluteus wraps. Of the cohort, 104 were treated for faecal incontinence, and 35 underwent total anorectal reconstruction following abdominoperineal resection for cancer. Success rates for graciloplasty were 71% for patients with acquired incontinence and 50% for those with incontinence due to a congenital abnormality. There was a total of 138 complications for the entire group. Wound complications (41 major and 35 minor) were both the most prevalent and the most consequential. Other complications included pain in 28 patients (22%), hardware problems in 14 (11%) and tendon detachment in 4 patients (3%). Centres with significant prior experience of the procedure had substantially fewer major wound complications (17.4 vs. 33.1%) and significantly higher success rates (80% vs. 47%).

Mander *et al*. [376] reported the results of dynamic graciloplasty in 64 patients with refractory faecal incontinence treated at 7 UK centres. There were 24 infective complications, 5 of which involved perineal wound breakdown and 3 of which required re-operation. Forty-four (69%) patients became continent to solid stool 1 month following stoma closure. Evacuation problems developed in 16 patients (25%), and this led to failure in 14. At a median of 10 months follow-up, 29 patients had a good functional result.

Baeten *et al.* [377] reported the results of dynamic graciloplasty in 123 patients treated at 20 centres as part of the Belgium Dynamic Graciloplasty Therapy Study Group (DGTSG). The aims of this study were to assess both the safety and efficacy of this treatment; 189 adverse events occurred in 91 patients, including one death due to pulmonary embolism. There were 18 major and 31 minor infectious complications. There were 42 instances of therapy-associated pain, occurring variably in the donor leg, at the anal canal, or at the device site. There were 11 lead dislodgements but no problems with lead breakage or pulse generator malfunction.

Longer-term data are available on a smaller number of patients [Table 10]. Thornton *et al*. [378] reported on the 5-year follow up of 38 patients who had undergone dynamic graciloplasty. Of the 33 patients available for follow-up by telephone interview, obstructive defaecation was a problem for 11% of the cohort and 16% had been converted to a permanent colostomy. Of those with a functioning graciloplasty (22 patients) who reported a faecal incontinence score of less than 12 (range 0-24), 50% reported problems with obstructive defaecation and 64% felt their bowel habits had negatively affected their quality of life. Long-term complications were primarily related to stimulator problems; ten patients required 15 operations to replace stimulator components. However, 72% of patients reported pain, swelling or paresthesia of the donor leg and 27% reported sexual dysfunction. These results typify other long-term experience with high rates of therapy attrition due to poor function or accumulating adverse events / technical failure. **LEVEL OF EVIDENCE 3**

Two systematic reviews have reached similar conclusions regarding the effectiveness of dynamic graciloplasty. Chapman *et al.* [379] on behalf of the Australian Safety and Efficacy Register of New Interventional Procedures-Surgical (ASERNIP-S) reviewed 37 original articles published between 1991 and October 2000. All papers were judged to be of poor evidential quality (all case series except one case-control study using historic controls). Mortality excluding cancer deaths was 1% (95% confidence interval 1-3%) and morbidity 1.12 events per patient (95% CI 0.14 - 2.08). Success was variably defined between studies but was reported as ranging from 42-58%. The ASERNIP-S Review Group determined that “the safety of the procedure cannot be determined at the present time due to an incomplete and/or poor-quality evidence base” and that “efficacy is established.” Tan *et al.* [338] examined three treatments for faecal incontinence including dynamic graciloplasty, artificial bowel sphincter and end stoma. They concluded that the most cost-effective intervention was an end stoma, the artificial bowel sphincter was most cost-effective after 10 years and that dynamic graciloplasty should only be considered as an alternative in highly specialized centres. **LEVEL OF EVIDENCE 3**

Summary:
Stimulated graciloplasty may still be offered to highly selected patients who have failed or are unsuitable for other modalities of treatment (particularly where there has been gross loss of native sphincter tissue) and who are willing to accept the high risk of harm associated with this procedure. Otherwise, it has largely been superseded by sacral neuromodulation. **Grade of Recommendation: B** [NB: this recommendation is based on availability of suitable implantable devices: the original Medtronic device is no longer available].

2.4. Artificial Anal Sphincter

Various types of artificial sphincter devices have been designed and proposed to treat severely incontinent patients. These had some common characteristics. They frequently derived from innovations and experiments from sister specialties, urology for instance, but also upper GI surgery and their development was supported by

significant investments from companies to establish them in the market. Due to concerns about risks, effectiveness in mid/long-term and reproducibility they have all now been abandoned.

2.4.1. Artificial bowel sphincter (ABS) - Acticon™ Neosphincter

This procedure for anal sphincter replacement was developed in the 1990s. During the surgical procedure, a silicone-made pressure-regulated inflatable cuff was placed around the upper anal canal and tubing from the cuff was directed along the perineum and connected to a pump placed in the scrotum or labia. Tubing was used to connect the pump to a pressure regulating balloon implanted in the pre-vesical space. The balloon gave approximately 100cm H_2O pressure into the perianal cuff. The control pump allowed a fluid transfer from the cuff to the balloon when the patient squeezed the pump to empty the cuff and allow for the anal canal to open and defaecation to occur. The fluid then slowly returned to the cuff which resulted in the closing of the anal canal and restoration of continence.

In a systematic review [1] the primary concerns with ABS implantation were infection, with rates ranging from 20 to 45% and mechanical failure, with a revision rate proportional to the length of follow-up. A further systematic review found that need for surgical revision increased, while continence decreased, with time[389]. The authors concluded that both device refinements by the manufacturer and meticulous aseptic procedures at implantation were keys to help improve these outcomes.

In the previous edition [5] the long-term outcomes of ABS from two specialist institutions were reported. From the Cleveland Clinic, Florida, USA among others[390] the risk of explantation at 5 years after ABS implantation was 57%. In a series of 52 patients from Nantes, France[391] 35 patients (67.3%) still had an activated device *in situ* at last review (mean follow-up: 64.3±46.5 months) but 14 (26.9%) required definitive explantation, the majority due to infection. Very recently a further experienced institution (Maastricht, Netherlands) reported their long-term results with ABS. These concurred with previous data: at a mean 5-year follow-up, 50% patients had the device explanted, 80% suffered from complications and only 29% had faecal continence restored[392]. **LEVEL OF EVIDENCE 3.**

With this background, even specialist centres with a dedicated interest and experience in ABS reduced frequency of implantations and in 2018 the ABS Acticon Neosphincter™ became no longer commercially available after the acquisition of AMS by Boston Scientific. To the authors' knowledge the only similar device is currently the Anal Soft Band [AMI, Feldkirch, Austria] but no recent reports on its use and results were found by systematic review. It is perhaps a pity that an effective and well-performing device is no longer available for patients with end-stage faecal incontinence whose options are very limited.

Horizon scanning, several reports on an artificial anal sphincter mimicking the effect of the puborectalis muscle have come from Chinese centres but to the authors' knowledge it has not been applied to humans to date [393].

Summary:
The artificial bowel sphincter (ABS) was a treatment for patients who failed other modalities of treatment. Obstructed defaecation, device infection/erosion or failure were problematic. ABS is no longer commercially available. **Grade of Recommendation. NOT APPLICABLE**

2.5. Magnetic Anal Reinforcement – Fenix™

The magnetic anal reinforcement device (or magnetic anal sphincter – MAS (FENIX™; Torax Medical, Inc, Shoreview, MN – USA) was a device made of a series of titanium beads with magnetic cores (not MRI-compatible) and designed to augment the native anal sphincter. It formed a flexible ring around the external anal sphincter [394]. The procedure used for MAS device implantation included a single anterior incision. A perianal tunnel was created and a sizing tool allowed for measurement of the correct device size.

Table 10. Dynamic Graciloplasty: General measures of continence

Authors (ref)	Year	Number patients	Follow-up (months)	Percentage continent*
Baeten et al 380	1995	52	25.2 (mean)	73
Geerdes et al 381l	1996	67	32.4 (mean)	78
Cavina et al 382	1998	31	37.8 (mean)	85
Madoff et al 375	1999	131	24 (median)	66
Mander et al 376	1999	64	16 (median)	69
Baeten et al 377	2000	123	23 (mean)	74
Wexner et al 383	2002	83	24	53
Rongen et al 384	2003	200	16.3 (median)	72
Pennickx et al 385	2004	60	48 (median)	55
Thornton et al 378	2004	38	60 (mean)	16 †
Tillin et al 386	2006	49	43 (median)	70
Hassan et al 387	2010	31	67 (median)	71
Mege et al 388	2021	40	100 (mean)	55

*KEY: *variable definitions; does not necessarily denote perfect continence. Issues of divergence in technique arose from these studies, each of which has seen increasing consensus in the literature despite a lack of randomised trial data. Thus, intramuscular (vs. epineural) electrodes are now universally employed and divert-ing stomas and 'vascular delay' prior to muscle transposition are no longer utilized; † as defined by FI score < 12.*

The MAS was then placed with sutures to secure the device around the upper anal canal. Unlike the ABS, the MAS worked immediately once implanted, without the need for further manipulation by either the patient or surgeon.

Interestingly while developing a model of physical simulation of the human defecatory system, bench phantom testing demonstrated a positive action of the MAS to increase resistance to faecal leakage and reduce anorectal angles required to maintain continence [395].

Data concerning safety and efficacy of MAS were limited until recently to several small case series. These showed good restoration of continence with a limited number of complications, mainly infection and/or erosion, at short-[396], medium-[397, 398] and 5 year [399] follow up.

Two recent controlled studies in France (MOS STIC –Clinicaltrials.gov NCT01920607) and in the UK (SAFARI: ISRCTN:16077538 http://ukctg.nihr.ac.uk) [400] sought to compare MAS to SNM in terms of effectiveness and cost-effectiveness. Both were suspended before recruitment was complete due to withdrawal of the Fenix™ device after the acquisition of Torax Medical Co. by Johnson & Jonhson. SAFARI recently reported the outcomes of 99 participants from 18 UK sites (of a prior sample size of 350)[401]. 50 participants were randomised to FENIX vs. 49 participants to SNM. A total of 45 out of 50 participants underwent FENIX implantation and 29 out of 49 participants continued to permanent SNM. Overall, success (defined as 50% reduction in Cleveland Clinic Incontinence Score) was achieved for only 10 out of 80 (12.5%) participants, with no statistically significant difference between the two groups [FENIX 6/41 (14.6%) participants vs. SNM 4/39 (10.3%) participants]. At least one postoperative complication was experienced by 33 out of 45 (73.3%) participants in the FENIX group and 9 out of 40 (22.5%) participants in the SNM group. A total of 15 out of 50 (30%) participants in the FENIX group ultimately had to have their device explanted.

Summary:
The magnetic anal sphincter was a novel treatment for patients who had failed other modalities of FI treatment. Early results were promising, however the device is not available due to commercial decisions. **Grade of Recommendation: NOT APPLICABLE.**

2.6. Pudendal nerve stimulation

Pudendal nerve stimulation has been applied in the field of urology since the 1990s with several publications demonstrating benefit for patients with urge incontinence (mainly OAB) and bladder retention syndromes.

There have been only four observational studies of patients with faecal incontinence including a total of 32 patients who had either failed SNM or who had been deemed unsuitable due to neurogenic indications (mainly cauda equine syndrome) [402-405]. Results were promising with 60-100% success rates accepting the significant caveat of small, uncontrolled, single centre results (noting that three of the four studies came from the same centre).

It is unclear why the procedure fell from favour other than the decision of the manufacturer (Medtronic) not to pursue its license for faecal incontinence further. Reasons may include the relative difficulty (compared to SNM) of accurately placing and securing an electrode lead close to the pudendal nerve, although several methods have now been described to achieve this [406, 407], including now under direct vision [408].

Summary:
Pudendal nerve stimulation has scientific rationale and some clinical data to support its use in patients who have failed or who are unsuitable for SNM. Current use would however be off license. Grade of Recommendation: NOT APPLICABLE

III. SURGERY FOR PAEDIATRIC FAECAL INCONTINENCE

1. ANORECTAL MALFORMATIONS

Anorectal malformations (ARM) occur once in every 3000- 5000 live births. ARMs range from the minor defects that are easily treated and have excellent functional outcome, to complex malformations involving the urinary and genital tracts that are difficult to manage and invariably associated with defaecatory problems including incontinence. Infants with complex ARM may also have associated congenital abnormalities grouped as VACTERL Syndrome **V**ertebral, **A**nal, **C**ardiac**, T**racheooesophageal fistula, **R**enal, **L**imb [409]. Certain syndromes such as Currarino, Townes-Broack and Pallister-Hall syndromes are inherited in an autosomal dominant manner [410 411]. Infants with trisomy 21 also have a higher incidence of ARM.

ARMs have traditionally been classified into high, intermediate, and low malformations depending on the relationship with the levator ani muscle and fistula type [412]. ARM should be suspected at birth and a careful examination of the perineum may reveal a pit or dimple with absence of an anal opening or anterior displacement of the anus indicating a fistula. In a female, careful examination of the vestibule may reveal urogenital malformation. Multidisciplinary assessment is required with appropriate radiological investigation including 3-D image reconstruction.

Surgical treatment depends on the complexity of the ARM and associated abnormalities. A low, simple ARM may require primary anoplasty, whereas more complex ARM require a diverting colostomy with later definitive reconstruction [413]. In a male infant with a urinary fistula, the colostomy should be divided with a mucus fistula to fully disconnect the bowel from the urinary tract. A later distal colonogram is helpful in planning reconstruction [414].

Posterior sagittal anorectoplasty (PSARP) allows the abnormal anatomy to be assessed under direct vision and facilitates precise corrective surgery [415]. In brief, a mid-sagittal incision is performed, and the sphincter mechanism is completely divided in the midline. The rectum is separated from the genitourinary tract and moved down to the perineum. The most challenging aspect of the operation is separation of the rectum from the vaginal or urinary tract, which effectively requires creating two walls out of one septum without damaging each structure. This approach can also be used for reoperation in anorectal malformations [416] and can be applied for reconstruction of severe perineal trauma [417].

In both male and female infants, urethral-perineal fistula is the simplest to correct. This requires the so-called “minimal posterior sagittal approach” which enlarges the stenotic orifice and relocates the rectal orifice posteriorly within the limits of the sphincter complex. For males with recto-urethral-bulbar fistula or recto-urethral-prostatic fistula and females with recto-vestibular fistula or cloaca with a short (less than 3cm) common channel, the posterior sagittal approach is the main operation performed. For males with higher fistulae such as a recto-bladder neck fistula and other complex and

unusual defects and females with cloacae with a long (greater than 3cm) common channel and complex defects, the posterior sagittal approach needs to be coupled with abdominal access.

Laparoscopic assisted anorectal pull-through procedure (LAARP) [418], is associated with shorter hospital stays and fewer wound complications [419 420]. Robotic assisted LAARP has also been described[421] and may offer short term benefits [422]. In brief, a sharp dissection and cautery is used laparoscopically to expose the rectal pouch down to the urethral or vaginal fistula, which is clipped distally and divided. The pelvic floor musculature and the puborectal sling are identified and electrostimulation is used externally to define the centre of the anal dimple. A skin incision is made, centred at the strongest cephalad contraction. Guided by laparoscopic visualization, a trocar, consisting of a radially expandable sheath over a Veress needle, is passed through the defined plane in the external sphincter muscle complex and advanced into the pelvis between the two limbs of the pubococcygeus muscle, forming a passage through the centre of the striated muscle complex and levators. The rectal fistula, which has been dissected out laparoscopically, is grasped using the perineal trocar and exteriorized to the perineum. Anorectal anastomosis is then performed [418] .

A recent study of long term functional outcome comparing PSARP (n=34) to LAARP (n=32) ARM children with recto-bladder neck and recto-prostatic fistula found that LAARP is a less invasive procedure (shorter operative time and post-operative hospital stay) and both short term- and long term outcomes after LAARP were equivalent if not better than those of PSARP in children with high ARM [420, 423] **LEVEL OF EVIDENCE: 3.**

The most complex malformations are cloaca and cloacal exstrophy. In females with cloaca, the rectum, vagina, and urethra fail to develop separately and instead drain via a common channel that opens into the perineum as a single orifice. The repair of cloacal malformations is most often performed using a posterior sagittal anorecto-vagino-urethroplasty (PSARVUP) or total urogenital mobilization (TUM) with or without laparotomy [424]. The PSARVUP extends the anorectoplasty with a meticulous dissection of the combined vaginal–urethral walls, followed by the reconstruction of distal parts of both structures. In 1997, total urogenital mobilization (TUM) was presented by Peña as a new, faster, surgical approach for certain cases of cloacal repair with better cosmetic results[425], however a recent systematic review found that complications rates after PSARVUP and TUM were similar [424].

TUM separates the rectum from the vagina and both vagina and urethra are then mobilised together. The advantage of this technique is to avoid separating rectum, vagina, and urethra completely which is not always feasible and risks damaging these structures. This technique avoids the risk of urethrovaginal fistula and vaginal stricture previously reported as complications in 10% of the cloacal repair and also gives enough mobilisation to allow more than 50% of all cloacal repairs without opening the abdomen [426 427] . Functional outcomes depend on the severity of the malformations.

A review of more than 1000 anorectal malformation cases showed 100% of infants who had perineal fistula repair achieved continence. Approximately 55% of patients who had been operated for recto-vestibular fistula had bowel control. Any malformations more complicated resulted in only up to 30% achieving continence. All patients who had recto-bladder neck fistula repair were incontinent. The defects were categorised by the length of the common channel that can be measured endoscopically. The length of the common channel can vary from 1 to 10 cm. The longer the common channel (>3 cm), the higher the chance for poor bowel control, neurogenic bladder, and reproductive abnormalities[426]. Overall, it is estimated that nearly 40% will have voluntary bowel movement and no soiling but some of them may still lose bowel control in case of severe diarrhoea and 25% of all repairs will result in total incontinence[427].

For the group of patients with persistent incontinence following the corrective surgery, the next aim will be to keep the colon clean to avoid incontinence and improve quality of life. A good option is implementation of a bowel management program whereby the patient and family are instructed in the use of a daily enema, manipulation of diet and medication to remain clean[428]. This is also a good treatment for constipation, which is the most common difficulty after corrective surgery.

The Pediatric Colorectal and Pelvic Learning Consortium found that bowel management programmes need to be individualized and to change as children age [429]. Although most young children accept their parents administering enemata, when they get older, they want privacy and rectal enemata on daily basis become an unpleasant routine. In such cases, continent appendicostomy is a feasible option, whereby a conduit for the administration of an antegrade continence enema (ACE) is created. First described by Malone [430] , it has become an important option in paediatric surgery for functional bowel disorder [431]. According to the initial description, appendicostomy was created by dividing the appendix at its base and reimplanting by a reverse manner into the cecum, which was then exteriorized through the right lower quadrant. Malone later revised the technique and reimplantation of appendix is no longer considered necessary [432] . Levitt introduced utilising the appendix in situ and added caecal plication to prevent reflux of stool and exteriorizing through umbilicus fold rendering it less noticeable [433]. This appears to yield good long-term results though other studies have shown that caecal fixation and wrap may be unnecessary for appendicostomy [434]. The construction of appendicostomy with burial of the appendiceal tip appears to help avoid problems of exposed mucosa such as bleeding and mucus discharge. From this perspective, a few techniques have been suggested such as V-Y flap [432] and Y-appendicoplasty [435] .

For patients without an appendix, a neoappendix could be formed from ileum or caecum [436-438]. A laparoscopic antegrade continence enema procedure has been reported to yield as good result as the open procedure [439-442]. This procedure is not a cure to the problem but a more acceptable method for many children to engage in a bowel management programme without the need for rectal enemata. The success rate is variable, between 61-96%[438, 441, 443-446] with older children benefiting more[447]. Hoekstra *et al.* reported that almost 85% of patients were satisfied with their ACE stoma [448] **LEVEL OF EVIDENCE 3.**

As with any operation, there are complications associated with antegrade continence enema. Preteen patients (<12 years old) experience more stomal leakage than teenage patients[449]. These complications cause 10-33% of patients to undergo revision of the appendicostomy[427, 450]. Stoma prolapse, pressure sore, wound infection, anastomotic leak, stomal granulation, caecal-flap necrosis and caecal volvulus are less common complications reported after ACE [451, 452]. **LEVEL OF EVIDENCE: 3**

Summary:

Anorectal malformation is amenable to surgical reconstruction. Laparoscopically assisted anorectal pull-through procedure is offered as the preferred technique. Outcomes primarily relate to the height and complexity of the abnormality. Evacuation disorders and incontinence often require daily enemas. The Malone antegrade continence enema may provide a more acceptable means of managing continence. **Grade of Recommendation: C**

IV. SURGERY FOR EVACUATION DISORDERS AND INCONTINENCE

Significant rectal retention of faeces results in faecal incontinence in children and older people, indeed, constipation with or without faecal impaction may be the commonest cause of incontinence in these age groups[453, 454]. Similarly, if the rectum is completely empty then incontinence (at least of faeces) cannot occur. On this basis, health technologies that address rectal emptying are often recommended on a regular basis or for specific occasions e.g. enemata, trans-anal irrigation. There is however increasing recognition that a very significant proportion (approximately 40% in a recent study of over 4,000 patients)[455] of adults presenting for specialist management have coexistent symptoms and many have radio-physiological evidence of a significant rectal evacuation disorder. Such patients may describe classic symptoms of post-defaecatory leakage but as commonly have a mixed pattern of incontinence (e.g. urge / passive) that may not immediately indicate rectal evacuation disorder, not least because they may also have a functional or structurally defective sphincter concomitant on a shared pelvic pathophysiology[456]. **LEVEL OF EVIDENCE: 3.**

This observation has important implications to specialist management. First, it supports the use of tailored biofeedback therapy given that this has potential to improve both sphincter function, sensation of rectal filling and coordinated anorectal relaxation[457, 458]. Secondly, it promotes caution when using sphincter augmenting procedures. Worsened or new symptoms of obstructed defaecation have been reported in approximately one third of patients after overlapping anterior anal sphincter repair [116] and up to 50% patients after gracilis transposition[459]. There are also data suggesting that a pre-existent evacuation disorder prejudices the outcomes of neurostimulation[153]. This raises the question of whether proven structural causes of rectal evacuation disorder e.g. rectocele and internal prolapse should be surgically targeted before other procedures are offered. The latter is supported by some studies of rectocele repair that show significant improvement in faecal incontinence after surgery [460] but also by an evolving body of literature on use of rectal suspension procedures, notably laparoscopic ventral rectopexy (LVR) [461, 462]. Significant improvements in incontinence symptoms and prospectively studied summative incontinence scores[462-465] have been documented for several studies of LVR in patients treated primarily for obstructed defaecation syndrome with internal prolapse. Further, LVR has been specifically targeted to patients with faecal incontinence in two studies [466, 467]. The first of these studies evaluated the faecal incontinence severity index (FISI) in 72 patients with high-grade internal prolapse [Oxford grade III or IV] [465] with incontinence not responding to maximal medical treatment and demonstrated a reduction in median score from 31 to 15 points, [P <0.01]. These authors went on to suggest and a sequence of care where SNM is reserved for patients with persistent faecal incontinence after LVR [468]. Despite concern that nearly all studies supporting this line of reasoning have arisen from one institution (Oxford), it seems reasonable that patients presenting with faecal incontinence should be directly questioned regarding symptoms of obstructed defaecation and undergo appropriate clinical examination and radio-physiological investigations e.g. proctography as part of the decision-making process. **LEVEL OF EVIDENCE 4**.

Patients with high grade internal rectal prolapse should be considered for rectopexy to address the internal prolapse before consideration of other advanced interventions. This is especially true for patients with transanal rectal intussusception [Oxford grade IV or V] where the prolapse itself will compromise anal closure. A repair should be undertaken for clinically significant rectoceles in which trapping of contrast can be demonstrated post simulated defaecation. **LEVEL OF EVIDENCE 4.**

Stapled transanal resection of rectum (STARR), a technique developed by Antonio Longo from the PPH (procedure for prolapse and haemorrhoids, also known as stapled haemorrhoidopexy) may also have a role in managing patients with rectal intussusception and rectocele resulting in obstructed defaecation and associated incontinence. A detailed review is beyond the remit of this monograph, however the European STARR registry reporting outcomes in 2,838 patients, found significant improvements in the CCF-IS at both 6- and 12-months following surgery in addition to improvements in the symptoms of obstructive defaecation [469]. There is an increase in urgency of defaecation in 20% of patients and new onset incontinence in 1.8%. More recently a survey among colorectal specialists from European centres with experience of STARR reported up to 10% new onset incontinence following the procedure. The particular role for STARR in managing patients with incontinence associated with obstructed defaecation remains to be established [470] and the general poularity of this procedure is declining in any case due to concerns about other long-term complications e.g. chronic pain. **LEVEL OF EVIDENCE 4.**

Summary:
Obstructed defaecation is common and may contribute to incontinence. Comprehensive assessment is required. Rectocele repair or ventral rectopexy may improve continence in carefully selected patients. Randomized studies are lacking. Grade of Recommendation: C

V. OUTCOME MEASURES IN FAECAL INCONTINENCE

There is no doubt that this is another area of challenge for FI researchers. The current literature is beset with an over-reliance on choosing a single metric as a primary outcome for studies. The commonest choice by far has been some measure of FI episodes per unit time (usually per week). This continuous variable is then commonly converted to a binary category that takes a notional percentage change as indicative of treatment 'success'. On this basis, the proportion of patients with a 50% reduction in symptoms is compared between intervention and comparator.

There is general agreement that patient-based outcome measures (PROMs) are most appropriate for studies of faecal incontinence. However, standardisation of the optimal instrument or combination of instruments remains a challenge in clinical incontinence research. While many incontinence-related quality of life measures have been proposed and claim to have been "validated,", adequate psychometric validation is lacking for many [471]. Whether the main outcome measure following incontinence treatment ought to be incontinence severity, incontinence-related quality of life, or a combination of these factors is unknown.

FI is a complex symptom relating not only to the continence mechanism itself, but also to the general bowel function in terms of motility, sensory and/or motor disturbances on spinal and supra-spinal levels. Thus, FI as a symptom can present differently depending on the underlying disease and lifestyle.

Hallbook and Sjodahl developed a bowel questionnaire for assessment of functional outcome following restorative rectal resection that took account of how the function affected the individual's daily life[472]. Bakx *et al.* [473] developed this concept with a colorectal functional outcome (COREFO) questionnaire which they validated in 179 patients. When compared with that of Hallbook, more patients found that the psychometric questions in the COREFO questionnaire reflected their concerns. ICI has extended the focus on psychometric outcomes in the recently developed[474, 475] and validated[476] ICIQ-B questionnaire suitable for use in patients with incontinence of varying cause, however the large number of items (forty-two) thus far limit the application of ICIQ-B. A short version of this questionnaire (8 questions) has been used in two recent clinical trials[190, 477] where it proved highly acceptable to patients. Full validation of this shortened version is now underway.

However, how patients and physicians rank the severity of faecal incontinence differs. Clinicians put greatest importance on actual episodes and frequency of incontinence to solid stool, whereas patients are generally more concerned about leakage, hygiene, smell and social embarrassment [478]. A study examining colorectal specialists' perception of symptom severity using the LAR score revealed that specialists did not have a very thorough understanding of which bowel symptoms truly mattered to the patient after sphincter-preserving treatment, nor how these symptoms affected the patient's QoL. Although the specialists performed better than chance , there was considerable discrepancy between the specialist's perspective and patient experience [479]. The same was also true for specialists' perception of symptoms bothering patients after restorative proctocolectomy[480].

Disease specific incontinence scores have been developed for neurogenic bowel dysfunction[481], Low Anterior Resection Syndrome[482, 483] and pouch dysfunction after ileo-anal anastomosis[484]. Included items were selected from a pool extracted from existing bowel function assessment instruments and the current literature. By applying binomial regression on the response to these items obtained from disease specific cohorts of Danish patients, those showing the highest prevalence and impact on QOL were identified and included in the score creating a patient-based outcome score. This has provided a platform for a common understanding and evaluation of functional outcomes for these patient categories. However, as these scores have been developed specifically in collaboration with these patient categories, they are not necessarily applicable in others, regardless of similar symptoms. Recently, the ICIQ-B questionnaire has been revised and validated for use in patients with inflammatory bowel disease as the ICIQ-IBD[485]. For other non-specific diseases with a FI component both the CCF-FIS[67] and St Mark's scales[486] are available. Whereas the CCF-FIS does not score the urgency component, the St Mark's scale scores it as ability to defer defaecation for more or less than 15 minutes. Though both scores include elements of severity, preventive measures, and impact on quality of life, the individual elements are not weighted in the total score according to patient perception. Other newer scores include the faecal incontinence severity index[487].

Bowel movement diaries are considered to be the gold standard measurement, but these are highly influenced by the patient's willingness to stray from the toilet and the validity of the data has never been evaluated. A study on the effect of SNM for FI showed that 46% of the patients with more incontinence episodes at follow-up than at baseline were satisfied with the treatment result. These patients explained that they had obtained a more active social life after the SNM therapy, an aspect of social behaviour that is not addressed in the bowel habit diary, and traditional evaluation would consider these patients as failures[195]. For both the bowel movement diaries and the FI scores additional validation work is needed to assess the potential effect of recall bias

The FIQL[70] is a well-validated quality outcome measure but it yields separate scores on 4 individual scales. It is desirable that a single score outcome be developed. Furthermore, quantitative changes in FIQL have not been anchored to the corresponding impact on patient quality of life and thus remain speculative.

In the future, evaluation of surgical interventions for FI should focus on patient satisfaction and QOL, in combination with bowel scores and diaries to obtain a more accurate measure of therapy efficacy. Striving to develop and implement a standardized tool the approach should be based on appropriateness, reliability, validity, responsiveness, precision, interpretability, acceptability and feasibility.

Summary:
PROMs should be developed and validated according to the impact of symptoms from a patient perspective. It remains to be established if PROMs should be general / disease / treatment specific. Currently available technologies allow real time data capture that may be more relevant in assessing continence outcomes. **Grade of Recommendation: C**

VI. RESEARCH PRIORITIES IN FAECAL INCONTINENCE

1. BASIC SCIENCE AND PATHOPHYSIOLOGY

A quick review of this chapter shows that the focus, past and present, remains on trying to augment the barrier to treat faecal incontinence. However, a summary of techniques that are still in common use must lead the reader to speculate on the logic of this approach. In fact, many procedures are no longer in use. The current gold standard in surgery – sacral neuromodulation does not appear to modify sphincter structure or gross motor function. The problem is that far too much emphasis has been placed on the position of the sphincter in anal incontinence and too little on more important supra-sphincteric mechanisms, especially the rectum. In contrast, urology focuses much more on bladder function even though, arguably, with a fluid like urine, the sphincter should have a much greater role than it does for faeces that must be pushed out of its storage organ by coordinated contraction or compression of the rectum – this is why stress incontinence represents 50% of urinary leakage and only about 5% anal (and then mostly flatus). A relevant research question is what is wrong with the rectum and how can it be fixed? This has been addressed superficially with studies of rectal mucosa[488] but a real understanding will require knowledge of the initiation and control of defaecation[489]. Such an approach is now supported by some SNM literature which points to modulation of afferent activity, including spinal and probably spinobulbar reflexes as the mechanism of action for both UI and FI. It may also help to explain the failure of misguided attempts to constrict the sphincter

that disturb important local and pudendal reflexes from the anus to the rectum – this accounting for the very common problems of rectal evacuation following sphincter augmentation. Such studies can build on the human electrophysiological studies of Swash and Parks [490] and Read and Sun [491] or maybe in animals where there is more written on reflex functions of the rectum in primary studies of bladder physiology than there has been in dedicated colorectal studies.

Tied in with the understanding of the pathophysiology is a need to advance diagnostics. Currently, dependence on manometry leads to measurement of two main variables: resting pressure, which does not distinguish health from incontinence, and maximal squeeze pressure, which measures a non-physiological task – continence is not maintained by volitional squeeze. Newer techniques that evaluate both sphincter contractile function and anal closure are under evaluation[492] and may in time come to complement current techniques.

FI is an important quality of life issue amongst patients who have survived pelvic cancer[482, 493]. The mechanism of FI related to pelvic surgery/radiotherapy are not fully understood. Volumetric changes of the neorectum compared to the original rectum or neuronal damage due to surgery/radiation are postulated, however, there are a limited number of histological or manometric studies in this field and more work is needed to elucidate the mechanism of FI relating to pelvic surgery and/or chemoradiotherapy[494]. Any research into mechanisms underlying FI that may lead to new approach of diagnosis and treatment is strongly encouraged.

2. IMPROVING EVALUATION OF SURGICAL TECHNIQUES

There are almost no adequately powered, high quality randomised trials in the field of FI surgical treatment with an overdependence on quantity rather than quality when it comes to evidence. For some therapies, like SNM, there are multiple observational studies of varying quality but no single high quality trial. While there are data concerning immediate repair of the anal sphincter after OASIS, there are no level 1 data concerning sphincteroplasty and evidence is derived from observational data, much of which comes from low-quality observational series.

Some high quality RCTs like SAFARI (SNM vs Magnetic anal sphincter) [401] failed to recruit before the Fenix device was withdrawn; others like SUBSONiC (SNM vs Sham) [495] are underway but have been delayed by COVID. Some are funded and due to start e.g. AMELIE (anchored autologous muscle cells) [https://www.ucl.ac.uk/comprehensive-clinical-trials-unit/news/2020/oct/amelie-trial]. These offer encouragement, however, there has been little progress since the last ICI. Thus, there remain unanswered questions on colostomy, choice between SNM and sphincteroplasty and the role of bulking agents.

A study to randomise patients with sphincter injury for SNM versus sphincteroplasty was strongly recommended by the both the 2007 and 2016 Committees. Attempts were made but these collapsed due to a combination of reduced enthusiasm from industry, lack of funding and evolution of a pragmatic treatment algorithm in Europe [496]. This emphasizes a requirement for coordinated efforts to collaborate between multiple centres with a large institutional or governmental funding for swift delivery of large trials.

Recognition of the impact of obstructed defaecation on incontinence symptoms[455] is a major area of uncertainty that requires investigation. Laparoscopic ventral rectopexy may improve some elements of FI symptoms such as those related to transanal rectal intussusception. At the same time, such mechanical phenomena may be part of global weakness of the pelvic floor and rectopexy may correct only a part of pelvic floor dynamics. How does the outcome of rectopexy compare with posterior repair of the vagina for large rectoceles? In the absence of expertise-based trial designs, large mulitcentre (multinational) prospective studies backed by radio-physiological tests are strongly recommended.

3. OUTCOME MEASURES

The lack of an agreed core outcome set for patients undergoing therapies for FI continues to cause uncertainty when evaluating existing and new surgical interventions. Various outcome measures and scoring systems exist but most of them have been devised by clinicians with little formal input from patients or attention to psychometric performance. The only scoring system to be designed with rigorous qualitative interview of patients is International Consultation on Incontinence Modular Questionnaire-Bowel Symptoms (ICIQ-B) [474]. However, it is lengthy and contains items that are not scored. A form short version of the ICIQ-B performed well in a recent high quality trial [477] but has not undergone rigorous validation. Comparison of outcomes of different surgical interventions thus remains hampered by use of different scoring systems and various definitions of 'successful treatment'. Patient-facing studies of symptom impact and quality of life [487, 497] are providing further data but formal Delphi intiatives and international consensus to define a core outcome set for faecal incontinence are still eagerly awaited.

4. HORIZON SCANNING: NEW TECHNOLOGIES

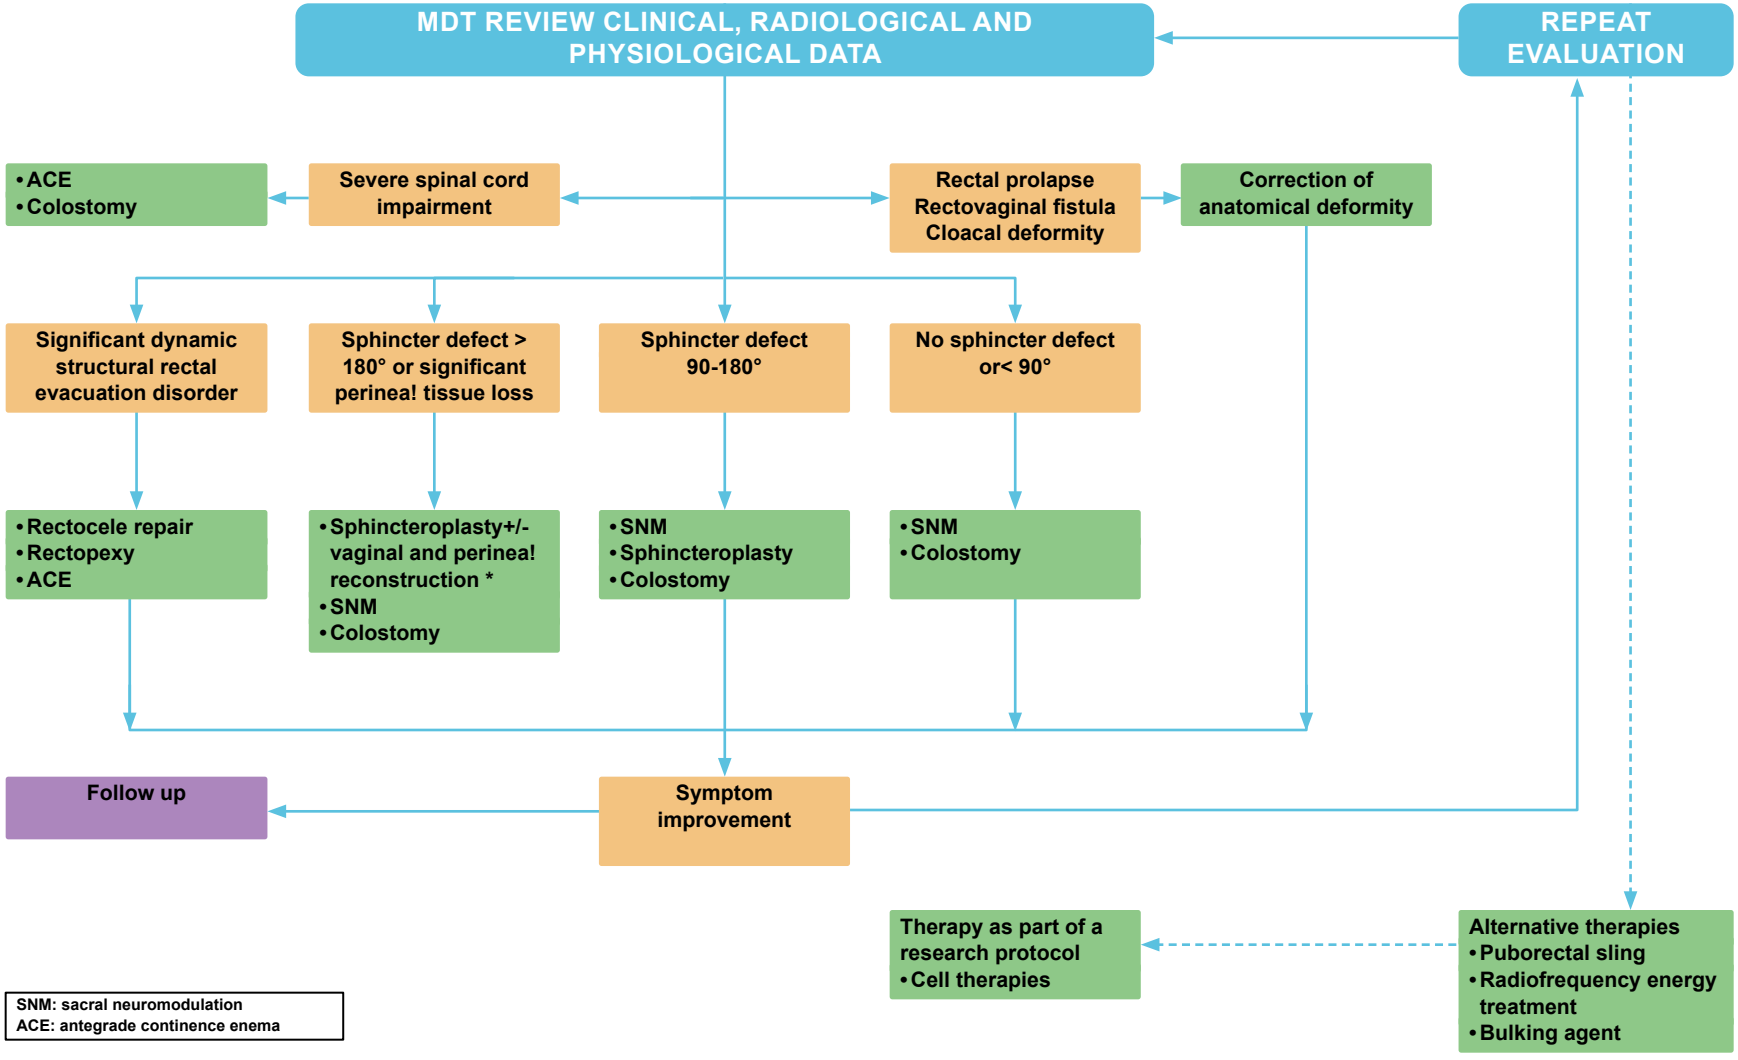
Where does the future lie in surgical treatments for FI? One thing is certain - approaches that use surgical methods to fix, tighten or reinforce the sphincter mechanism regularly fail. The future lies in the restoration of function. Sacral neuromodulation is far from perfect with modest long-term functional outcomes. Evolving regenerative medical approaches with autologous muscle cells will prove costly and are likely to be subject to regulatory constraints. Nevertheless, these are heading in the right direction and further innovation is certainly possible. In neuromodulation, targeting nerves other than the S3 root may be more appropriate in certain individuals. Stimulation parameters might might vary with closed loop feedback and real-time therapy modulation in response to physiological sensing. Integrated therapies with a combination of locally injected growth factors and neurostimulation may give enhanced results. All is possible with an open mind, investment and attention (methodologically) to delivering better evidence than in the past.

ALGORITHM: SURGERY FOR FAECAL INCONTINENCE

Figure 1 presents a summary of the chapter in relation to decision-making for adult patients with FI. In keeping with the 2016 iteration there are 4 main groupings based on clinical and diagnostic findings. These each lead to several possible surgical choices of procedure with little evidence to inform choice beyond patient pref-

erence after the benefits and potential harms of each are adequately explained.

SURGICAL MANAGEMENT OF FAECAL INCONTINENCE



* Consider dynamic graciloplasty: if local expertise and device hardware available
Consider appropriate use of CONTINENCE PRODUCTS

COMMITTEE 17

PELVIC ORGAN PROLAPSE SURGERY

Chair
Maher, Christopher (Australia)

Members
Antosh, Danielle (United States)
Baessler, Kaven (Germany)
Cheon, Cecilia (Hong Kong)
de Tayrac, Renaud (France)
Deffieux, Xavier (France)
Gutman, Robert (United States)
Lee, Joseph (Australia)
Nager, Charles (United States)
Schizas, Alexis (United Kingdom)
Sung, Vivian (United States)

COMMITTEE 17

PELVIC ORGAN PROLAPSE SURGERY

LIST OF ABBREVIATIONS **1730**

I. EPIDEMIOLOGY **1730**
1. Incidence and prevalence of Pelvic Organ Prolapse (POP) 1730
2. Incidence and Prevalence of Pelvic Organ Prolapse Surgery 1732

II. OUTCOME ASSESSMENT **1732**
1. Outcome Assessment: Anatomy 1732
2. Outcome Assessment: Symptoms 1733
3. Outcome Evaluation: Patient report outcomes & Quality of Life 1733
4. Outcome Assessment: Reoperation 1734

III. ANTERIOR COMPARTMENT SURGERY **1735**
1. Native tissue repairs 1735
2. Synthetic Grafts in anterior compartment surgery 1739
3. BIOLOGIC GRAFTS IN ANTERIOR COMPARTMENT SURGERY 1741
4. Recurrent Anterior Prolapse 1742

IV. SURGICAL TREATMENT OF UTEROVAGINAL PROLAPSE **1743**
1. Patient Selection 1744
2. Native Tissue Hysteropexy Procedures 1745
   2.1. Partial Colpocleisis without Hysterectomy 1745
   2.2. The Manchester Procedure 1745
   2.3. Sacrospinous Hysteropexy 1746
   2.4. Uterosacral Hysteropexy 1748
3. Mesh Hysteropexy Procedures 1749
   3.1. Sacrospinous Hysteropexy with Graft 1749
4. Sacrohysteropexy 1750
   4.1. Laparoscopic Sacrohysteropexy vs. Sacrospinous Hysteropexy with Graft 1753
   4.2. Laparoscopic vs. Open Sacrohysteropexy 1753
   4.3. Sacrospinous Hysteropexy with Mesh vs. Dermal Graft 1753
   4.4. Laparoscopic Uterosacral Hysteropexy vs. Sacrohysteropexy 1753
   4.5. Laparoscopic Sacrohysteropexy vs. Sacrospinous Hysteropexy 1753
   4.6. Different Hysteropexy Procedures vs. Hysterectomy Using Database/Registry 1753
5. Hysterectomy risks 1754
   5.1. Premature ovarian failure 1754
   5.2. Mesh exposure 1754
   5.3. Spread of unanticipated malignancy 1755

V. APICAL PROLAPSE SURGERY **1757**
1. Sacrospinous Ligament Fixation (SSLF) 1757
2. Ipsilateral Uterosacral Ligament Suspension (USLS) 1759
   2.1. Sacrospinous Ligament Suspension versus Uterosacral Ligament Suspension 1763
   2.2. Midline plication USLS (Mayo/McCall's Culdoplasty) 1763
   2.3. Levator Myorrhaphy 1763
   2.4. Iliococcygeus Fixation 1764
3. Sacrospinous Ligament Fixation with graft (Transvaginal Mesh Apical Prolapse) 1764
4. Sacrocolpopexy 1767
   4.1. Abdominal sacrocolpopexy (ASCP) 1767
   4.2. Abdominal sacrocolpopexy (ASCP) versus sacrospinous ligament fixation (SSLF) 1767
   4.3. Laparoscopic Sacrocolpopexy (LSCP) 1767
   4.4. Robotic Sacrocolpopexy (RSCP) 1771
   4.5. Laparoscopic versus Robotic Sacrocolpopexy 1771
   4.6. Sacrocolpopexy versus transvaginal mesh 1772
   4.7. Sacrocolpopexy with mesh versus biological grafts 1772
5. Obliterative Procedures: LeFort Colpocleisis, Total Colpocleisis 1772

VI. SURGERY FOR POSTERIOR VAGINAL WALL PROLAPSE **1773**
1. Midline Plication (Traditional Posterior Colporrhaphy) 1774
2. Site-specific Posterior Vaginal Repair 1774

3. Graft (absorbable) or Mesh (permanent) Augmentation of Posterior Vaginal Repair 1775
4. Ventral Rectopexy 1776
4.1. Recurrence 1776
4.2. Functional Outcome 1777
5. Ventral Mesh Rectopexy Morbidity 1777
6. Biological Graft Rectopexy 1777
7. Rectocele as an Indication for Ventral Mesh Rectopexy 1777
8. Combined Vaginal and Rectal Prolapse 1778
9. Prolapse surgery and coexistent bowel symptoms 1778

VII. SURGERY FOR PELVIC ORGAN PROLAPSE AND BLADDER FUNCTION 1784
1. Continent women undergoing POP surgery 1786
2. Women with POP and occult SUI 1787
2.1. Women with SUI and POP 1787
3. Overactive bladder symptoms 1787
4. Urinary Voiding dysfunction 1788

VIII. PELVIC ORGAN PROLAPSE SURGERY AND SEXUAL FUNCTION 1789
1. Sexual Function After Prolapse Surgery With Native Tissue Repairs 1790
2. Sexual Function After Prolapse Surgery with Mesh 1790
3. Sexual Function After Prolapse Surgery with Sacrocolpopexy 1790

IX. COMPLICATIONS AND METHODS OF PREVENTION 1795
1. Reoperation after Vaginal Surgery 1795
2. Reoperation after Abdominal Surgery 1797
3. Vaginal Mesh Exposure 1798
3.1. Prevalence of vaginal mesh exposure after vaginal mesh surgery 1798
3.2. Prevalence of vaginal mesh exposure after abdominal surgery 1798
3.3. Risk factors of vaginal mesh exposure 1798
3.4. Treatment of vaginal mesh exposure after vaginal mesh surgery 1799
3.5. Treatment of vaginal mesh exposure after abdominal surgery 1800
4. Visceral (bladder, rectum) Mesh Exposure 1800
5. Infectious Complication 1800
6. Pelvic Pain 1801
6.1. Pelvic pain after vaginal surgery (with/without mesh, including mesh contraction) 1801
6.2. Pelvic pain after abdominal surgery 1801
7. Methods of Prevention 1802
7.1. Methods of Prevention for both vaginal and abdominal approaches 1802
8. Prevention Methods for Vaginal Mesh Surgery 1803
8.1. Learning curve 1803
8.2. Concomitant hysterectomy 1803
8.3. Vaginal sutures 1803
8.4. Vaginal packing 1804
9. Prevention Methods for Abdominal Sacral colpopexy 1804
9.1. Learning curve 1804
9.2. Choice of surgical route for sacrocolpopexy 1805
9.3. Choose the right mesh for abdominal surgery 1805
9.4. Choose the right fixation technique to the promontory, vaginal wall and levator ani 1805
9.5. Concomitant hysterectomy 1806

I. EPIDEMIOLOGY

Pelvic organ prolapse (POP) is a common problem affecting up to 50% of parous women and between 620% of women will have undergone a surgical correction for pelvic organ prolapse by the age of 80.(1-3) Prolapse surgery is an increasingly important aspect of gynaecological practice due to our ageing population, and already prolapse surgery is performed at least as frequently as continence surgery and, the operating and admission times are at least three times greater than for continence surgery. Given the increasing time and resources that will be required for POP surgery in the future it is paramount that we perform effective, durable, cost-effective interventions with minimal morbidity. This chapter serves to outline and summarise the information relating to POP surgery reported in the English-language scientific literature after searching PubMed, Medline, Cochrane library and Cochrane database of systematic reviews, published up to Apr 2021.

1. INCIDENCE AND PREVALENCE OF PELVIC ORGAN PROLAPSE (POP)

There is a lack of robust epidemiological studies of the natural history, incidence and prevalence of POP.

It is widely accepted that 50% of women will develop prolapse with an increasing prevalence with age, but only 10-20% of those seek evaluation for their condition.(4) In the current literature, the overall prevalence of POP varies significantly depending upon the definition utilised, ranging from 3-60% (Table 1). A recent systematic review also found a wide range of POP prevalence rates from 1.1% to 14.6% across four racial/ethnic groups in USA.(5) Where POP is defined, and graded on symptoms, the prevalence is 3-6% as compared to 41-50% when based on examination, as mild prolapse on examination is common and frequently asymptomatic.(4,6-8) On examination anterior compartment prolapse is the most frequently reported site of prolapse and is detected twice as often as posterior compartment defects and three times more commonly than apical prolapse.(9,10) Following hysterectomy 6-12% of women will develop vaginal vault prolapse(11,12) and in two-thirds of these cases multi-compartment prolapse is present.(13)

There is little knowledge about the natural history of POP. The reported incidence for cystocele is around 9 per 100 women-years, 6 per 100 women-years for rectocele and 1.5 per 100 women-years for uterine prolapse.(9) Some data shows that there is a 1-year incidence of POP of 26% and a 3-year incidence of 40% with regression rates of 21% and 19%,(14) respectively consistent with another community cohort from Australia,(15) showing an incidence of 45% in 5 years, progression rate of 29%, regression rate of 17%. In general, older parous women are more likely to develop new or progressive POP than to show regression. Over a three year period 11% of the women aged over 65 had prolapse progression of more than 2 cm whilst only 2.7% had a regression by the same amount.(16) A similar study of women who declined treatment, a progression rate of 19% was reported,(17) whereas another study showed a progression rate of 15% (18) in women who waited over 9months for their surgery. Overall rate of prolapse increased from 40.9% to 43.8% over 5 years, in a large cohort of post-menopausal women, who gained on average 4.4kg during that time suggesting that being overweight or obese is associated with progression of prolapse.(19) In a study of patients who underwent mid-urethral sling surgery, patients with asymptomatic stage 2 prolapse are un-

likely to progress over 5 – 7 years and even more unlikely to require surgery(20).

Luber has shown in a large demographic study that the peak incidence of symptoms attributed to prolapse is between ages of 70 to 79 whilst POP symptoms are still relatively common in women of younger age.

Demographic changes including an ageing population have significant implications for the future planning of women's health services. Wu et al (22) have predicted that by 2050 the number of women suffering from symptomatic POP in the United States will increase at minimum by 46% (from 3.3 up to 4.9 million women and in a "worst-case scenario" up to 200% or 9.2 million women with POP. These figures were based upon population growth statistics in the United States however models that evaluate the impact of decreasing parity and increasing elective caesarean section rates are required to more accurately predict future rates of POP.

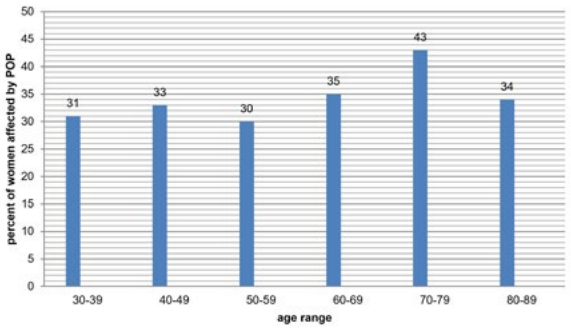

Figure 1. Shows the distribution of POP among women seeking care, US 2000 (Modified Luber 2001(21))

Table 1. Prevalence and Incidence of Pelvic Organ Prolapse

Study	Definition	Prevalence	Incidence	Country
Rorveit, 2007	Symptom	5.7%		USA
Nygaard, 2008	Symptom	2.9%		USA

2. INCIDENCE AND PREVALENCE OF PELVIC ORGAN PROLAPSE SURGERY

Both incidence and prevalence for prolapse surgery increase with age. Women older than 80 years are currently the fastest growing segment of the population. The estimated lifetime risk of an American woman undergoing at least one surgical intervention by the age of 80 was frequently reported as 6.3%.(1) More recently the estimated lifetime risk of prolapse has been reported at 13.7% in the USA(3), 18.7% in Denmark (28) and 19% in Western Australia. (2) Also the reoperation rate reported by Olsen et al was 29.2% rate however, a more recent, prospective study showed a significantly lower reoperation rate of only 13% at 5 years, which may be explained by improved surgical procedures.(29)

Not only is there significant variation in the reported lifetime risk of prolapse surgery there is also wide variation in the rate at which surgical interventions for pelvic organ prolapse are performed. Haya et al (30) demonstrated significant variation in the rates and types of surgical interventions for prolapse in 2012 in various countries in the Organisation for Economic Co-operation and Development (OECD). The rate of prolapse procedures were five times higher in the USA (2.6/1000 women) as compared to Switzerland (0.5/1000 women). There was also very significant variation in the type of interventions undertaken. Transvaginal mesh for anterior compartment prolapse was used eight times more frequently in Germany (26%) than in England (3.3%). Sacral colpopexy was employed 13 times more frequently in France (66%) than in Sweden (5%) for apical vaginal prolapse. Such large variation in rate and types of surgery performed for pelvic organ prolapse maybe explained by a variety of factors including women's preferences, cultural and demographic variables, access to healthcare professionals, health professional training and a lack of clear consensus guidelines on the surgical management of prolapse. The lack of consistency in the rates and types of surgical intervention for pelvic organ prolapse needs further evaluation and ensures difficulty in the allocation of health care resources for future planning for pelvic organ prolapse.

The annual incidence for POP surgery is stated to be between 1.5 and 1.8 cases per 1000 women-years with the incidence peaking in women between 60-69 years,(31,32) although annual rates were lower in Germany (0.87), France (1.14) and England (1.13). Shah et al (32) also demonstrated a peak incidence in 70 year old women however surprisingly high numbers of younger women were also undergoing surgical treatments reflecting a similarity in the prolapse symptoms reported in younger women by Luber 2001 (Figure 2).(21) Wu et al found the annual incidence of prolapse surgery increased linearly with age and peaked at 72 years of age at 4.3 cases per 1000 women.(3)

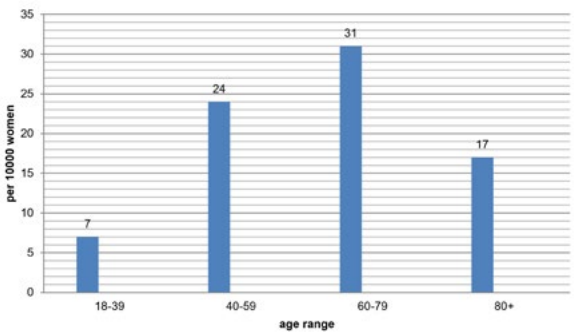

Figure 2. Shows the surgical treatment for POP/ rate per 10000 women (2003)

In the US, POP is thought to be the leading cause for more than 200,000 surgical procedures per year (22.7 per 10,000 women) with 25% undergoing reoperations at a total annual cost of more than 1 billion dollars.(31-34) Also of note during a nine-year period (1996 – 2005) the ambulatory costs related to pelvic floor disorder increased by 40% and if these figures are extrapolated to POP surgery the total annual cost would be over 1.4 billion dollars. While it has been predicted that due to our aging populations the rate and cost of surgery for prolapse will rise by as much as 40%, counter-intuitively some studies are demonstrating decreasing rates of surgical interventions for prolapse. In Denmark, the lifetime risk of prolapse surgery by age of 80 decreased from 26.9% in 1978 to 18.7% in 2008.(28) Over a similar time period in Washington state USA, the rate of surgery for pelvic organ prolapse decreased from 2.1 in 1987 to 1.4 per 1000 women aged 20-84 years in 2009.(35) The authors eloquently linked the decrease in the rate of in-patient prolapse surgery to higher rates of caesarean section and lower rates of instrumental delivery during the same time period. Further detailed modelling of factors that will impact on future rates of POP in the community are required so that services can be provided to match the future demands of POP surgical interventions.

II. OUTCOME ASSESSMENT

Pelvic organ prolapse, like all pelvic floor disorders, is a multidimensional phenomenon and "success" of treatment is often difficult to define. Historically, most studies evaluating the treatment of pelvic organ prolapse have focused exclusively on anatomic success without considering other important areas such as symptoms, vaginal compliance, quality of life, or socioeconomic outcomes. For an individual patient, the most important outcome of a surgical procedure is the relief of her symptoms and improvement in her quality of life,(36) yet until recently these areas have largely been ignored. Fortunately, over the last 15 years, measures to evaluate POP have improved; there is now an internationally-accepted and reliable assessment of the anatomic support of the uterus and vagina (POPQ) and a number of valid, reliable and responsive symptom questionnaires and condition-specific HRQOL instruments. (37-42) A recent joint report from the International Continence Society (ICS) and International Urogynaecology Association (IUGA) recommended that the following outcomes be reported in studies of POP surgery: Objective (e.g. POPQ), Patient reported outcomes (particularly the presence or absence of vaginal bulge symptoms), Satisfaction, Quality of Life, and Perioperative data (e.g. operative time, hospital stay, etc.).(43) A careful report of short- and long-term complications are also essential to assess the risk-benefit ratio of each procedure.

1. OUTCOME ASSESSMENT: ANATOMY

The Pelvic Organ Prolapse Quantification system (POPQ), introduced in 1996, is the international standard for describing female pelvic organ support.(39) The POPQ allows a reproducible and reliable description of the support of the anterior, posterior and apical vaginal segments using precise measurements to a fixed reference point, the hymen, and established criteria for "staging" the various levels of pelvic organ support from good support (POPQ Stage

0 or I) to almost complete lack of support (POPQ Stage IV).(39) The POPQ system has proved a valuable measurement tool that over the last 15 years has improved our understanding of POP and allowed a reliable assessment of the anatomical success of POP surgeries. However, there remain several critical challenges in the anatomical assessment of POP surgery.

First, it is difficult to establish dichotomous anatomical outcome criteria for success and failure, especially in the absence of symptoms. Traditionally researchers have defined surgical success using the NIH satisfactory anatomic outcome (POP-Q Stage 0-1) and defined surgical failure as POPQ stage 2 or greater. More recently it is suggested that these anatomic definitions are too strict as over 75% of women presenting for annual gynaecological examinations without symptoms of pelvic organ prolapse would not meet the definition of “optimal anatomic outcome” and almost 40% would not meet the definition of “satisfactory anatomic outcome”.(7,44) Thus, a substantial number of women considered “surgical failures” by these definitions would be within the normal distribution of vaginal support for parous women. The hymen maybe a more clinically relevant anatomic threshold for surgical success and some researchers have begun defining anatomic failure after surgery as POP that extends beyond the hymen.(36,45-48)

Second, the five-level staging system of the current POP-Q (Stages 0-IV) may be insufficient to discriminate among clinically important groups of women with POP, placing virtually all such women into Stage II or III. While the staging may facilitate comparisons, it may not describe sufficient detail as the individual POP-Q measurements provide. A third area of uncertainty is whether or not apical prolapse should be considered by the same anatomic standards as prolapse of the anterior or posterior vaginal wall. Some researchers have chosen descent more than one-third or one-half of total vaginal length as anatomical failure for the apex.(49,50)

The recent joint committee of IUGA/ICS on the terminology of female pelvic organ prolapse evaluated these points and elected to leave the POP-Q staging unchanged.(51) The decision was based on the principle that POP-Q was developed to address uniform anatomical reporting which it has undoubtedly achieved. POP-Q classification was never designed to replicate subjective outcome and anatomical outcome remains vitally important to surgeons when evaluating, undertaking surgical interventions and reporting these interventions. The division of Stage II prolapse into Stage IIa (-1cm to hymen) and Stage IIb (hymen to +1cm) was also considered. The committee felt the subdivision of Stage II prolapse in POP-Q classification would be open to significant observer and inter-observer error as each subgroup has a range of only 1cm, and would further complicate a grading system already criticised for being too complicated. An alternative proposal to classify Stage II as extending to the hymen and Stage Ш beyond the hymen was also rejected. The committee remained open to further evaluation of all aspects of terminology relating to female pelvic organ prolapse.

Controversy also surrounds the impact that the observer recording the anatomical outcomes has upon reported success rates. Traditionally in the retrospective assessment of anterior compartment trials the reported success rates ranged from 80-100%.(52-55) However, prospective assessment of similar surgical interventions utilising similar definitions of success under the auspices of randomised controlled trials report significantly lower success rate ranging from 37-64%.(56,57) Further variation is also reported in prospective evaluations of prolapse staging depending upon whether the assessor is blinded to the surgical intervention. Antosh et al (58) demonstrated that the recurrence rate in a RCT comparing native tissue and transvaginal mesh repairs was significantly higher when performed by a blinded versus unblinded assessor at 3 months (68 versus 53%) and at 1 year (57 versus 43%). Finally, it is not uncommon for authors with financial conflict of interest related to the commercial products being evaluated reporting the outcomes of surgical interventions, which further increases the risk of reporting bias.

2. OUTCOME ASSESSMENT: SYMPTOMS

Women seeking care for POP often have concurrent pelvic symptoms. Ellkermann et al found that in 237 women evaluated for POP 73% reported urinary incontinence, 86% reported urinary urgency and/or frequency, 34-62% reported voiding dysfunction and 31% complained of faecal incontinence.(59) The evaluation of a patient with vaginal prolapse requires a comprehensive review of the full spectrum of pelvic floor symptoms and an assessment of how these symptoms affect their quality of life. The most valid way of measuring the presence, severity, and impact of pelvic floor symptoms on a patient’s activities and well-being is through the use of psychometrically robust self-administered questionnaires.(37-42)

We have gained an improved understanding of the relationship between pelvic organ support and the development of symptoms. Most symptoms often attributed to POP have at best weak to moderate correlations with worsening pelvic organ support, however, the one symptom that is almost consistently acknowledged by patients with advanced POP is the presence of a vaginal bulge that can be seen or felt.(8,59-62) The absence of vaginal bulge symptoms post-operatively has a significant relationship with a patient’s assessment of overall improvement and improvement in quality of life after surgery, while anatomic success alone does not and ensures that symptom of vaginal bulge remains an important outcome assessment of POP surgery.(36)

3. OUTCOME EVALUATION: PATIENT REPORT OUTCOMES & QUALITY OF LIFE

The United States Food and Health Administration (FDA) introduced the term patient reported outcomes (PRO).(63) In the United Kingdom, it is sometimes known as patient reported outcome measures PROM. A PRO tool could measure any aspect of a patient’s health status that comes directly from the patient (ie without the interpretation of the patients responses by a physician or anyone else). A PRO could be used to measure the impact of an intervention on one or more aspects of patients’ health status ranging from symptoms to more complex concepts like ability to carry out activities of daily living, to extremely complex concepts such as quality of life, which is widely understood to be a multidomain concept with physical, psychological, emotional and social components. Health-related quality of life (HRQOL) is a type of PRO. Measures of PRO can be classified into two types: generic and condition-specific. Generic PRO instruments are used to assess health status in a broad range of illness or populations while condition-specific measures are designed to measure the impact of a specific disease. Women with advanced POP (Stage IIIIV) have decreased generic and condition-specific HRQOL compared to women with normal vaginal support.(64) It is recommended that investigators describe the impact of POP surgical treatment using psychometrically robust

PRO tools. Validated PRO tools are reliable, valid and responsive. Robust validation require reliability over time (test/retest), across items (internally consistent), across different researchers (interrater reliability), demonstrate face, content, criterion & discriminant validity as well responsiveness to change, or minimally important difference (MID,) in a clinically meaningful way. One or two questions within a validated PRO (65) (eg Q3 of PFDI20, Q16 UDI, Q28 APFQ) has often been used to define subjective success in prolapse intervention trials.

Most studies that have assessed condition-specific PRO after POP surgery have demonstrated a significant improvement post-operatively. Improvements in generic PRO after POP surgery have been seen in some studies but not others. Maher et al reported significant improvements in condition-specific and generic PRO after SSLF, similar to that after abdominal sacrocolpopexy.(66) The CARE trial reported significant improvements in condition-specific quality of life following sacrocolpopexy at three months and two years.(67,68) Barber et al demonstrated significant improvements in generic and condition-specific HRQOL in a prospective cohort of elderly women receiving vaginal surgery for POP and demonstrated similar improvements in women undergoing reconstructive surgery and those receiving colpocleisis.(69) While some of these condition-specific HRQOL incorporate assessment of sexual function (42) (APFQ) specific validated questionnaires on sexual function are available and provide a discreet and reproducible method for evaluating sexual health. The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire (PISQ)(70) or PISQ-IR(71) and the Female Sexual Function Index (FSFI)(72) are two validated frequently used questionnaires. FSFI could dichotomise women into those with or without sexual dysfunction, helping clinician understand if pelvic floor interventions contribute to sexual dysfunction. In contrast, PISQ-IR is suitable for women with pelvic floor dysfunction, including those who are not sexually active. The joint ICS/IUGA paper on reporting outcomes after prolapse surgery has also recommended authors report the sexual function status of all individual participants pre and post intervention as seen in Figure 3.(43)

Patient satisfaction is the subjective, individual evaluation of treatment effectiveness, achieved when results of therapeutic intervention are aligned with patient's expectations, therefore allowing clinicians to ascertain appropriateness of treatment. Many factors could potentially influence a patients determination of their satisfaction, including treatment's efficacy, side effects, cost, availability of information on condition, general information giving, availability of resources, continuity of care, accessibility/convenience as well as pleasantness of surroundings or facilities. Patient satisfaction is commonly used as an anchor to determine MIDs for PRO tools. Patient global impression (of severity or improvement PGI-S or PGI-I(73)) is often used as the validated PRO to measure improvement and satisfaction following prolapse treatment. PGI-I gives a more overall global overview of treatment, more likely to encompass the range of benefits and harms of treatment, as it covers other aspects of treatment such as de novo incontinence or persistent pain.

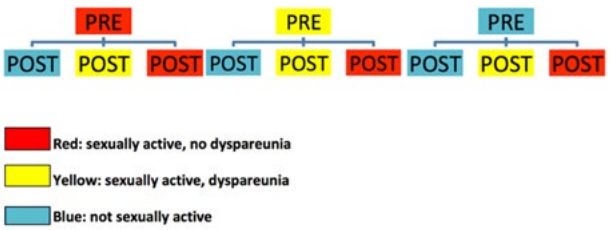

Figure 3. Describes colour coordinated approach to systematically recording pre-and post-intervention sexual function outcomes from Toozs-Hobson 2012(43)

4. OUTCOME ASSESSMENT: REOPERATION

Reoperation after POP surgery for recurrence is an important measure of procedure efficacy. It is important to realise that reoperation rates are likely to represent the "tip of the iceberg" in terms of unsuccessful surgical outcomes as many women with recurrence of symptomatic prolapse may not elect to undergo another operation, nonetheless the repeat surgery for recurrent POP is an undesirable outcome that should, in most cases, be considered a surgical failure. The rates of reoperation after POP surgery vary widely in the literature, in large part because of varying definitions and timeframes. Olsen et al using administrative data from a large U.S. healthcare system reported a lifetime reoperation rate of 29.2%.(1) Importantly, this study included both POP and stress incontinence surgery and did not distinguish between reoperation for incontinence or POP in their report. Moreover, the authors did not distinguish between reoperation for POP in the same compartments originally operated versus the development of new POP in a new segment of the vagina ("de novo POP"). More recently several investigators have looked specifically at the issue of site-specific recurrence with reoperation rates ranging from 3.4%-9.7%.(74,75) In a meta-analysis of 258 studies evaluating reoperation rates after apical prolapse repairs, Diwadkar et al, reported a reoperation rate of 3.9% (95% CI 3.5-4.4%) for traditional vaginal vault suspensions (sacrospinous ligament suspension and uterosacral vault suspensions) after a mean of 32 months, 2.3% (95% CI 1.9-2.7%) for sacrocolpopexy with a mean follow-up of 26 months and 1.3% (95% CI 1.0-1.7%) after transvaginal mesh procedures at a mean follow-up of 17 months.(76) Notably, the total reoperation rate if one includes reoperations for recurrent POP and for complications was highest in the transvaginal mesh group (8.5%).(76)

In order to provide some clarity for future studies reporting reoperation rates after POP surgery, the joint ICS/IUGA report on reporting outcomes after prolapse surgery has proposed the following standardised terminology for POP surgery studies(43):

4.1 Primary surgery for POP is the first procedure required for the treatment of POP in any compartment.

4.2 Further surgery gives a global figure for the number of subsequent procedures the patient undergoes directly or indirectly relating to the primary surgery. This is subdivided into:

4.2.1 Primary prolapse surgery/different site: A prolapse procedure in a new site/compartment following previous surgery in a different compartment (e.g. anterior repair following previous posterior repair).

4.2.2 Repeat surgery: is a repeat operation for prolapse arising from the same site. Where combinations of procedures arise, e.g. new anterior repair plus further posterior repair these should be reported separately i.e. repeat posterior repair and primary anterior repair.

4.2.3 Surgery for complications: e.g. mesh exposure or extrusion or pain or patient compromise e.g. haemorrhage (see complications section).

4.2.4 Surgery for non-prolapse related conditions: e.g. subsequent surgery for stress urinary incontinence or faecal incontinence.

4.3 Defining Treatment Success

The definition of success substantially affects treatment success rates following POP surgery.(36) Since the publication of the NIH Workshop recommendations, considerable variability in defining treatment success still persists in studies evaluating surgery for prolapse. A number of trials define success as POP-Q stage 0 or I consistent with the Workshop's "satisfactory anatomic outcome" definition with one reporting success rates as low as 30% using standard surgical techniques.(57,77) Some have used the Baden-Walker prolapse grading system rather than the POP-Q system.(66) Other studies have used a combination of anatomic criteria and the presence or absence of symptoms to define treatment success.(77-79) A recent analysis of RCTs evaluating interventions for anterior vaginal prolapse, showed significant heterogeneity in reported outcomes. Such variability makes it difficult to compare study results, let alone patient counselling. Moreover, there are many unknowns, including clinical relevance of these definitions or how different outcome definitions might affect the comparison between treatment arms within a study.

Despite avoiding the definition of success or failure, the joint ICS/IUGA paper on reporting outcomes after prolapse surgery(43) has recommended reporting subjective outcome (presence or absence of vaginal bulge), objective outcomes (POP-Q), validated reliable and responsive symptom questionnaires (bladder, bowel, prolapse, sexual function), condition-specific HRQOL instruments, satisfaction, and clearly defined reoperation rates as well as perioperative data including complications. Complications relating to mesh and native tissue repairs should be reported using tools such as IUGA/ICS classification system for prosthesis/graft complication (80) or the Clavien-Dindo classification.(81) The reporting of these single outcome measures individually rather than as composite measures, allows more ready and reliable comparison in meta-analysis.

CONCLUSION

The committee made the following points:

- Significant variation is reported in the rates and types of interventions performed for pelvic organ prolapse. Such variation requires further analysis and standardisation of guidelines for the surgical management of prolapse maybe helpful. (GoR C) should be reported as levels of evidence 1-4 and based on that.
- Early evidence of decreasing rates of surgical intervention for prolapse over the last 30 years are unexpected and require further evaluation.
- (GoR C) Anatomical outcomes reported should include all POP-Q points and staging utilising traditional definition of success. Assessment should be prospective and assessors blinded as to the surgical intervention performed if possible and without any conflict of interest related to the assessment undertaken. (GoR C)
- Subjective success post-operatively should be defined as absence of vaginal bulge. (GoR C)
- Functional outcomes are best reported using valid, reliable and responsive symptom questionnaires and condition-specific HRQOL instruments. (GoR C)
- Sexual function is best reported utilising validated condition specific HRQOL that assess sexual function or validated sexual function questionnaires such as the Pelvic Organ Prolapse/Incontinence Sexual Questionnaire (PISQ) or the Female Sexual Function Index(FSFI). The sexual activity status of all study participants should be reported pre-and post-operatively under the following categories: sexually active without pain, sexually active with pain or not sexually active. (GoR C)
- Prolapse surgery should be defined as primary surgery, and repeat surgery sub-classified as primary surgery different site, repeat surgery, complications related to surgery and surgery for non-prolapse related conditions. (GoR C)

III. ANTERIOR COMPARTMENT SURGERY

Ahlfelt stated in 1909 that the only remaining problem in plastic gynaecology was the permanent cure of cystocele and now more than a century later unfortunately this problem persists.(82) Following high reported objective failure rates and reoperation rates after native tissue repairs and the success of mesh tapes in continence surgery and mesh utilised abdominally at sacral colpopexy, the last decade has seen both a rapid uptake and subsequent decline of transvaginal permanent meshes utilisation in the management of anterior compartment prolapse.

1. NATIVE TISSUE REPAIRS

Historically anterior colporrhaphy was the standard procedure in the management of anterior compartment prolapse with objective success rates ranging from 80-100% in retrospective series.(52-55) White (83) as early as 1912 demonstrated the importance of paravaginal defects in anterior compartment prolapse. Richardson (84) in 1976 described a series of defects in the pubocervical fascia explaining why no single repair should be applied indiscriminately to all with anterior compartment defects. He also advocated the abdominal paravaginal repair which has a 75-97% success rate for cystoceles reported in case series (Table 2).(84-88) The surgical technique of the laparoscopic paravaginal repair is well described however little information is available on the efficacy of this approach. Shull (89) also reported on the safety and efficacy of the vaginal paravaginal repair in 1994. Although the success rates of the vaginal paravaginal repair for cystoceles in case series vary from 67–100% (83,89-93) significant complications have been reported recently. Mallipeddi (92) reported on complications in a series of 45 including: 1 bilateral ureteric obstruction, 1 retropubic hematoma requiring surgery, 2 vaginal abscesses; 2 transfusions. In a series of 100 women Young (93) reported a 21 major complications and a 16% transfusion rate.

No randomised control studies have evaluated the abdominal or vaginal paravaginal repair in isolation. Benson et al (94) and Maher et al (95) have reported RCT's on upper vaginal prolapse comparing abdominal sacral colpopexy and vaginal sacrospinous

colpopexy. Abdominal paravaginal repair was performed in the abdominal group if required and an anterior colporrhaphy with or without vaginal paravaginal laterally. Both authors reported the abdominal group to have a statistically lower rate of postoperative anterior vaginal prolapse than the vaginal group.

Raz et al (96) popularised the needle suspension type procedure for cystoceles and reported success rates in case series may vary from 90-98%.(97-99) The addition of polyglactin mesh to the repair appears to have little impact on the success(100,160). Dmochowski et al (101)reported a lower success rate using a stricter outcome definition of success.

Goldberg et al (102) reported results from a case control study of women with cystocele and stress urinary incontinence. He suggested that the addition of the pubovaginal sling to the anterior colporrhaphy significantly reduced the recurrence rate of cystocele from 42% in the control group to 19% in the anterior colporrhaphy and sling group (P<0.05).

The role of adequate apical support has long been thought to be important in reducing the recurrence rate of AC used for Delancey Level 11 defects. Recently, Eiber et al (103) demonstrated that 10 years after an AC, the reoperation rate for prolapse could be reduced by nearly half, from 20.2% to 11.3% by performing an apical suspending procedure at the time of AC. Unfortunately, this message is not reflected in clinical practice. In a sample of just over 1500 hysterectomies performed for vaginal prolapse in Michigan in the 17months from January 2013 only 25% underwent some form of colpopexy at the time of surgery.(104)

APR Abdominal paravaginal repair
AC Anterior colporrhaphy Definition varies between authors

In line with our surgical colleagues from early 2000's there has been a move towards the use of prosthesis to augment native tissue repair in reconstructive Gynaecology. This movement took much of its impetus from two early papers. Firstly, Olsen et al (1) reported a reoperation of 29% following prolapse and or continence surgery and Weber (57) reported a 70% failure rate of native tissue anterior compartment repair. Recent re-evaluation of the Olsen's same demographic 10 years later revealed a significantly lower re-operation rate of 17% (108) and the reader should be cautious in making conclusions even from this data as the surgical interventions performed in 1995 are not representative of interventions performed today. More importantly, Weber et al (57) and Sand et al (56) in randomised control trials reported the anterior colporrhaphy to be successful in the management of cystocele in only 30% and 57% respectively. Recent re-analysis of data from Weber's paper using the hymen as the threshold for objective success reported considerably better outcomes with only 10% of subjects developing anatomic recurrence beyond the hymen, 5% of subjects developing symptomatic recurrence and re-operations less than 1% at 23 months follow-up.(109)

During the decade between these initial and subsequent publications surgeons introduced a plethora of biological and mesh grafts to improve the outcomes of anterior compartment prolapse surgery.

2. SYNTHETIC GRAFTS IN ANTERIOR COMPARTMENT SURGERY

As seen in Table 3 as early as 1996 Julian et al (110) demonstrated in a prospective case control study that in women who had undergone at least 2 previous vaginal repairs, the overlaying of a Marlex (Bard) mesh to the anterior colporrhaphy reduced the recurrence rate of cystocele from 33% to 0%. The Marlex mesh was associated with a mesh erosion rate of 25%. Flood et al (112) in a retrospective review of 142 women with Marlex mesh augmentation of anterior colporrhaphy demonstrated a 100% success rate for cystoceles at 3.2 years and a mesh erosion rate of only 2%.

Absorbable meshes are an attractive option as an augmenting material as they offered the increased strength during the early healing phase without the long-term complications of permanent mesh and have been evaluated in 2 randomised controlled trials. Weber et al (57) in a randomised control trial compared the anterior colporrhaphy (33), ultra-wide anterior colporrhaphy (24) or anterior colporrhaphy with absorbable polyglactin (Vicryl) 910 mesh (26) in the management of cystocele. The study size was too small to detect small differences in efficacy or adverse events. However, at a mean follow-up of nearly 2 years the groups had similar proportions of women experiencing satisfactory or optimal anatomic results, 30%, 46% and 42% respectively.

Sand et al (56) in a larger RCT allocated cystoceles to anterior colporrhaphy alone (n=70) and to anterior colporrhaphy plus polyglactin mesh underlay (n=73). At I year the success rate in the mesh group was 75% and significantly greater than the 57% success rate in the anterior repair group alone (P=0.02). Concurrent paravaginal defects were present in 11 women and concomitant paravaginal repair was significantly associated with a lower recurrence of cystocele overall (P=0.02).

The 2016 Cochrane review on anterior compartment prolapse reported on three trials that evaluated the effects of using absorbable polyglactin (Vicryl) mesh inlay to augment prolapse repair. (56,57,133) There was insufficient data for analysis on awareness of prolapse and reoperation for prolapse. There was no difference in rate of recurrent anterior wall prolapse between the groups (RR 0.82, 95% CI 0.57 to 1.18). The authors concluded there was little advantage to utilising an absorbable mesh as opposed to anterior colporrhaphy for anterior compartment prolapse.

The 2016 Cochrane review also reported on 16 trials evaluating nearly 2000 women comparing anterior colporrhaphy with permanent polypropylene mesh for anterior compartment prolapse. The meta-analysis demonstrated some advantages and disadvantages to the utilisation of polypropylene mesh and the summary of findings is reproduced in Table 4. Moderate quality evidence demonstrated that awareness of prolapse (RR 0.56, 95% CI 0.43 to 0.73), recurrent anterior wall prolapse (RR 0.34, 95% CI 0.25 to 0.46) and reoperation for prolapse RR 0.44, 95% CI 0.24 to 0.46) were significantly less common following mesh repair as compared to AC

There were no differences between the groups in terms of quality-of-life outcomes or rates of dyspareunia. However, the transvaginal polypropylene mesh group had higher rates of reoperation rate for mesh exposure, stress urinary incontinence or prolapse (RR 1.62, 95% CI 1.15 to 2.28), prolapse in the apical or posterior compartment (RR 1.85, 95% CI 1.01 to 3.37) and at POP-Q point Bp (MD 0.53, 95% CI 0.10 to 0.95,) as compared to AC. The operating time (MD 17.9 mins, 95% CI 10.0 to 25.8), rate of transfusion (RR 2.37, 95% CI 1.32 to 4.24), cystotomy (RR 4.65, 95% CI 1.22 to 17.77;) and de novo stress urinary incontinence (RR 1.55, 95% CI 1.02 to 2.35) were higher after transvaginal polypropylene mesh as compared to AC. The mesh erosion rate after polypropylene mesh was 11.5% and 7% underwent surgical correction for the mesh exposure.

More recently the majority of the polypropylene mesh products evaluated in this meta-analysis have been voluntarily withdrawn by the manufacturers in the face of ongoing litigation. The products with tradename Ugtex and Paritiene (Sofradem, France) and Nazca (Promedon, Argentinia) remain available in some countries.

Newer light-weight transvaginal polypropylene mesh products that have been introduced to decrease the complication rate, specifically mesh erosion, Uphold (Boston Scientific, USA) and Restorelle (Colpoplast, USA) remain available in some countries. Altman et al (134) reported a multi-centre prospective case series evaluating 207 women with apical prolapse undergoing Uphold pelvic floor system and reported a subjective success rate of 90% at one year. However, the complication profile was similar to other transvaginal mesh kits at one year with a mesh exposure rate of 6.3%. Contrarily, De Tayrac et al found at 3-years, in 79 women with grade 3-4 cystocele, an anatomic success rate of 95%, a satisfaction rate of 98% and a mesh exposure rate of 1.3% using a lightweight (28 g/m^2) polypropylene mesh (Surgimesh® Prolapse Xlight, Aspide Medical, France).(135)

Recently Nager et al reported a large multicenter RCT comparing hysteropexy with Uphold Lite mesh in the anterior and apical compartment compared to vaginal hysterectomy with uterosacral support and native tissue anterior colporrhaphy and demonstrated no significant difference between the groups with three-year review on a wide variety of outcomes. The mesh exposure rate was not insignificant at 8% following the lightweight mesh.(136)

Two RCTs have compared permanent anterior vaginal mesh at vaginal surgery with sacral colpopexy for the management of cystoceles. Lucot et al in a large multicenter French RCT compared laparoscopic SC (n=130, hysteropexy and subtotal hysterectomy) with 4-armed monofilament polypropylene anterior mesh with hysteropexy or hysterectomy (n=132) at one year.(137) They reported a significantly lower rate of grade three Clavein-Dindo complications in LSC as compared to vaginal mesh (0.8% versus 9.4%) without a difference in quality of life or subjective outcomes. The vaginal length was significantly shorter and dyspareunia higher in the vaginal mesh group as compared to LSC.

De Castro et al reported a single centre trial that evaluated polyvinylidene fluoride (PVDF) mesh (Dynamesh, Aachen, Germany) as a newer non polypropylene permanent mesh in the anterior compartment at time of vaginal hysterectomy and sacrospinous colpopexy (n=35) compared to open sacral colpopexy (OSC n=36) in those with grade 3-4 uterine prolapse.(138) The study failed to achieve required recruitment and at 12 months demonstrated no difference in subjective and objective outcomes between the groups however the surgical reintervention rate was significantly higher for compilations in the vaginal group (11%) as compared to OSC (0%). Furthermore, the mesh exposure rate for the PVDF mesh at 11% was similar to that reported with polypropylene mesh.

One anomaly remains challenging from the Cochrane 2016 meta-analysis of anterior compartment prolapse. Only one case of

reoperation for dyspareunia or pain were reported in the nearly 1000 cases of transvaginal mesh evaluated. However, pain and dyspareunia were leading causes of adverse events that triggered the 2011 FDA warnings on the safety of transvaginal mesh.(139) In series reporting on re-intervention after transvaginal mesh pain and dyspareunia are the leading indicator for re-operation and at a rate equal to higher than mesh exposure.(140-142) These findings raise the possibility that pain and dyspareunia following transvaginal mesh reviewed in the Cochrane review maybe under-reported and possibly only identified in trials with longer-term evaluation.

Table 4. Summary of Findings tables comparing anterior colporrhaphy and polypropylene mesh for anterior compartment prolapse. Reproduced from the 2016 Cochrane review on anterior compartment prolapse.

Outcomes	Anterior repair (col-porrhaphy)	Polypropylene Mesh	Relative effect (95% CI)	No of Participants (studies)	Quality of the evidence (GRADE)
Awareness of prolapse	256 per 1000	143 per 1000 (110 to 187)	RR 0.56 (0.43 to 0.73)	974 (7 studies)	⊕⊕⊕⊠ moderate1

Variable definitions of success used.

3. BIOLOGIC GRAFTS IN ANTERIOR COMPARTMENT SURGERY

Alternatively to synthetic prosthetic grafts autologous material may have a lower risk of host rejection or infection. Cosson (143) described an autologous 6-8cm long and 4cm wide vaginal patch suspended from the tendinous arches of the pelvic fascia and tucked under the anterior repair. The success rate (<grade 1 POP) was 93% at a mean follow-up of 16 months.

Allografts from post-mortem tissue banks have been used for many years in orthopaedic surgery and decrease the risk associated with harvesting autologous rectus sheath or fascia lata. Cadaveric fascia lata with or without pubovaginal sling has been utilised to correct anterior compartment prolapse with a success rate varying from 81-100% with acceptable complication rates. (144, 145, 148, 149) Gandhi et al have reported preliminary results of a randomised control trial comparing anterior colporrhaphy alone and augmented with fascia lata graft for cystoceles. (150) At 1 year they were not able to demonstrate that the addition of the fascial lata graft improved outcomes with the success rate

after anterior colporrhaphy alone being 71% as compared to 82% in those augmented with the fascia lata graft (P=0.07). No complications were reported. Cadaveric dermis has been employed as a graft material in the anterior compartment with success rates varying from 42-84% at 2 years (146,147,151,167). Concerns regarding prion transmission causing infectious diseases (168) or residual antigenicity (169) that may cause host graft reactions have encouraged the use of porcine or bovine xenografts as detailed in Table 4.

Leboeuf et al retrospectively reviewed 24 women with native tissue four corner defect repair (FDR) and 19 FDR with porcine dermis.(170) At 15 months the success rate was 100% in the FDR group and reduced to 84% if porcine dermis overlay was utilised. Wheeler et al reported on 36 women who all underwent high uterosacral vault suspension with anterior repair augmented with porcine dermis and at 17 months found a 50% recurrence rate. (155) The authors highlighted that despite the high objective failure rate greater that 90% of the women were satisfied or somewhat satisfied with the repair and 83% would undergo the surgery again. Handel et al retrospectively compared anterior colporrhaphy (n=18), porcine dermis (n=56) and polypropylene graft (n=24) in those with cystocele.(157) The success rate at 13 months was 94%, 64% and 96% respectively with a 21% rate of vaginal extrusion of the porcine dermis graft. Alternatively to these relatively disappointing results, a number of groups have reported satisfactory objective results utilising porcine dermis.(154) (158)

Meschia et al in a multicentre randomised clinical trial compared the anterior colporrhaphy (n=103) and anterior colporrhaphy-augmented with 4x7cm piece of porcine dermis.(171) The success rate at 1 year was 93% in the anterior colporrhaphy with porcine graft overlay group as compared to 81% in anterior colporrhaphy alone group (P<0.001) with a 1% rate of graft erosion.

Hviid et al reported a smaller randomised controlled trial comparing polyglactin plication anterior colporrhaphy and porcine dermis 4x7cm graft at one year.(161) The objective failure rate (defined as point Ba ≥-1) was 2/28 in the porcine dermis group as compared to 4/26 in the anterior colporrhaphy and was not significant. Guerette et al compared the anterior colporrhaphy group (n=17) and anterior colporrhaphy with bovine pericardium collagen (n=27) matrix graft reinforcement and reported no difference on objective examination with success rate of 63% after the AC and 77% in the bovine pericardium collagen repair at 2 years.(160) The reoperation rate for prolapse was 37% in AC group and 23% in the bovine pericardium group. De novo dyspareunia occurred in 5% following AC only. There was no difference in quality-of-life outcomes between the groups utilising Urinary Distress Inventory and Pelvic organ prolapse and Incontinence sexual questionnaire.

Feldner et al compared anterior colporrhaphy with 7x10cm small intestine submucosa (SIS) graft in a randomised control trial and demonstrated reduced operating time in AC group (30 min versus 46) as compared to SIS (p=0.02).(162) The objective failure rate of 33% (9/27) was significantly higher after the AC versus 14% (4/29) in the SIS group. The dyspareunia rate was similar in both groups (AC 4/27 versus 5/20 SIS) and no reoperations were reported. Prolapse quality of life assessment (P-QOL) improved postoperatively in both groups with no significant difference between the groups. In another RCT, Natale_ et al compared polypropylene mesh (Gynemesh) with porcine dermis (Pelvicol). At two years, significantly fewer women had anterior vaginal wall recurrence in the mesh group 28% (27/96) versus to 44% (41/94) of the porcine graft group (RR 0.64, 95% CI 0.43 to 0.96). Mesh erosion was seen in 6.3% following mesh surgery. Although similar numbers of women reported dyspareunia (10 versus 12), the authors reported superior sexuality outcomes in the porcine graft group as compared to polypropylene mesh (p = 0.03).(163)

Finally, Menefee et al in a randomised control trial compared three operations, anterior colporrhaphy, vaginal paravaginal repair using porcine dermis graft and vaginal paravaginal with self-styled polypropylene mesh and also reported a higher objective success rate after the polypropylene mesh 86% (25/29) as compared to 52% (12/23) in the porcine dermis arm (124) and 53% (10/19) in the AC arm. The subjective failure rate was not significantly different and was 3.4%, 12% and 13% respectively. The graft erosion rate was 1/23 (4.3%) in the porcine dermis group and 4/29 (13.8%) in the mesh group.

In 2016 Cochrane review on the surgical management of anterior compartment prolapse eight trials (124,150,156,160-162,164,165) compare AC (n=413) with various biological grafts (n=450). Porcine dermis (Pelvicol) was utilised in four trials (Dahlgren 2011; Hviid 2010; Menefee 2011, Meschia 2007), small intestine submucosa in two trials (Feldner 2010, Robert 2014), cadaveric fascia lata patch in Gandhi 2005 and bovine pericardium collagen in Guerette 2009. Meschia 2007 evaluated only primary anterior compartment prolapse and Dahlgren 2011 only included those who had at least one failed prior surgical intervention in the treated compartment. Hviid 2010 included those only with anterior compartment prolapse and concomitant surgery was excluded.

There were no differences detected between porcine dermis graft or small intestine submucosa and AC for the primary outcomes of awareness of prolapse, prolapse on examination and re-operation for prolapse. When all biological grafts were analysed together biological grafts had similar outcomes to AC in awareness of prolapse and reoperation for prolapse, however the recurrent anterior prolapse rate on examination was less after biological graft repair as compared to anterior colporrhaphy (RR 0.74, 95% CI 0.55 to 0.99 n= 646, I^2=29%, low quality evidence). The AC operating time was less than the biological graft procedure (MD -10.35, 95% CI -14.45 to -6.24).

4. RECURRENT ANTERIOR PROLAPSE

Many clinicians believe the primary role of polypropylene mesh may be in complex or high risk prolapse such as recurrent prolapse. Fayyad et al prospectively evaluated 36 women with recurrent anterior compartment prolapse and reported an objective success rate (less than stage 2 anterior compartment prolapse) of 47% with a mesh exposure rate of 19%.(172) In a prospective multicentre Dutch RCT trial in women with recurrent anterior or posterior compartment prolapse were randomised between native tissue repairs and tension-free vaginal polypropylene mesh.(173) The authors reported little advantage to mesh augmentation at 7 years. The composite success was 53% (95% CI 41, 66) for mesh and 54% (95% CI 42, 65) for native tissue. Repeat surgery for POP was 25% for mesh and 16% for native tissue (difference 9%; 95% CI -5, 23) and occurred in untreated compartments in the mesh group and treated compartments in the native tissue group. Mesh exposure rate was 42% and the rates of vaginal pain (mesh 39% NT 50% and dyspareunia (mesh 20%, NT 17%) similar in both groups.(174)

More recently Ow et al, reported on a retrospective comparison of 237 women undergoing 185 native tissue repair and 161 transvaginal mesh repairs (self-styled and mesh kits) for recurrent prolapse. The transvaginal mesh group had significantly lower rates of symptomatic prolapse, prolapse on examination and reoperation for prolapse than the native tissue repairs. However, the mesh exposure rate (15% anterior, 21% posterior mesh) and reoperation for mesh exposure (anterior 9%, posterior 15%) were significant. There was no difference in the total reoperation rate between the groups (mesh 24%, NT 19%).

In 2020 the Prospect group reported a RCT that compared native tissue versus polypropylene mesh in those with recurrent anterior or posterior vaginal wall prolapse. Using the unvalidated primary outcome measure of Pelvic Organ Prolapse Symptom score no difference was detected in the two interventions. However the validated and blinded assessors demonstrated anatomical improvement in the mesh group for Point Ba, total vaginal length and stage of POP and the validated QOL scale EQ-5D-3L also reported a more favourable outcome in the mesh group. The mesh exposure rate in the mesh kit group was 9% at 2 years.(175)

The data from these three trials suggest that in women with recurrent anterior prolapse transvaginal mesh has advantages and dis-advantages to native tissue repairs. The risk profile is similar to that described for primary repairs except the mesh exposure rates appear to be higher in recurrent prolapse surgery.

Clinical practice worldwide.
In a 2017 survey of members of British Urogynaecology Society to which about 50% responded over 90% performed anterior colporrhaphy for primary anterior compartment prolapse.(176) For recurrent anterior wall prolapse only 11% would utilise a permanent synthetic mesh as compared to 56% in a similar survey conducted 5 years previously. Clinical practice in the BSUG responders closely reflects the data presented above. There remains significant variation in clinical practice worldwide with transvaginal mesh for vaginal prolapse prohibited in many countries including USA, United Kingdom and Ireland, Canada, France, Australia and New Zealand(177) in response to concerns outlined above including high rates of mesh exposure and vaginal pain/ dyspareunia that are challenging to treat. In many European and Asian countries transvaginal mesh remain a viable option for women with vaginal prolapse.

CONCLUSION
The following conclusion can be made regarding surgical interventions for anterior vaginal compartment repairs:

- Absorbable mesh augmentation of native tissue repair improves the anatomical outcome as compared to native tissue repair alone with no increased complication rate in meta-analysis of 2 RCTS (GoR B).

- Biological grafts have improved anatomical outcomes with no change in subjective outcomes as compared to native tissue repairs (GoR B). Conflicting level one evidence supports porcine dermis graft (Meschia, Hviid, Menefee) and single RCT supports small intestine submucosa as graft material in anterior compartment prolapse surgery (Feldner) (GoR B).

- Polypropylene mesh has a superior anatomical outcome as compared to biological graft (Pelvicol) in the anterior compartment (Feldner, Menefee). Mesh exposure rate was significantly higher in the polypropylene mesh group (GoR A).

- Polypropylene mesh demonstrates improved anatomical and subjective outcomes as compared to AC with no difference in functional outcomes using validated questionnaires or a lower reoperation rate for prolapse. The mesh group was also associated with longer operating time, greater blood loss and a non-significant tendency towards higher cystotomy, de novo dyspareunia and de novo stress urinary incontinence rate as compared to AC. Apical or posterior compartment prolapse was significantly more common following polypropylene mesh and mesh extrusion rate was 10.4% with 6.3% undergoing surgical correction (GoR B).

- Data for recurrent anterior vaginal wall prolapse is conflicting regarding the advantages for polypropylene mesh compared to AC with relatively high rates of mesh complication reported in the longterm (GoR C).

IV. SURGICAL TREATMENT OF UTEROVAGINAL PROLAPSE

It has been shown that defects in Level 1 support, the uterosacral cardinal ligament complex, lead to uterine descent.(178) Despite the fact that most gynaecologists and pelvic reconstructive surgeons consider the uterus to be a passive structure in prolapse development, it is frequently removed during uterovaginal prolapse surgery. In fact, prolapse is one of the most commonly listed indications for hysterectomy.(179) As interest in uterine preservation increases, it is important to critically evaluate the safety and efficacy of hysteropexy to determine if similar results can be achieved with uterine conservation compared to hysterectomy.

Queries of United States (US) women presenting for prolapse care suggest that 36-60% would choose uterine preservation assuming equal surgical efficacy.(180,181) Similar results were observed during queries of women from the Netherlands, Austria/Germany and Russia with 43%, 40% and 54% respectively that preferred uterine preservation assuming equal outcomes.(182,183) However, 66% of female gynaecologists in the Czech Republic, Slovenia and Slovakia preferred concomitant hysterectomy at the time of hypothetical prolapse repair assuming equal outcomes. (Urdzik 2020) Women elect uterine preservation for a variety of reasons including the desire to preserve future fertility, that the uterus contributes to their sense of feminine identity and wish to avoid hysterectomy perceived as a major surgery associated with significant risks. However, surveys have shown that many of the reasons for desiring uterine conservation have more to do with ovarian conservation. These include beliefs that removal of the uterus will worsen mood, relationships, quality-of-life, sex drive and result in weight gain.(180) Patient demographics have been associated with hysteropexy preferences. For example, college educated women were almost three times more likely to choose uterine conservation, and women living in the southern US were less likely to request uterine preservation (OR 0.17 95% CI 0.050.7)).(181) Whether it is cause or effect, a greater number of hysterectomies are performed in the US south compared to other geographic regions.(179) Each patient's interest in uterine conservation should be assessed during surgical planning. This can easily be accomplished by listing the patient's goals and preferences early on during the informed consent process.

Conservative management with a pessary is recommended for women with uterovaginal prolapse that are interested in future childbearing or uncertain about their reproductive plans. Due to limited data regarding risks associated with subsequent pregnancy

and delivery, surgery should be reserved for those that cannot be managed with a pessary. We do not know which type of hysteropexy is the safest with respect to fertility, pregnancy and delivery. We also do not know the impact of pregnancy and vaginal or cesarean delivery on postpartum pelvic support with hysteropexy. Assuming pregnancy and delivery decreases the long-term success of the prolapse repair, native tissue vaginal or laparoscopic hysteropexy may be preferable as a temporising solution. This is based on the belief that future surgical management will likely be required for recurrent prolapse. This review focuses on women who have completed childbearing and are postmenopausal or practicing reliable contraception.

1. PATIENT SELECTION

Candidates for uterine conservation should be carefully considered and strict selection criteria applied to decrease the likelihood of subsequent hysterectomy, which may be more technically challenging. Most contraindications to hysteropexy are relative since the majority of cases (except LeFort colpocleisis) maintain access to the cervix and endometrial cavity for screening and sampling. Women at increased risk for endometrial, cervical or ovarian cancer and those with a personal history of oestrogen receptor positive breast cancer, especially those taking Tamoxifen should have their uterus, cervix and possibly ovaries removed at the time of prolapse repair. Hysteropexy should also be avoided in cases of uterine abnormalities listed in Table 1. Patients with recent postmenopausal bleeding even with a negative workup should probably undergo hysterectomy based on a 13% risk of unanticipated endometrial cancer or hyperplasia.(184) Premenopausal women and those without postmenopausal bleeding had low rates of endometrial pathology. The overall rate of endometrial cancer was 0.3% in this study (184) and 0.8% in another large study.(185) During the consent process for post-menopausal women considering uterine preservation or hysterectomy, women should be informed of the lifetime risk of cervical (0.6%), uterine (2.7%), and ovarian cancer (1.4%).(186,187) While ovarian cancer is uncommon, the general late presentation of disease is associated with poor outcomes. Routine bilateral oophorectomy demonstrated a 10-fold decrease in the small risk of ovarian cancer without increased morbidity when results were stratified by age.(188,189) Furthermore, all women who have completed their family and are considering prolapse surgery should be informed that bilateral salpingectomy may decrease the risk of ovarian cancer by 42-56%, is cost effective at hysterectomy and is not associated with increased morbidity.(190,191)

The 2019 updated ACOG Committee Opinion recommends counseling all women planning hysterectomy or other pelvic surgery (ie prolapse surgery) about the benefits of opportunistic salpingectomy. Performance of opportunistic salpingectomy is not feasible during vaginal hysteropexy repairs and as such is a relative contraindication. When considering vaginal hysterectomy for the treatment of uterine prolapse, salpingectomy can be successfully performed 74 to 88% of the time.(192-194) However, route of hysterectomy may impact ability to successfully complete salpingo-oophorectomy for women that are at higher risk of ovarian disease or desire removal. A retrospective comparison of women undergoing vaginal hysterectomy (n=163) and laparoscopic assisted vaginal hysterectomy (n=144) for prolapse found that rates of salpingectomy (1% vs 34%) and salpingo-oophorectomy (45% vs. 66%) were lower in the vaginal hysterectomy group plus planned salpingo-oophorectomy was unable to be completed in 36% of vaginal hysterectomies vs. none of the laparoscopic hysterectomies. Peri-operative complications and inpatient stay were significantly greater in the vaginal hysterectomy group.(195) The ACOG Committee Opinion further recommended not altering the route of surgery based on the decision for opportunistic salpingectomy, but route may need to be altered for those in desiring salpingo-oophorectomy or hysteropexy. Consequently, this should be part of the informed consent process and surgical planning. Higher risk women with hereditary conditions (BRCA mutations, Lynch Syndrome) and obesity should consider hysterectomy with or without oophorectomy during prolapse repair. Table 6 lists possible contraindications to uterine preservation and includes pre-operative cervical elongation. A prospective two-part study showed an almost 11-fold increased risk of failure in patients with cervical elongation undergoing sacrospinous hysteropexy (SSHP). Success rates were 96-100% after excluding patients with severe prolapse and performing partial trachelectomy for cervical elongation.(196) Other studies have shown similar high success rates using partial trachelectomy at the time of hysteropexy.(197,198) The majority of studies exclude women with menstrual disorders and abnormal uterine or cervical pathology. One study performed over 20 concomitant uterine/cervical procedures among 65 laparoscopic sacrohysteropexy (SHP) subjects to correct abnormal pathology.(199) Procedures included 8 trachelectomy for cervical elongation, 5 cervical/endometrial polypectomy, 4 myomectomy/uterine artery occlusion, 2 cervical conisations for CIN2 and 1 mesh excision. The relaxed exclusion criteria may be a factor that led to more symptomatic recurrences that required treatment (9 pessary, 1 surgery) in the hysteropexy group. This example illustrates the need for stringent selection criteria.

Table 6 Relative contraindications to uterine preserving surgery

Uterine abnormalities
Fibroids, adenomyosis, endometrial pathology sampling
Current or recent cervical dysplasia
Abnormal menstrual bleeding
Post-menopausal bleeding
Cervical elongation
Familial cancer BRAC1&2: ↑risk ovarian cancer and theoretical risk fallopian tube and serous endometrial cancer
Hereditary Non-Polyposis Colorectal Cancer (Lynch Syndrome): 60% lifetime risk endo-metrial cancer
Tamoxifen therapy
Obesity: up to 3-fold increased risk endometrial cancer18
Vaginal uterine preserving surgery in those desiring opportunistic salpingectomy
Unable to comply with routine gynaecology surveillance

Hysteropexy Outcomes

A variety of hysteropexy techniques have been described to treat uterovaginal prolapse. Studies show short-term safety and efficacy with decreased blood loss, shorter operating time and more rapid recovery compared to hysterectomy. Although the quantity and quality of hysteropexy studies is growing, most studies lack controls and contain variable techniques and definitions of success. The primary purpose of this analysis is to compare hysteropexy and hysterectomy surgical outcomes for treatment of uterovaginal prolapse. Hysteropexy procedures can be subdivided into native tissue and mesh repairs. While apical or anatomic success is most commonly reported, a few studies used composite outcomes and most

reported reoperation rates for prolapse. Mesh exposures have also been included when applicable. Only studies containing a control or comparison hysterectomy group with an apical support procedure are included. Studies lacking controls, non-English language, containing poorly defined outcomes as well as those that are unable to distinguish between various hysteropexy and hysterectomy outcomes are excluded.

2. NATIVE TISSUE HYSTEROPEXY PROCEDURES

There are ostensibly four different types of native tissue repairs involving uterine conservation. LeFort colpocleisis involves obliteration of the vaginal lumen and is an excellent option for women that are no longer sexually active and are not interested in preserving coital function. The Manchester procedure had fallen out of favor for years but is gaining increased interest with encouraging results (200,201) despite the fact that it is primarily a treatment for cervical elongation. Sacrospinous hysteropexy and uterosacral hysteropexy (USHP) (vaginal, abdominal or laparoscopic) are the most commonly utilised native tissue procedures that maintain coital function.

2.1. Partial Colpocleisis without Hysterectomy

Partial colpocleisis is the ultimate hysteropexy procedure due to high success and low morbidity in an older population with advanced prolapse and multiple medical comorbidities. It is reserved for women who are not sexually active and are not interested in preserving coital function. Shorter operating time, less blood loss and similar anatomic success was reported after partial colpocleisis compared to total colpocleisis.(202) An older, retrospective cohort comparing LeFort colpocleisis (n=21) to vaginal hysterectomy with anterior and posterior repair (n=42) for complete uterovaginal prolapse found shorter operating time with no differences in prolapse symptom resolution or complications.(203) There are no prospective trials and three retrospective cohort studies that compared LeFort colpocleisis to colpocleisis with hysterectomy.(204-206) One single institution study involving LeFort colpocleisis (n=46) and colpocleisis with vaginal hysterectomy (n=65) with median 4 month follow-up showed no difference in overall adverse event rates excluding urinary tract infections (15.2% vs 13.8%, p=0.84) . Concurrent hysterectomy resulted in longer operating time (144 vs 111 minutes, p<0.001), higher estimated blood loss (253 vs 146 mL, p=0.01) and higher transfusion rate (9.3% vs 4.3%, p=0.02)[21] (Hill 2016) Another study utilized the ACS-NSQIP database to compare colpocleisis (n=893) to colpocleisis with vaginal hysterectomy (n-134) and showed shorter operating time with fewer serious medical complications (0.8% vs 3.7%, p=0.03) in the colpocleisis group.(204) The third more recent study compared LeFort colpocleisis (n=70) to vaginal hysterectomy and total colpocleisis (n =172) at a mean follow-up of 44 months. (Lu 2021) The authors found shorter operating time and less blood loss with uterine conservation. Both groups had high satisfaction (98.6% vs 98.8%) and low regret (0 vs 0.6%). In the hysterectomy group, there was one case of bleeding that required reoperation and transfusion, one case of recurrent prolapse and one case of endometrial cancer (0.6%) diagnosed on pathology despite the absence of postmenopausal bleeding and a negative ultrasound preoperatively. The authors concluded hysterectomy should be reserved for uterine abnormalities identified preoperatively or concerns about difficulty evaluating subsequent vaginal bleeding and a decision analysis favored LeFort colpocleisis over colpocleisis with vaginal hysterectomy after balancing risk of delayed endometrial cancer with hysterectomy complications plus the need for possible laparotomy.(207)

2.2. The Manchester Procedure

The Manchester procedure is one of the oldest prolapse repairs that involves amputation of the cervix and reattachment to the cardinal ligaments. Modified Manchester repairs include plication of the uterosacral ligaments posteriorly and cardinal ligaments anteriorly for apical support. Premenopausal women wishing to maintain fertility and older women with medical co-morbidity, originally considered good candidates for a Manchester procedure, have better surgical options since the repair is primarily a treatment for cervical elongation. It is more important than ever to critically evaluate the quality of the literature with respect to this prolapse surgery as interest in uterine conservation increases prompting a relative resurgence of this technique. All of the studies using this technique are retrospective and the majority are case series showing relatively good anatomic and symptomatic improvement with low complication rates. There are no RCT's and four retrospective cohort studies comparing Manchester to vaginal hysterectomy.(208,209) (201,210) Table 7) These retrospective cohort studies generally showed no difference in anatomic or symptomatic outcomes with decreased operating time and blood loss in the Manchester group. Unfortunately, several of the studies contained poorly defined anatomic outcomes, variable lengths of follow-up and limited reporting of anatomic outcomes and reoperation rates especially for the hysterectomy group so meta-analysis was not performed. Two of the four comparative trials appear to lack an apical support procedures at the time of vaginal hysterectomy (201,210) and only one study describes a high midline plication uterosacral suspension (USLS).(208) The latter study showed 100% vs. 96% successful apical support but only 40% overall anatomic success < stage 2 with high rates of anterior wall recurrence (46-48%).(208) The most recent cohort revealed no difference in their primary outcome of no prolapse symptoms (69% vs 74%) using the prolapse domain of Urogenital Distress Inventory.(201) Reoperations for recurrent prolapse ranged from 2-4% in the Manchester group and two studies also commented on retreatment with a pessary being 3-4%. There were several additional procedures required to evaluate and treat abnormal cervical cytology and menstrual disorders. All of the Manchester descriptions include the use of Sturmdorf sutures to close the amputated cervical stump potentially leading to cervical stenosis and future menstrual issues. Due to the quality of the data, a combined analysis of Table 7 is not possible but there appears to be no differences in anatomical success and reoperation between Manchester and hysterectomy. Despite good success rates, Kalogirou concluded, "that the Manchester procedure has a limited place in modern gynecology…".(209)

The data from the Danish database on Manchester repairs is discussed fully below.

Table 7 Manchester versus Hysterectomy

Reference	Study type and surgery	Review (months)	Success N (%) < stage/grade 2		Reoperation prolapse		Complications
			Hysteropexy	Hysterectomy	Hysteropexy	Hysterectomy	
Thys 2011	Retrospective Matched Cohort Manchester vs TVH USS	72	79/98 (81)	80/98 (82)	4/98 (4)	9/98 (9)	Hemorrhage: 4 vs 5 Bowel lesion: 1 vs 0 Urinary retention: 33 vs 11 Dyspareunia: 4 vs 5

Thomas 1995	Retrospective Cohort Manchester vs TVH	30	61/67 (91%)	MD (?/105)	2/67 (3%)	MD	Transfusion: 3% vs 10%

2.3. Sacrospinous Hysteropexy

Sacrospinous hysteropexy (SSHP) is performed by transfixing the cervix or uterosacral ligaments (USL) to the sacrospinous ligament (SSL) using permanent or delayed absorbable sutures. Most studies approach the SSL via a posterior or apical approach with attachment to the posterior cervix. A cohort study suggested that better subjective outcomes may be achieved when approaching the SSL posteriorly and anchoring to both the anterior and posterior cervix compared to posterior cervical attachment.(211) Another case series promoted an anterior approach to the SSL with anterior cervical attachment as a safe and efficacious SSHP technique.(212) These findings were reinforced by a recent retrospective cohort comparing anterior approach SSHP to vaginal hysterectomy and uterosacral or sacrospinous suspension.(213)

An initial RCT, reported more apical recurrences (21% vs. 3%, p=0.03), similarly frequent anterior recurrences (51% vs. 64%) and similar subjective improvement comparing SSHP (n=37) to vaginal hysterectomy with uterosacral suspension (USLS) (n=34).(214) All three hysteropexy women with stage 4 prolapse had apical recurrences within one year. The largest RCT showed SSHP (n=103) to be non-inferior to vaginal hysterectomy with USLS (n=105) at one year.(215) Success rates were 100% vs 96% for the primary composite outcome using the apex less than stage 2 as the threshold. Most of the recurrences occurred anteriorly. This same group published two-year outcomes for sexual function showing no difference between the procedures using the Pelvic Organ Prolapse Urinary Incontinence Sexual Questionnaire short form (PISQ-12).(216) More recently, the authors reported five-year study outcomes revealing no differences in anatomical failure, reoperation for prolapse (3% vs 7%) or symptomatic outcomes including quality of life and sexual function. Interestingly, the rate of anterior wall recurrent prolapse did not increase over time and anterior prolapse recurrence beyond the hymen was uncommon (6% vs 8%) at 5 years. They did report less anatomic apical failure (1% vs 8%) and more successful treatment (87% vs 76%) in the SSHP group using a similar apical composite outcome for failure as well as a composite outcome for success including no prolapse beyond the hymen.(217) Another RCT comparing SSHP to vaginal hysterectomy only reported sexual function outcomes using the Female Sexual Function Index-7.(218) There were no differences noted between groups and sexual function remained relatively unchanged with infrequent dyspareunia (5%). Transient buttock pain is a common complaint in up to 15% of patients and usually resolves without intervention.(218-220) As mentioned previously, women with cervical elongation should consider partial trachelectomy to improve apical cure.(196) No differences in anatomic success or symptomatic improvement were reported among 6 other prospective (221) and retrospective (219,220, 222,2013) cohort studies except for one retrospective cohort that revealed worse anatomic outcomes in the SSHP group that were no longer significant after adjusting for baseline differences.(223) Combined analysis of data from Table 8 revealed similar high anatomic success (89%) and a low reoperation rate (4.5% vs 3.8%) for SSHP and hysterectomy.

2.4. Uterosacral Hysteropexy

Uterosacral hysteropexy (USHP) involves shortening or plicating the uterosacral ligaments ipsilaterally or in the midline with permanent or absorbable sutures placed vaginally, abdominally or laparoscopically. There are no RCTs comparing USHP to hysterectomy. A prospective cohort study comparing laparoscopic USHP (n=28) to total laparoscopic hysterectomy (TLH) with USLS (n=27) found similar anatomic success (79% vs. 78%).(224) A retrospective cohort study comparing laparoscopic USHP (n=25) to age-matched vaginal hysterectomy prolapse repair (n=25) reported better symptomatic (92% vs. 80%) cure with fewer reoperations for recurrent prolapse (0 vs 3) following laparoscopic USHP.(225) Another retrospective cohort found lower anatomic success (47% vs. 63%) and more reoperations for recurrent prolapse (28% vs. 21%) after laparoscopic USHP (n=104) compared to laparoscopic hysterectomy with USLS (n=160).(226) A more recent retrospective cohort reported similar anatomic (94% vs. 85%) and composite cure rates (98% vs. 96%) with no reoperations for recurrent prolapse after laparoscopic USHP (n=48) compared to vaginal hysterectomy with USLS (n-103).(227) (Haj-Yahya 2020) A retrospective cohort comparing vaginal USHP (n=100) to vaginal hysterectomy with USLS (n=100) reported similar outcomes with good apical (96% vs. 97%), anterior (87% vs. 94%) and posterior (98% vs. 100%) support.(198) A more recent retrospective cohort comparing vaginal USHP (n=52) to vaginal hysterectomy and USLS (n=52) age and prolapse severity matched controls found similar anatomic (73% vs. 75%) and symptomatic (81% vs 90%) cure and satisfaction using the patient global impression of improvement (1.7 vs 1.4).(228) However, there were more apical recurrences (21% vs 2%, p=0.002) and reoperations (13% vs 2%, p=0.04) in the USHP group due to cervical elongation despite the fact that 15% had concomitant partial trachelectomy. Complications were rare for all of the studies with only 2 ureteric obstructions identified for over 700 USLS. Combined analysis from Table 9 revealed a non-significant tendency to a lower anatomic success rate -6.1% (-12.7%, 0.2%) p=0.06 and higher reoperation rate 4.7% (-0.8%, 10.2%) p=0.09 for USHP compared to USLS with hysterectomy. Overall success rates and reoperation rates are extremely variable among the six studies.

3. MESH HYSTEROPEXY PROCEDURES

There are two main types of mesh hysteropexy procedures, SSHP with graft previously referred to as vaginal mesh hysteropexy and sacrohysteropexy (SHP) done abdominally or laparoscopically. Technique, graft type and configuration varies considerably for each of these procedures. The use of vaginal mesh repairs with mesh kits was on the rapid decline following the US Food and Drug Administration (FDA) safety communications in 2008 and 2011 resulting in reclassification from class II, moderate-risk devices, to class III, high-risk devices in 2016. In November and December of 2017, Australia and New Zealand banned the use of transvaginal mesh for prolapse surgery. In July 2018, the United Kingdom halted sales of transvaginal mesh until a registry was developed to track complications when performed by properly trained surgeons. On April 16, 2019, the US FDA banned commercial transvaginal mesh kits for prolapse stating that the risks outweigh the potential benefits. Based on the current situation, the SSHP section with graft contains previous ICI findings and recommendations plus provides an update on the recent results of a large RCT. On the other hand, laparoscopic sacrohysteropexy (SHP) has been gaining popularity as a minimally invasive approach to uterine conservation with the potential for increased durability, though long-term data is lacking for this procedure. While transabdominal mesh use for prolapse has not been banned, the class action lawsuits and advertisements have fuelled patients' fears about mesh use in reconstructive pelvic surgery resulting in a further shift toward native tissue prolapse repairs.

3.1. Sacrospinous Hysteropexy with Graft

SSHP with graft is performed with vaginal placement of mesh into the anterior wall with uterine conservation. In order to be a hysteropexy procedure, a concomitant apical support procedure must be performed such as a SSLF or USLS. Level 1 evidence demonstrates improved anterior wall support with the addition of vaginally mesh.(229) Thus, the addition of anterior mesh has the potential to decrease rates of anterior recurrences seen with other hysteropexy repairs. Early anterior mesh kits did not include apical support unless a concomitant posterior mesh kit with apical support was inserted or a separate apical support procedure was performed. These products were replaced by trocarless anterior mesh kits that are anchored into the sacrospinous ligament via an anterior approach. Notably, all of the first and second generation anterior and posterior mesh kits are no longer commercially available.

The only multicentre RCT conducted by the Pelvic Floor Disorders Network compared SSHP with anterior graft (n=88) using Uphold to vaginal hysterectomy with USLS (n=87) at and at 5 years there were fewer failures for the hysteropexy and permanent mesh group than hysterectomy group (adjusted hazard ratio, 0.58; 0.36-0.94; P 0.03), with failure rates of 37% vs 54%, respectively. With the exception of the Urogenital Distress Inventory, no group differences were demonstrated in patient reported pelvic floor symptoms, prolapse symptoms, bowel function symptoms, general quality of life, body image, or pelvic pain.(230) Mesh exposures occurred in 8% of hysteropexy (all related to prolapse mesh, no sling exposures) and 5% of hysterectomy (all from slings). There was more granulation tissue and suture exposures observed with hysterectomy (1% vs 11% and 3% vs 21% respectively) although none of the mesh exposures, suture exposures or granulation tissue required reoperation.

A single prospective cohort study compared SSHP with mesh (n=66) to vaginal hysterectomy with vaginal mesh repair (n=30) using Uphold and revealed high anatomic success with only 1 mesh exposure at 6 months follow-up.(231) Three retrospective cohort studies compared SSHP with mesh graft to vaginal hysterectomy with vaginal mesh repair using Perigee/Apogee (American Medical Systems, Minnetonka, MN, USA), Total Prolift (Ethicon, Somerville, NJ, USA) and Posterior Intravaginal Slingplasty (Tyco Healthcare, Norwalk, CT, USA).(197,232,233) Combined analysis from Table 10 showed no difference in anatomic support (96% vs. 97%, p = 0.5), but more mesh exposures in the hysterectomy group (5% vs. 11%, p = 0.02). These findings are consistent with an early Prolift study that reported a 5-fold increased odds of mesh exposure with concomitant hysterectomy.(234) Thus, there may be a benefit for uterine conservation at the time of vaginal mesh repair for uterovaginal prolapse to decrease mesh exposure risks. The only study that included reoperations for prolapse found more reoperations (5% vs. 0) in the hysteropexy group when using total Prolift.(233) Currently all of the devices used in Table 10 are no longer commercially available and no comparative data exists for surgeons that fashion their own vaginal mesh implants.

4. SACROHYSTEROPEXY

Sacrohysteropexy (SHP) typically involves the attachment of at least one graft from the cervix and uterus to the anterior longitudinal ligament near the sacral promontory. This is an abdominal procedure that can be performed via an open, laparoscopic or robotic approach. A variety of graft materials, configurations and operative techniques have been described. The most common technique involves a single polypropylene mesh strap extending posteriorly from the sacrum to the uterus. The graft then bifurcates and the two smaller arms are passed through windows in the broad ligament and secured to the anterior cervix. The length of graft extension down the anterior and posterior vaginal walls as well as the use of a second mesh strap varies and may explain differences in anterior wall recurrences and development of cervical elongation. Some studies use a single anterior graft attached to the proximal anterior vaginal wall similar to sacral colpopexy (SCP). The graft bifurcates and the arms are passed through windows in the broad ligament and anchored into a posterior graft if present or directly into the anterior longitudinal ligament. The majority of studies compare SHP to total hysterectomy with SCP or supracervical hysterectomy with sacrocervicopexy (SCerP) plus a few studies using native tissue controls.

One RCT comparing abdominal SHP (n=41) to vaginal hysterectomy with USLS (n=41) found similar subjective and anatomic outcomes. However, the hysteropexy subjects underwent more planned or performed reoperations (22% vs. 2%).(235) Similarly to this, a pilot RCT comparing laparoscopic SHP (n=40) to vaginal hysterectomy with USLS (n=39) demonstrated that while apical support and total vaginal length were superior in the laparoscopic SHP group, 21% of the hysteropexy group required additional anterior colporrhaphy compared to none in the vaginal hysterectomy group.(236) The laparoscopic approach had a longer operating time however blood loss, admission and recovery time were reduced compared to the vaginal hysterectomy group. A prospective cohort comparing laparoscopic SHP (n=44) to vaginal hysterectomy with midline plication USLS (81) discovered similar subjective outcomes, sexual function and rates of reoperation or pessary use at two years. (237) Similarly, another recent retrospective cohort comparing laparoscopic SHP (n=46) to vaginal hysterectomy with midline plication USLS (n=86) revealed no significant differences in symptomatic prolapse recurrence, satisfaction and reoperation.(238)

A retrospective cohort compared abdominal SHP (n=35) to abdominal hysterectomy with SCP (n=63) or USLS (n=70).(239) In this cohort, SHP had superior anatomic success (100% vs. 74%) over abdominal hysterectomy and USLS. For the combined native tissue comparisons in Table 11, SHP had similar anatomic success (80% vs. 69%, p = 0.09) and reoperation rate (13% vs. 9%).

**includes 2 subjects with symptomatic prolapse using pessary*

There are no RCTs comparing SHP to hysterectomy and SCP. Meta-analysis from nine comparative studies evaluating 815 women found a lower anatomic success rate -6.3% (-12, -1%) p=0.01 and higher reoperation rate 5.4%(2%,9%) p=0.001 after SHP as compared to SCP and hysterectomy although the hysterectomy group were associated with significantly greater risk of mesh exposure 7% (3, 11%) p<0.001

Supracervical hysterectomy and sacrocervicopexy (SCerP) was introduced to obtain benefits of SCP and hysterectomy without the risk of mesh exposure.

A recent retrospective cohort study compared one-year outcomes for laparoscopic SHP (n=38) to laparoscopic supracervical hysterectomy (LSH) and SCerP (n=195) or total laparoscopic hysterectomy (TLH) and SCP (n=38).(240) There were no apical failures and more anterior recurrences (stage 2) in the SHP group (21% vs 8%, p = 0.02). Mesh complications were similar between groups (2.6% vs 1.3%, p = 0.46). We contacted the authors to obtain a breakdown of the outcomes for each of the three separate arms (see Table 6) and there were no differences in anatomic success or mesh related complications when comparisons were done among the three groups. Another retrospective cohort study comparing robotic assisted LSH with SCerP (n=43) and TLH with SCP (n=40) found more recurrent anatomic prolapse (≥ stage II) (41.9 % vs 20.0 %, p = 0.03; OR 2.8, 95 % CI, 1.07-7.7) and a tendency to greater prolapse beyond the hymen (18.6% vs. 12.5%, p=0.45) and symptomatic recurrence (18.6 % vs 10.3 %, $p = 0.29$) that did not reach statistical significance in the group that underwent LSH and SCerP. The composite success rate (67.4% vs. 75%, p=0.45) were not significantly different and mesh exposures were more common with total hysterectomy (2.3% vs. 7.5%, p=0.35).(241) The anatomic and symptomatic outcomes between LSH SCerP and TLH SCP need to be further investigated with larger prospective studies. This will help surgical planning and informed consent when considering the balance between anatomic and symptomatic success compared to mesh related complications.

† reoperation prolapse or pessary use

4.1. Laparoscopic Sacrohysteropexy vs. Sacrospinous Hysteropexy with Graft

A recent prospective multicentre cohort study compared laparoscopic SHP using anterior and posterior mesh straps (n=64) to SSHP with graft using Uphold (n=61).(242) There was no difference at 1 year in composite cure (72% vs. 74%, p=0.27) using validated outcome measurements/POP-Q. Composite cure was defined as no prolapse beyond the hymen, apex above the mid vagina, no symptoms and no reoperation or pessary use. There were only 2 reoperations for recurrent prolapse, both in the vaginal group. Mesh exposure rates were 2.7% for laparoscopic and 6.6% for vaginal hysteropexy. Satisfaction was 95% for both groups and symptoms resolved in 90-95%.

4.2. Laparoscopic vs. Open Sacrohysteropexy

A retrospective cohort compared laparoscopic (n=54) and open (n=57) SHP repairs.(243) Aside from longer operative time and blood loss with open abdominal surgery, there were no differences in satisfaction (94% vs. 91%), anatomic success (POP-Q < stage 3: 96% vs. 98%), reoperation (4% vs. 2%) and mesh exposure (0 vs. 5%).

4.3. Sacrospinous Hysteropexy with Mesh vs. Dermal Graft

An ambidirectional cohort comparing SSHP with mesh (Uphold) (n=247) to human dermal graft (n=45) found improved anatomic support and lower anatomic failure rates at 1 year (hymen – 3% vs. 9%, p=0.007; stage 2 – 18% vs. 29%, p=0.03) with the mesh augmented repairs.(244) Mesh exposures occurred in 6% of mesh augmented repairs with 2% requiring surgical excision and there were no exposures in the dermal group.

4.4. Laparoscopic Uterosacral Hysteropexy vs. Sacrohysteropexy

A retrospective cohort study with cross- sectional survey comparing laparoscopic USHP (n=55) to laparoscopic SHP (n=42) discovered more bulge symptoms and/or retreatment with a pessary or surgery at 6 months after SHP (36% vs 13%, p=0.007).(245) However, after controlling for baseline differences including older age, menopausal status and worse prolapse in the SHP group, the results were no longer statistically significant.

4.5. Laparoscopic Sacrohysteropexy vs. Sacrospinous Hysteropexy

A multicentre non-inferiority RCT (LAVA-trial) is underway in the Netherlands comparing laparoscopic SHP with vaginal SSHP. A methods paper has been published for this trial.(246) They will include women with stage 2 or higher uterine descent. Success is defined as a composite outcome with the cervix above the mid-vagina (C < -TVL/2), no bulge symptoms and no retreatment at 1 and 5 years. They plan to enrol an estimated sample size of 124 subjects.

4.6. Different Hysteropexy Procedures vs. Hysterectomy Using Database/Registry

A recent large retrospective cohort study using the California Office of Statewide Health Planning and Development database for women undergoing reconstructive prolapse repairs or uterovaginal prolapse compared reoperation rates without hysterectomy (n=51,491) and with hysterectomy (n=42,340).(247) There were many baseline differences between the two groups and mesh was more commonly implanted in the no hysterectomy group (17.6% vs. 9.6%). Reoperation rate for prolapse was lower in the hysterectomy group (3% vs. 4.4%, RR 0.67, p<0.001) and this difference persisted after multivariate modelling. Furthermore in those undergoing apical suspensions only (hysterectomy 21,487 and hysteropexy 18,839), hysterectomy was protective for recurrent prolapse in the apical (1.9 versus 3.3% p<0.001), anterior (1.3% versus 2.2% p <0.001) , posterior (1.3% versus 2.2% p<0.001) or more than one compartment (1.1% versus 1.9% p<0.001) when compared to hysteropexy. Perioperative complications were more common with hysterectomy including transfusion (2.5% vs 1.5%), infection or sepsis (0.9% vs. 0.4%), readmission for infection (0.7% vs 0.3%) and urologic injury or fistula (0.9% vs. 0.6%).

Another recently published retrospective population-based cohort study identified a total of 310,938 French patients that underwent surgical procedures for prolapse (primary, recurrent and vault) from 2008 to 2014.(248) Reoperation for recurrent prolapse represented 4.4% of the sample. Procedures performed included anterior and/or posterior repair, SSLF, LeFort colpocleisis, laparoscopic or open SCP (with or without hysterectomy), and laparoscopic or open rectopexy. The authors were unable to differentiate vaginal mesh and non-mesh interventions. The route of POP surgery was vaginal 55%, abdominal 36%, combined 4% and transanal in 4%. Hysterectomy was performed in approximately 50% of vaginal cases but only 12.5% of abdominal interventions. Unfortunately, we are unable to differentiate between the non-hysterectomy group that includes those with post hysterectomy prolapse or uterine preserving interventions. However, despite these limitations and after multiple regression analysis, concomitant hysterectomy (aHR 0.51 [0.49-0.53]) and the abdominal approach (aHR 0.62 [0.59-0.65]) at the first surgery was associated with a significantly lower risk of reoperation for recurrence.

Another recent large cohort study compared Manchester procedure (n=2,786), vaginal hysterectomy (n=4,045) and SSHP (n=416) for apical prolapse using the Danish National Patient Registry from 2010 to 2016.(249) The surgical procedures evaluated and the lower rate of hysteropexy compared to hysterectomy (1/10) in the Danish trial speaks to the uniqueness of the Danish data set compared to the Californian and French database evaluations. There were many baseline differences between the three groups including the vaginal hysterectomy group being older and having greater stage 3 and 4 apical and posterior compartment prolapse pre-intervention compared to Manchester procedure. SSHP had higher risk of reoperation compared to Manchester (aHR 5.0) and vaginal hysterectomy (aHR 3.3) with greater risks of reoperations in the apical compartment (aHR 40.2 and 8.5 respectively). Vaginal hysterectomy had slightly increased risk of reoperation compared to Manchester (aHR 1.5) that was worse in the apical compartment (aHR 4.2). Five-year reoperations rates were highest with SSHP (30%) followed by vaginal hysterectomy (11%) and Manchester (7%). It is unclear what type of apical support procedure was performed at the time of vaginal hysterectomy.

These three large database studies confirm the general tendency to poorer outcomes associated with hysteropexy interventions demonstrated above from level I and II evidence. The Danish data also suggests that Manchester has advantages over vaginal hysterectomy and SSHP but there is the potential for large selection bias with many potential confounders and limitations in this study.

A multicentre non-inferiority RCT (SAM study) is underway in the Netherlands comparing modified Manchester procedure with SSHP for primary uterovaginal prolapse that will address many of these unanswered questions.(217) Women with symptomatic prolapse of any stage are included if the uterine descent and POP-Q point D is less than or equal to minus 1cm. Thus, they are evaluating treatment for milder cases of uterine prolapse due to the belief that the Manchester procedure is not appropriate for more severe prolapse. Success is defined as a composite outcome with no prolapse be-

yond the hymen, no bulge symptoms and no retreatment at 2 years. They plan to enrol an estimated sample size of 424 subjects.

5. HYSTERECTOMY RISKS

Most providers recognise that hysterectomy is a relatively safe procedure with low risks of severe morbidity. The most common injuries that occur during pelvic reconstructive surgery involve the urinary tract system. These injuries are often preventable or recognised with routine cystoscopy and repaired prior to leaving the operating room. Most hysterectomies performed for prolapse involve small uteri, especially in postmenopausal women, leading to short operative times for this portion of the procedure. If we assume similar success with hysteropexy and hysterectomy, risks of hysteropexy and subsequent hysterectomy, which may be more challenging, must be weighed against concomitant hysterectomy risks. This section reviews some of the risks that may be encountered when hysterectomy is performed at the time of uterovaginal prolapse repair.

5.1. Premature ovarian failure

Performance of a hysterectomy alone or at the time of prolapse repair (native tissue or mesh) may have a negative impact on ovarian function among premenopausal women. Two large prospective cohort studies showed an increased risk of earlier onset of menopause in women undergoing hysterectomy compared to nonsurgical controls, even with conservation of both ovaries.(250,251) There was an approximately 2-fold increased risk of undergoing menopausal over a 5-year time period with hysterectomy alone. The risk increased to almost 3-fold with removal of one ovary.(251) While this may not be a major factor in peri- and postmenopausal women, it must be considered during surgical planning for premenopausal women.

5.2. Mesh exposure

Total hysterectomy at the time of SCP has been shown to increase mesh exposure rates when compared to SHP or supracervical hysterectomy with SCerP. In Tables 10 and 11, mesh exposure risks were 6% versus 14% for vaginal mesh repairs and 1% versus 8% for SCP. Even with cessation of vaginal mesh repair and the trend toward primary native tissue prolapse repairs, laparoscopic SCP with or without robotic assistance still may have a role in the primary treatment of uterovaginal prolapse. This is based on the assumption that minimally invasive SCP will provide better anatomic support with more durable outcomes. However, evidence favouring SCP as the best prolapse repair is largely founded on studies involving surgical management of post-hysterectomy vault prolapse. Many providers have extrapolated these results to primary uterovaginal prolapse despite a lack of good quality data and consensus. Additionally, with the increased popularity of uterine conservation during primary native tissue prolapse repair, specialists will be faced with the dilemma of what to do with the uterus at the time of minimally invasive SCP for recurrent uterovaginal prolapse. In a review of over 125,000 robotic or laparoscopic SCP in the US between 2009 and 2011, nearly 50% of cases involved concomitant hysterectomy.(252) Thus, to further evaluate the data on SCP and uterine prolapse, we compared mesh exposure rates for studies describing results with no hysterectomy (post-hysterectomy or hysteropexy), total hysterectomy with SCP and supracervical hysterectomy with SCerP.(Table 13) Procedures were further subdivided into open and laparoscopic. Mesh exposure rates were 3.5-fold higher ($p < 0.0001$) after a SCP with concomitant total hysterectomy (7.3%) compared to no hysterectomy (2.1%). The differences in mesh exposure rates between SCP with hysterectomy versus no hysterectomy were greater for open procedures (9.8% vs 2.3%, $p < 0.0001$) compared to laparoscopic repairs (5.9% to 2.0%, $p < 0.0001$). Many of the open repairs use grafts other than polypropylene, such as polytetrafluoroethylene (Teflon) and polyethylene (Mersilene, some Marlex), which have been shown to increase risk of mesh exposure.(253) The rate of mesh exposure was significantly lower with SCerP and supracervical hysterectomy (0.6%).

If hysterectomy was considered at the time of SCP, techniques for graft attachment to the vaginal may also play a role. Three studies included in Table 8 contain subjects that underwent total vaginal hysterectomy or laparoscopic assisted vaginal hysterectomy with vaginal attachment of the mesh at SCP.(254-256) Two of these studies reveal a 2 to 4-fold decreased rate of mesh exposure (14% vs. 32% and 3% vs. 14%) with vaginal attachment of mesh compared to laparoscopic attachment of the vaginal portion of the mesh with concomitant total hysterectomy during laparoscopic SCP.(256-258) A third study showed a low rate of mesh exposure (1.6% vs. 1.7%) comparing total vaginal hysterectomy with vaginal attachment to laparoscopic supracervical hysterectomy (LSH) at the time of laparoscopic SCerP.(257) Alternatively, Visco et al evaluated mesh erosions after sacrocolpoperineopexy and demonstrated that when sutures (HR 5.4 95% CI 1.6-18) or mesh HR19.7 95% CI 4-101) was placed vaginally the risk of mesh erosions increased significantly when compared to traditional SCP.(259)

One potential explanation for the decreased rate of mesh exposure with vaginal compared to laparoscopic attachment of mesh when hysterectomy and SCP are conducted concomitantly is less vaginal cuff manipulation and disruption during the laparoscopic portion of the case. More long-term prospective data is needed to determine the role of hysterectomy at time of SCP.

5.3. Spread of unanticipated malignancy

There is insufficient data to compare laparoscopic SHP and LSH with SCerP. Cervical conservation appears to decrease mesh exposure risk when hysterectomy is performed with SCP (Table 13). A common concern with LSH involves the spread of unanticipated pathology associated with electronic power morcellation. On April 17, 2014, The U.S. FDA issued a safety communication discouraging the use of laparoscopic uterine power morcellation in hysterectomy and myomectomy for the treatment of uterine fibroids due to the "risk of spreading unsuspected cancerous tissue, notably uterine sarcomas beyond the uterus".(273) The FDA later issued an updated guidance communication November 24, 2014 recommending that manufacturers of power morcellators include a boxed warning with product labelling safety statements. This included the following contraindications: 1) removal of suspected fibroids in peri- or post-menopausal patients and 2) gynaecologic surgery with tissue known or suspected of malignancy. This prompted many manufacturers to withdraw their products from the market for fear of litigation. Many hospitals placed an immediate ban on laparoscopic power morcellation, while a smaller number of institutions crafted policies to permit usage under strict guidelines.

In women with fibroids, the risk of undiagnosed leiomyosarcoma is between 1:495 to 1:1100 according to the FDA. The prognosis is poor with this condition, and intraperitoneal spread of tissue may worsen the prognosis. This risk is presumably much lower in women without fibroids. Since the majority of women undergoing prolapse surgery do not have fibroids, the American Urogynecologic

Society (AUGS) issued the following comments in a position statement in July 2014 that was updated in December 2018.(274) "After appropriate preoperative evaluation, supracervical hysterectomy facilitated by power morcellation during mesh SCP is a reasonable procedure. Shared decision making between a patient and her surgeon to perform power morcellation during supracervical hysterectomy for a minimally invasive mesh sacrocolpopexy should include the risks and benefits during the informed consent process." On February 25, 2020, the FDA issued a Draft Guidance: Product Labelling for Laparoscopic Power Morcellators.(275) One of the new labelling recommendations includes: "Laparoscopic power morcellators should only be used with a containment system. The containment system should be compatible with the laparoscopic power morcellator."

So, what is the true risk of unanticipated pathology and cancer in a population undergoing prolapse surgery? Table 14 includes data from several studies reporting the rate of unanticipated pathology and malignancy at the time of hysterectomy for prolapse repair. The studies were retrospective and evaluated low risk patients excluding cases involving preoperative symptoms of postmenopausal bleeding or abnormal findings on screening. The overall rates were low with only 1.5% unanticipated pathology, the majority of which were endometrial hyperplasia, and 0.3% of endometrial cancer. There were no cases of sarcoma identified during prolapse surgery. Consequently, for low-risk women, it is reasonable to perform laparoscopic power morcellation during prolapse repair after obtaining adequate informed consent. However, the recent FDA product labelling now mandates contained morcellation, which may result in increased usage of either mini-laparotomy or extracorporeal scalpel morcellation with a bag for containment through the expanded umbilical incision. Both of these options potentially increase the risk of wound complications, hernia formation and postoperative pain.

Conclusion

There are numerous options for primary treatment of uterovaginal prolapse. The following are evidence-based guidelines regarding uterine preservation.

- Hysteropexy is reasonable in women undergoing surgery for uterovaginal prolapse without contraindications to uterine preservation. However long-term data are limited and the need for subsequent hysterectomy unknown (GoR C).
- When considering relative contra-indications to uterine preservation, opportunistic salpingectomy which is not able to be performed at vaginal hysteropexy should be included in the shared decision-making process (GoR C).
- Large database studies demonstrated lower reoperation rates for recurrent prolapse and slightly higher complication rates in the hysterectomy group compared to hysteropexy (GoR C).
- Consistent Level one and two evidence reveal no differences in outcomes comparing sacrospinous hysteropexy to vaginal hysterectomy with native tissue prolapse repair with the exception of a single smaller RCT showing a higher risk of apical recurrence for patients with advanced prolapse undergoing hysteropexy (GoR B).
- Partial Colpocleisis is preferred over vaginal hysterectomy and total colpocleisis when there is no specific indication for hysterectomy and no interest in preserving coital function (GoR C).
- The role of the Manchester procedure for treatment of mild uterovaginal prolapse with or without cervical elongation has yet to be determined based on limited, poor Level two and three evidence (GoR D).
- The data are not supportive of transvaginal mesh and hysterectomy for uterine prolapse. Consistent Level two evidence shows no difference in anatomic success comparing sacrospinous hysteropexy with mesh graft to hysterectomy with graft; and, the mesh exposure rate was significantly higher after hysterectomy than hysteropexy (11% vs. 5%) (GoR C).
- Sacrohysteropexy (SHP) has a similar success rate and reoperation for prolapse when compared to vaginal hysterectomy and USLS, however lower success rates than sacrocolpopexy with total or supracervical hysterectomy (GoR C).

- Sacrocolpopexy with total hysterectomy is not recommended due to 3-5 fold higher mesh exposure rate (GoR C).
- In a single small study sacrocolpopexy with supracervical hysterectomy had a lower anatomic success rate than sacrocolpopexy with total hysterectomy (GoR D)
- Level three evidence reveals low rates of unanticipated pathology (1.5%) and endometrial cancer (0.3%) with no cases of sarcoma identified during hysterectomy in women with low risk of malignancy and dysplasia undergoing prolapse surgery. (GoR C)

V. APICAL PROLAPSE SURGERY

While anterior vaginal prolapse is most common, loss of apical support is usually present in women with prolapse that extends beyond the hymen.(284,285) There is growing recognition that adequate support for the vaginal apex is an essential component of a durable surgical repair for women with advanced prolapse.(286-288) There is a strong correlation between anterior vaginal prolapse and apical descent seen on anatomical studies.(289,290) While recognition of apical defects is one of the biggest challenges in the preoperative evaluation of pelvic support defects, surgical correction of the apex has several good options with relatively high success rates. Apical suspension procedures can broadly be separated into those performed transvaginally and those performed abdominally. Abdominal procedures, predominantly sacrocolpopexy, can be performed via laparotomy or using conventional laparoscopic or robotically assisted-laparoscopic techniques. Although precise estimates are not available, most studies suggest that the vaginal approach is most common with 80-90% of procedures being performed through this route.(1,31,33,77)[FDA] Transvaginal apical suspension procedures include both non-mesh (native tissue) procedures and mesh repairs. The individual woman's surgical history and goals, as well as her individual risks for surgical complications, prolapse recurrence and de novo symptoms affect surgical planning and choice of procedure for apical POP.

1. SACROSPINOUS LIGAMENT FIXATION (SSLF)

One of the most popular and widely reported native tissue transvaginal procedures for correcting apical prolapse is the SSLF. First described in 1958,(291) this procedure suspends the vaginal apex to the sacrospinous ligament either unilaterally or bilaterally, typically using an extraperitoneal approach. Observational series and clinical trials suggest that while apical recurrence after SSLF is uncommon (0.6% to 19%), recurrence of anterior vaginal prolapse is more problematic (3.7% to 28.5%) (Table 15). A meta-analysis by Morgan et al found an overall failure rate at any site of 28.8% (95% CI 18.4%-36.3%) with failure of the anterior segment seen in 21.3% (17-3-25.3%), apical segment of 7.2% (95% CI 4.0 – 10.4%) and posterior segment of 6.3% (95%CI 4.2-8.4%). Whether the relatively high rate of anterior vaginal prolapse recurrence seen with SSLS is due to the posterior deflection of the vaginal axis, as many authors suggest (78,94,292,293), or simply represents a general predilection of anterior support to fail after pelvic reconstructive surgery remains unknown.(294) The Pelvic Floor Disorders Network (PFDN) reported prospective longitudinal follow-up thru 5 years with strict composite criteria and "once a failure, always a failure" methodology.(295) Surgical failure rates (including symptoms and retreatment) reached 71.2% with a 59.7% anatomic failure rate, suggesting continued anatomic deterioration of this surgery over time, but low reoperation rates (4.6%) and high patient satisfaction rates. Reoperation rates after SSLF range from 1.3% to 37%, with all but three of the 30 series reporting rates less than 10%.

Maher et al demonstrated significant improvements in condition-specific and generic QOL after SSLF, similar to that after abdominal sacrocolpopexy.(95) A meta-analysis of randomised and observational studies found a pooled average for failure to provide relief of prolapse symptoms after SSLF of 10.3% (95% CI 4.4-16.2%).(296) The pooled average for failure to provide patient satisfaction after SSLF in this analysis was 13% (95% CI 7.4%-18.6%).(296) Although infrequent, serious complications associated with SSLF include buttock pain and sacral/pudendal neurovascular injury. Unilateral buttock/gluteal pain occurs in 3-15% of patients and typically resolves within 6 weeks after surgery.(142,297) In one multi-centre trial, neurological pain requiring medical or surgical intervention occurred in 12.4% immediately after SSLF and persisted in 4.3% at 4-6 weeks after surgery.(297) In a review of 22 studies that included 1229 SSLF procedures, three patients (0.2%) had life-threatening haemorrhage from sacral or pudendal vascular injury and the overall transfusion rate was 2%.(298)

2. IPSILATERAL UTEROSACRAL LIGAMENT SUSPENSION (USLS)

The USLS was first described by Miller (299) in 1927 and later popularised by Shull in the late 1990s. The USLS suspends the vaginal apex to the proximal remnants of the uterosacral ligaments using an intraperitoneal surgical approach. This procedure restores the vagina to a near normal axis, avoiding the more retroflexion associated with SSLF. The current evidence supporting the use of USLS is mostly retrospective case-series but now includes two recent RCT's by the Pelvic Floor Disorders Network (PFDN) (295, 300) In the OPTIMAL RCT of SSLF compared to USLS there was no significant difference in the rate of surgical failure at 5 years between the two procedures. In the SUPeR RCT comparing vaginal hysterectomy and USLS with a sacrospinous hysteropexy with graft, there was no statistically significant difference at 3 years,(136) but by 5 years the USLS was inferior.(230) In reviewing 36 studies with 5354 patients the mean anatomic success rate is 80% (range 46-96%) with a mean reoperation rate for prolapse of 5.7% (range 0-35 %) (Table 15a). Consistent with other prolapse surgeries, most failures are in the anterior segment. A meta-analysis performed by Margulies et al found pooled rates of anatomical success (POP-Q Stage 0-1) of 81.2% (95%CI 67.5-94.5%) for the anterior segment, 98.3% (95% CI 95.7-100%) for the apical segment and 87.4% (95% CI, 67.5%-94.5%) for the posterior segment.(301) Post-operative prolapse symptoms were reported in 5 of 11 studies in this review and were relieved in 82-100% of patients. These promising results are balanced against ureteric kinking/injury rate of 1%-11% with this procedure.(301) A review of 700 consecutive vaginal prolapse

surgeries found intraoperative ureteric kinking/injury rate of 5% directly attributable to USLS, however, 87% were identified at cystoscopy before the completion of the index surgery and corrected by removing suspension sutures intraoperatively with no long-term consequence to the patient.(302) Only three of 355 USLS (0.9%) performed in this series required additional procedures to relieve or correct ureteric obstruction or injury. A retrospective review of over 900 patients receiving USLS found an overall adverse event rate of 31.2% with 20.3% being attributed to peri-operative urinary tract infection.(303) Rates of pulmonary and cardiac events were 2.3% whereas the rate of ileus and small bowel obstruction were less than 0.5%. The intraoperative bladder injury rate was 1%. There were no intraoperative ureteric injuries; however, 4.5% of cases were complicated by ureteric kinking, all of which were resolved without subsequent sequelae with intraoperative suture removal with or without replacement of the vault suspension stitches. (303) Margulies et al identified 10 studies including a total of 820 women that reported on perioperative complications of USLS.(301) The ureteric reimplantation rate in this series was only 0.6%. Blood transfusions were reported in 1.3%, cystotomy in 0.1%, and bowel injury in 0.2%.

Abdominal and laparoscopic ipsilateral USLS techniques have also been described. Lowenstein et al reported a retrospective review of 107 women who underwent prolapse surgery that included an abdominal USLS.(304) In the 75 patients who completed one year follow-up, 12% reported recurrent or persistent prolapse symptoms and 7% had an anatomical failure (POP-Q stage 2 or greater). Complications were relatively few, however exposure of the apical sutures (expanded PTFT, Gore-Tex) occurred in 9% at an average time of 56 months (range 3-75 mo.).(304) In a retrospective comparative study, laparoscopic uterosacral suspension with uterine preservation had comparable anatomic outcomes to total vaginal hysterectomy with uterosacral ligament suspension.(227) Two retrospective comparisons between vaginal and laparoscopic USLS procedure found no significant differences in perioperative morbidity or anatomical or subjective outcomes.(305,306)

2.1. Sacrospinous Ligament Suspension versus Uterosacral Ligament Suspension

In 2014, the NICHD Pelvic Floor Disorders Network reported the results of the OPTIMAL trial whose primary objective was to compare the safety and efficacy of the SSLS to USLS in women with uterine or post hysterectomy apical prolapse.(297) To date, this is the only randomised trial to have compared these two commonly performed procedures. Success was defined as a composite outcome measurement and included the absence of: a) descent of the vaginal apex more than one third of the vaginal canal; b) anterior or posterior vaginal wall descent beyond the hymen, c) bothersome vaginal bulge symptoms as reported by the Pelvic Floor Distress Inventory and d) retreatment with surgery or a pessary. A total of 374 patients were randomised (188 USLS and 186 SSLF) from 9 U.S. centres. Two years after surgery, there was no statistical difference between the two groups for the composite outcome (USLS 64.5% vs SSLF 63.1%; adj. OR 1.1 95% CI 0.7 to 1.7). Additionally, bothersome vaginal bulge symptoms were seen in 18%, anterior or posterior prolapse beyond the hymen in 17.5% and retreatment with pessary or surgery 5.1% two years post-operatively with no differences between groups. Neurological pain requiring medical, behavioural or surgical intervention was higher in the SSLS group (12.4% vs 6.9%, p = 0.49) and persisted to 4-6 weeks in more participants (4.3% vs 0.5%). Intraoperative ureteric obstruction was noted in five patients (3.2%) in the USLS group and none in the SSLF. The long term (5 year) follow-up of this study showed steadily decreasing success rates of both procedures. At 5 years, using the same composite primary outcome the success rate was only 30% for SSLF and 38% for USLS (not statistically different).(295)

2.2. Midline plication USLS (Mayo/McCall's Culdoplasty)

Like the ipsilateral USLS, the midline plication USLS (commonly known as Mayo/McCall's culdoplasty) uses the proximal uterosacral ligaments to suspend the vaginal apex. The major difference is that with the midline plication USLS the uterosacral ligaments are plicated in the mid-line to obliterate the posterior cul-de-sac. While commonly performed, data describing the outcomes for this procedure are limited with almost no prospective studies (Table 16). Colombo and Milani retrospectively compared the outcomes of a modified-McCall's culdoplasty to the SSLS (n = 62 in each group). (292) Recurrence after the McCall's culdoplasty (Baden-Walker Grade $\geq$2) was 15% 4 to 9 years after surgery and not significantly different from the SSLS group. Recurrent anterior vaginal prolapse occurred less frequently in the McCall's group than the SSLS group (6% vs. 21%, p =.04; OR 4.1 (95% CI 1.3 to 14.2))(292) A large retrospective series of 693 women from the Mayo clinic described an 82% satisfaction rate on subjective follow-up with few complications.(307) The rate of subsequent prolapse repair in this population was 5.2%. A retrospective case series of 411 women undergoing Mayo culdoplasty found that a more dorsal "deep" placement of sutures through the uterosacral ligaments reduced the incidence of ureteric obstruction compared to other published series.(308) A retrospective long-term follow-up of 414 patients suggested that both the ipsilateral USLS and midline plication USLS had comparable effectiveness and safety. (309) Another retrospective review of 311 patients suggested that the midline plication USLS was as effective in advanced stage prolapse as in lesser degrees of prolapse.(310)

While the midline plication USLS is traditionally performed using an intraperitoneal approach, Dwyer and Fatton have described an extraperitoneal variant of the USLS.(311,312) In their series of 123 consecutive women undergoing an extraperitoneal USLS, 93 also received anterior and/or posterior synthetic mesh. The overall anatomical success (POP-Q stage 0 – 1) at a mean follow-up of 2 years (range 6 mo. – 5 years) was 85.5% with apical success of 95.4%. (312) The reoperation rate for recurrent prolapse was 7%. Urethral injury occurred in only 1.7%, however the blood transfusion rate was 4.9% and the rate of mesh exposure was 19.3%.

2.3. Levator Myorrhaphy

Francis and Jeffcoate described their retrospective series using levator myorrhaphy, in which a wide midline plication of the levator ani muscles is performed to which the vaginal cuff is fixed, in 1961.(313) A large sponge pack in the rectum is used to avoid over plication and bowel dysfunction. Five of 35 women responding to the questionnaire had transient ureteric complications, one requiring reoperation. Seventeen women were quite satisfied, while six were dissatisfied. Natale et al compared the levator myorrhaphy to the USLS in a randomised clinical trial of 229 women with stage 2-4 prolapse.(314) All women received a hysterectomy and all received placement of polypropylene mesh in the anterior vaginal segment. Anatomical success was not significantly different between groups. The mean total vaginal length was significantly shorter after levator myorrhaphy (7.9 cm vs. 8.9 cm, p = .04). Urinary, bowel and sexual function did not differ between groups post-operatively. Intraoperative ureteric obstruction was less common in the levator myorrhaphy group (0% vs. 7.9%); however all cases of ureteric obstruction in the USLS group were corrected intraoperatively with suture removal/replacement with no additional interventions required.(314) Other complications including mesh erosion were similar between groups.

2.4. Iliococcygeus Fixation

There are no randomised trials that support the use of this procedure. Several case series have provided some information. Shull reported that apical support was optimal in 39/42 (83%) of patients, but eight others had apical or other defects.(315) Meeks and colleagues reported a 96% objective cure in 110 women followed up to 13 years.(316) In a retrospective case-control study, Maher and colleagues reported similar subjective (91% vs 94%) and objective (53% vs 67%) cure rates with iliococcygeus fixation (n=50) compared to sacrospinous fixation (n=78).(317) A prospective cohort of 44 subjects receiving iliococcygeous fixation followed up for a median of 68.8 (range 60-92) months provides the longest-term data on this procedure.(318) Objective success (POP-Q stage 0 or 1) and subjective success (patient global impression of improvement < 2) were both 84%. Preoperative stage 4 vault prolapse was an independent predictor of failure (OR 8.8; 95% CI 1.3-9.4).(318)

3. SACROSPINOUS LIGAMENT FIXATION WITH GRAFT (TRANSVAGINAL MESH APICAL PROLAPSE)

Multiple commercially available transvaginal mesh devices have been marketed to correct apical prolapse, often designed to support both anterior and apical or anterior, apical and posterior vaginal segments. Table 16 summarises the results of 35 studies in 3270 patients. Early transvaginal mesh kits (Posterior Intravaginal Slingplasty (PIVS), Perigee, Apogee, and Prolift) used metal trocars to guide placement of mesh arms through the obturator foramen or the ischiorectal fossa. The PIVS was constructed of Type 3 multifilament polypropylene and because of mesh related complications this was removed from the market. The remaining studies in the table are Type 1 monofilament polypropylene meshes. Success rates of transvaginal meshes for apical prolapse from prospective and retrospective cohorts ranges from 61-100% for monofilament polypropylene meshes with mesh exposure rates vary from 0-17% (Table 16). Second generation device kits with typically lighter mesh loads and direct attachments to the Sacrospinous ligament (Uphold, Pinnacle, Boston Scientific, Elevate, AMS) demonstrate mesh exposure rates lower (0 to 8%) than those noted with older devices based on the limited data available.

The Cochrane Collaboration identified six randomised trials comparing native tissue vaginal repairs with transvaginal polypropylene mesh for apical prolapse in 589 women.(319) In all six of these trials, the native tissue repair included a SSLF or USLS and the mesh was polypropylene (Four trials monofilament weave (Prolift, Ethicon) and two trials multifilament weave). No significant differences in anatomical outcomes, vaginal bulge symptoms, repeat surgery for prolapse, dyspareunia or post-operative stress urinary incontinence were noted between groups. The average rate of mesh exposure after transvaginal mesh was 18% and surgery for mesh exposure was required in 9.5%. In that review. The Cochrane Collaboration authors concluded that the implication for clinical practice is that while the second generation newer mesh products may be as anatomically beneficial with a lower complication rate than their preceding mesh products this has not been rigorously evaluated and these products should be used cautiously until level one comparative data become available.(319) A summary of randomised trials comparing native tissue vaginal repair with monofilament mesh repair is in Table 17**.** In each study the SSLF with graft had a higher objective success rate, but mesh exposures were high (range 8.3- 42%) although they seemed to be lower (8%) with a second-generation mesh kit.(136) Since the 2011 FDA Public Health Notification on

surgical mesh for pelvic organ prolapse, many of these devices are no longer marketed and in 2019 all vaginal mesh kits were removed from the market in the U.S. by the FDA because at that time they did not conclusively show superiority over native tissue repairs. A more recent RCT comparing apical mesh and sacrospinous colpopexy for post-hysterectomy prolapse again demonstrated no significant advantage of the mesh intervention over the sacrospinous suspension .(320)

Table 17. Randomised Trials Comparing Native Tissue Apical Repair Versus Monofilament Polypropylene Transvaginal Mesh Apical Repair for Apical Prolapse

Author	Year	Group (N)	Mean Follow –up (Mos)	Objective Success rate (%)	Subjective Success rate (%)	Criteria for Objective (O) and Subjective (S) success*	Mesh exposure (%)	Comments

4. SACROCOLPOPEXY

Since its introduction by Lane in 1962, (321) sacrocolpopexy has proven to be an effective and durable technique for correcting apical prolapse. In 2010, approximately 34,000 sacrocolpopexy's were performed in the U.S. representing 11% of all prolapse surgeries performed during that time period.(139) Traditionally, sacrocolpopexy has been performed via a laparotomy (i.e. abdominal sacrocolpopexy, ASCP) but the use of minimally invasive approaches, both laparoscopic (LSCP) and robotic (RSCP), has become the norm over the last decade. The 2016 Cochrane review identified six randomised trials comparing sacrocolpopexy to vaginal prolapse repair including three trials comparing abdominal sacrocolpopexy (ASCP) to SSLF (94,95,322), one trial comparing ASCP to USLS, (323) one trial comparing laparoscopic sacrocolpopexy (LSCP) to transvaginal mesh repair (324) and one comparing abdominal or laparoscopic sacrocolpopexy to USLS with mesh augmentation. (319) On meta-analysis, they concluded that overall a broad group of vaginal surgery with and without mesh is associated with higher risk of awareness of prolapse (RR 2.11 95% CI 1.1-4.2), recurrent prolapse on examination (RR 1.9 95% CI 1.3-2.7), repeat surgery for prolapse (RR 2.3 95% CI 1.2- 4.3), post-operative SUI (RR 1.9 95% CI 1.2-2.9) and dyspareunia (RR 2.5 95% 1.2- 5.5) when compared broadly with sacrocolpopexy.(319) A systematic review by the Society of Gynecologic Surgeons Systematic Review Group that included both randomised trials and cohort studies comparing sacrocolpopexy with native tissue (non-mesh) vaginal repairs found improved anatomic outcomes with sacrocolpopexy and no difference in reoperation rates or post-operative sexual function.(325) Adverse event data compiled from 79 studies (RCT, cohort and case series) found sacrocolpopexy associated with a higher rate of ileus or small bowel obstruction (2.7% vs 0.2%, p<.01), mesh or suture complications (4.2% vs 0.4%, p <.01) and thromboembolic disease (0.6% vs 0.1%, p = .03).(325)

4.1. Abdominal sacrocolpopexy (ASCP)

Observational studies and clinical trials suggest that ASCP is a highly effective procedure for apical prolapse. The success rate of ASCP, when defined as lack of apical prolapse, ranges from 75-100% (Table 18). When success is defined as no recurrent prolapse in any segment the published success rates are 56-100%. A systematic review of ASCP performed by Nygaard et al reported a median reoperation rate for recurrent prolapse of 4.4% (range 0 -18.2%) and for post-operative stress incontinence of 4.9% (range 1.2 -30.9%) and a mesh erosion rate of 3.4%.(326) Subjects enrolled in the long-term follow-up (5-7 years) of the CARE trial (E-CARE), demonstrated objective failure rates of 24-48% depending upon the definition of failure and a cumulative mesh erosion probability rate of 10.5% by 7 years.(327) Clinical trials demonstrate significant improvements in prolapse symptoms, urinary function and quality of life after ASCP.(68,95) There is Level 1 evidence that ASCP has superior anatomical outcomes when compared to SSLF but this is balanced by longer operating time, longer recovery and higher cost.(229) A single RCT has compared ASCP (n=63) to USLS (n=61) and found ASCP associated with greater anatomical success, fewer reoperations, greater post-operative complications but no difference in improvement in symptoms or quality of life.(323)

Beyond mesh erosion, reported complications of ASCP are generally consistent with other major open pelvic surgeries. The systematic review by Nygaard et al reported that wound complications occurred in 4.6% (range 0.4% to 19.8%), haemorrhage or transfusion in 4.4% (.2% to 16.9%), cystotomy in 3.1% (0.4% to 15.8%), ureteral injury in 1.0% (0.8% to 1.9%), bowel injury in 1.6% (0.4% to 2.5%) and incisional hernia repair in 5% (0,4 to 11%).(326) 1 in 20 women in the CARE trial experienced significant gastrointestinal morbidity after sacrocolpopexy. Of 322 women in the study, 19 had symptoms of possible ileus or small bowel obstruction; of these, four had reoperation for small bowel obstruction, 11 were readmitted for medical management, and four had a prolonged initial hospitalisation for gastrointestinal symptoms.(328) In long-term review after the CARE trial the subjective success rate remained acceptable at 75% however the mesh exposure rate was 9.9%.(327) The high rate of mesh exposure maybe explained by specific surgical techniques employed including high rates of multifilament mesh, concomitant hysterectomy and permanent sutures all of which are associated with increased rates of mesh exposure.(329,330) Indeed, authors have reported mesh exposure rates of less than 3% at 5 years when monofilament macroporous mesh and absorbable sutures were utilised at sacrocolpopexy. (270,331)

4.2. Abdominal sacrocolpopexy (ASCP) versus sacrospinous ligament fixation (SSLF)

To date, there are three RCTs that directly compare ASCP to SSLF. (66,94,95,322) The 2013 Cochrane review on the surgical management of POP summarises these studies and concludes that these trials provide Level 1 evidence that there were no statistically significant differences in objective failure at any site (any pelvic organ prolapse RR 0.77, 95% CI 0.39 to 1.53), subjective failure (RR 0.53, 95% CI 0.25 to 1.09), reoperation for POP (RR 1.46, 95% CI 0.19 to 1.11) or patient satisfaction (RR 0.82, 95% CI 0.32 to 2.06).(229) However, ASCP was superior to SSLF for the following outcomes: Prolapse $\leq$ stage 2 (RR 0.29, 95% CI 0.09 to 0.97), recurrent vault prolapse (RR 0.23, 95% CI 0.07 to 0.77), post-operative stress urinary incontinence (RR 0.55, 95% CI 0.32 to 0.95) and less post-operative dyspareunia (RR 0.39, 95% CI 0.18 to 0.86). In contrast, ASCP was associated with a longer operating time (Weighted Mean Difference (WMD) 21 minutes, 95% CI 12 to 30), longer time to recover (WMD 8.3 days, 95% CI 3.9 to 12.7) and was more expensive (WMD US $1334, 95% CI 1027 to 1641) than SSLF.(229)

4.3. Laparoscopic Sacrocolpopexy (LSCP)

The laparoscopic approach of sacrocolpopexy has been adopted by many surgeons over the last decade as an alternative to ASCP with the hopes of reproducing the high success rate of the ASCP while decreasing the morbidity and delayed recovery associated with laparotomy. Table 18 summarises 45 prospective and retrospective case series of 5584 patients. The results show acceptable short to mid-term success rates with mean objective success rate of 93% (range 60 -100%), mean total reoperation rate of 7%, and a mean reoperation rate for recurrent prolapse of only 3%. Mesh exposure rates are only 2% and the risk of spondylodiscitis seems to be in the 1% range. Subjective success rates of 79-98% (332-334) have been reported. Prospective studies demonstrate significant improvements in pelvic symptoms and quality of life after LSC.(324,335,336) Most RCTs observed that laparoscopic sacrocolpopexy is as effective as open abdominal procedure, with a reduced rate of intraoperative bleeding, hospitalisation and wound complications.(337,338) However, a recent RCT showed that LSCP provides outcomes as good as those of open procedure for anatomical correction but not for anterior pelvic organ prolapse.(339) A retrospective study assessed the complication rates in 402 LSCP cases.(262) This study compared patients who received concurrent laparoscopically-assisted vaginal hysterectomy with those that had previous hysterectomy. They showed no differences in intra- or perioperative complications and similar rates of mesh erosion between the two groups.(262) Overall the complication rates for this cohort were 0.75% for hematoma, 2.2% for ileus or small bowel obstruction, 1.5% for bladder injury, 0.75% for bowel injury and 0.25% ureteric injury. At 1 year, the overall mesh erosion rate

was 1.2%. In contrast, Tan-Kim et al reported on a retrospective series of 188 minimally invasive sacrocolpopexy and found a significantly higher mesh exposure rate in those who received concurrent total vaginal hysterectomy (TVH) (23%) compared with those who were post-hysterectomy (5%) or received a supracervical hysterectomy (5%).(340) TVH was found to be an in independent risk factor for mesh erosion on multivariable regression analysis in this study (OR 5.67; 95% CI 2.88-17.10).

Despite the clinical advantages of a laparoscopic approach, adoption of LSCP has been limited possibly related to the steep learning curve associated with attaining laparoscopic suturing and knot tying skills that are required to attach the mesh to the vagina and sacrum. Claerhout et al evaluated their learning curve in the first 206 cases performed by a single surgeon.(341) Operating times declined rapidly during the first 30 procedures in this series and reached steady state (175 minutes) after 90 cases. Using a cumulative sum (CUSUM) approach to evaluate operative time and failures (laparotomy, complication or anatomic failures) they found that adequate learning occurred after 60 cases.(341) Complication rates remained unchanged throughout this series. Other studies have shown a decrease in operating time after 15-24 cases.(342,343) In a large database study of 3852 non-mesh vaginal surgeries and 2538 minimally invasive sacrocolpopexy's, minimally invasive sacrocolpopexy was associated with similar rates of 30-day complications, prolonged hospitalisation, readmission, and reoperation compared with non-mesh vaginal surgeries for apical prolapse.(344) Similarly, in the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) database of 1881 SSLF's, 975 USLS's and 4559 minimally invasive sacrocolpopexies, overall perioperative safety was comparable.(345)

4.4. Robotic Sacrocolpopexy (RSCP)

Because of the relatively long learning curve required for LSCP, many surgeons have turned to robotic-assisted surgery in order to offer patients a minimally invasive approach to sacrocolpopexy. Robotic surgical systems have been developed with the goal of facilitating technically difficult procedures by improving the surgeon's vision, dexterity and ergonomics. Limited data suggest that operating time and efficiency improves significantly after performing 20 RSCPs.(346) A systematic review of 27 studies including 1488 RSCPs found that the robotic approach is associated with objective cure rates of 84%-100% and subjective cure rates of 92-95% with mesh erosion rates of 2% (range 0-8%)(347) Overall, the post-operative complication rate in this meta-analysis was 11% (range 0-43%) with severe complications occurring in 2%.(347) Conversion to open ASCP occurred in <1% (range 0-5%).

4.5. Laparoscopic versus Robotic Sacrocolpopexy

In the majority of comparative studies RSCP is associated with longer operating time but similar objective success (Table 19).

To date, three randomised trials have compared robotic to laparoscopic sacrocolpopexy. Paraiso et al reported a single-centre, blinded randomised trial comparing RSCP (n = 40) to LSCP (n=38) in women with stage 2-4 post-hysterectomy vaginal prolapse. Patients undergoing a RSCP experience longer operating time (mean difference + 67 minutes; 95% CI 43-89, p<.0001), increased post-operative pain up to six weeks following surgery and required longer use of non-steroidal anti-inflammatory medications (20 vs 11 days) compared with LSCP. At one year, there was no difference between anatomical and quality of life measures between the two groups. Additionally, the cost of RSCP was significantly higher (mean difference +$1936; 95% CI $417-$3,454).(335) In 2014, Anger et al conducted a multi-centre trial comparing 78 women with stage two or greater pelvic organ prolapse to RSCP (n=40) or LSCP (n=38) with a primary outcome of cost.(348) The robotic sacrocolpopexy group had higher initial hospital costs ($19,616 compared with $11,573, P<.001) and over six weeks, hospital costs remained higher for RSCP ($20,898 compared with $12,170, P<.001). However, when excluding costs of robot purchase and maintenance there was no difference in hospital costs over 6 weeks ($13,867 compared with $12,170; P=.060). The robotic group had longer operating room times (202.8 minutes compared with 178.4 minutes, P=.030) and higher pain scores one week after surgery (3.5+/-2.1 compared with 2.6+/-2.2; P=.044). At one year, there were significant improvements in sexual activity, quality of life and symptoms improved in both groups with no differences between groups.(349)

No reoperations for mesh complications occurred in either group. In a study of 100 randomised patients, Iliano found longer robotic operative times (234 vs 193 minutes) compared to laparoscopic procedures, but otherwise no difference in outcomes.(350) A recent systematic review by Yang et al of RCT's and comparative studies that compared RSCP and LSCP for uterine and vault prolapse included 49 studies with 3014 participants. The pooled results suggested that RSCP was associated with a significantly longer operative time, significantly less estimated blood loss and significantly lower conversion rate compared with LSCP without any difference in intra- and post-operative complications or anatomic success. Cost was not evaluated and they concluded that the choice of surgical procedure with either RSCP or LSCP is according to surgeon discretions and patient preferences(351).

4.6. Sacrocolpopexy versus transvaginal mesh

Maher et al reported results from a randomised trial comparing laparoscopic sacrocolpopexy (LSCP) (n=53) to a total vaginal mesh (TVM) (Prolift, Ethicon, Sommerville NJ, USA) (n=55).(324) LSCP was associated with longer operating time (mean difference +52 min (95% CI 41.5-62.6], decreased hospital stay (mean difference -0.5 days (95% CI -.93 to -.10) and quicker return to normal activities (mean difference -5.3 days (95% CI -8.4 to -2.3). Two years after surgery, objective success (overall POP-Q Stage 0 or 1) was seen in 77% of the LSCP group compared with only 43% of the TVM group, p <.001).(324) Also, reoperations were significantly higher in the TVM group (22%) than in the group that received LSCP (5%, p =.006). In a RCT comparing an open abdominal sacrocolpopexy with a vaginal hysterectomy/SSLF/and anterior polyvinylfluoride mesh, anatomic success rates were similar however reoperations were significantly higher in the vaginal mesh arm (14% vs 0%).(138)

4.7. Sacrocolpopexy with mesh versus biological grafts

Some surgeons have attempted to decrease mesh complications of sacrocolpopexy by using biological materials instead of synthetic mesh. However, Level 1 evidence supports the superiority of polypropylene mesh to fascia lata for objective anatomical support following ASCP.(46,352) A randomised trial of 106 women undergoing ASCP compared polypropylene mesh to cadaveric fascia lata and found superior anatomical outcomes in those who received polypropylene at one year (success 91% vs. 68%, p = .007) and five years after surgery (93% vs. 62%, p =.02).(46,352) There were no differences in graft related complications overall between the two groups. Several retrospective case series support these data. (353-355) While Level three evidence suggests that use of xenografts such as porcine dermis and small intestinal submucosa also have inferior anatomic success rates compared with polypropylene mesh,(356-358) a single randomised trial comparing polypropylene mesh to porcine dermis in women receiving LSCP found no difference in objective or subjective outcomes at one year.(359)

5. OBLITERATIVE PROCEDURES: LEFORT COLPOCLEISIS, TOTAL COLPOCLEISIS

Obliterative surgery, such as total colpocleisis (also called colpectomy/colpocleisis) or the LeFort partial colpocleisis, corrects POP by reducing the pelvic viscera back into the pelvis and closing off the vaginal canal either in part or whole.(360) Obliterative procedures are less commonly performed in the Europe, Asia, and Australia compared to the United States, and are usually reserved for women who are elderly, medically compromised, and no longer sexually active.(361) The purported advantages of obliterative surgery in this population are decreased operative time, decreased perioperative morbidity, and an extremely low prolapse recurrence risk. The obvious disadvantage is the elimination of the potential for vaginal intercourse. Preoperative counselling is essential when choosing between the obliterative and reconstructive options. A systematic review of colpocleisis published in 2006 noted colpocleisis appears to be nearly 100% effective for correcting pelvic organ prolapse. (360) However, a small cohort study of 47 elderly women undergoing LeFort colpocleisis found objective success to be 81% and symptomatic improvement at 91.5% with longer post-operative vaginal length and wider genital hiatus as risk factors for recurrence. (362) Multiple cohort studies have found high rates of patient satisfaction and significant functional improvement with low rates of regret for loss of sexual function (0-4.3%). (69,363-367)

Barber et al reported results from a multi-centre study of obliterative surgery using a prospective cohort design with a concurrent control group of age-matched women undergoing vaginal reconstructive surgery.(69) Despite permanent alterations in sexual function, significant improvements in bladder, bowel and prolapse symptoms as well as body image were noted after surgery with no differences between those who received colpocleisis and those who underwent reconstructive surgery. Additionally, significant and clinically important improvements were noted in bodily pain, vitality, social functioning, role-emotional, and mental health summary scales of the SF-36.(69) Another multi-centre prospective cohort of 90 women undergoing colpocleisis found significant improvement in pelvic floor symptoms and body image with high satisfaction and low levels of regret on validated questionnaires six months after surgery.(366) Similarly, a retrospective cohort of women over age 65 by Murphy et al comparing women who underwent colpocleisis (n=45) and similar group women who underwent reconstructive surgery with transvaginal mesh (Prolift, Ethicon Women's Health and Urology) found that improvements in condition-specific quality of life and post-operative patient satisfaction were comparable between the two treatment groups.(368)

The Pelvic Floor Disorders Network has reported on a large series of women undergoing colpocleisis (n=153) with one year follow-up. (202) All pelvic symptom scores and related bother significantly improved at three and 12 months, and 125 (95%) patients said they were either 'very satisfied' or 'satisfied' with the outcome of their surgery.(202) Bothersome stress and urgency incontinence were present before surgery in 54% and 41% of subjects respectively. Forty percent of subjects received a concurrent mid-urethral sling at the time of their colpocleisis and the rates of bothersome stress and urgency incontinence one year after surgery were 14% and 15% respectively. Similarly, bothersome bowel symptoms were present in 77% of subjects at baseline. One year after surgery, the majority of bothersome bowel symptoms resolved, particularly obstructive and incontinence symptoms, and development of new bowel symptoms was uncommon (0-14%).(369)

While obliterative procedures are predominantly performed in elderly, frail women who often have multiple co-morbidities, the rate of serious adverse events after this procedure appears to be low. In general, major complications due to performance of surgery on the elderly (e.g. cardiac, pulmonary and cerebrovascular complications) occur at a rate of approximately 2%.(360) Major complications due to the surgery itself (e.g. pyelonephritis, blood transfusion) occur at a rate of approximately 4%.(360) A systematic review of published series of colpocleisis from 1966 to 2004 reported a surgical mortality rate of approximately 1 in 400 cases. (360) One complication that appears to be uniquely associated

with obliterative surgery is development de novo rectal prolapse after surgery.(370,371) Collins et al in a retrospective cohort of 916 women undergoing vaginal POP surgery at one institution and found that the incidence of post-operative full-thickness rectal prolapse in women who were > or = 65 years old who underwent obliterative surgery was 3 of 74 (4.1%; 95% CI, 1.4-11), with an estimated odds ratio of 22 (95% CI, 2.3-196; P < .002) compared with women who were > or = 65 years old who underwent reconstructive surgery.(370)

CONCLUSIONS

- A single large RCT suggests USLS and SSLF have similar anatomical, functional and adverse event outcomes. (GoR B)
- Level one evidence demonstrates transvaginal mesh procedures offer no significant advantage over vaginal native tissue apical repairs and are associated with mesh erosions. (GoR A)
- Level one evidence suggests that overall sacrocolpopexy is associated with lower risk of awareness of prolapse, recurrent prolapse on examination, repeat surgery for prolapse, post-operative SUI and dyspareunia when compared broadly with vaginal prolapse repairs with and without mesh augmentation. (GoR A)
- Level one evidence suggest ASCP has a higher success rate as compared to SSLS with less SUI and post-operative dyspareunia. ASC had greater morbidity including operating time, inpatient stay, slower return to activities of daily living and higher cost. (GoR A)
- In a single RCT, ASCP associated with greater anatomical success, fewer reoperations, greater post-operative complications than USLS but no difference in improvement in symptoms or quality of life. (GoR B)
- LSCP is associated with lower blood loss, longer operating time and shorter hospital stay than ASCP with no difference in objective or subjective cure rates. (GoR B)
- Compared to LSCP, RSCP is associated with longer operating times, greater post-operative pain and cost with similar rates of anatomic success and complications. (GoR B)
- ASCP performed with polypropylene mesh has superior outcomes to fascia lata. (GoR B)
- In a single RCT, LSCP had a superior objective and subjective success rate and lower reoperation rate compared to polypropylene transvaginal mesh for vault prolapse. (GoR B)
- Level three evidence suggest McCall culdoplasty, Iliococcygeus fixation and colpocleisis are relatively safe and effective interventions. (GoR C)

VI. SURGERY FOR POSTERIOR VAGINAL WALL PROLAPSE

Almost 200,000 women undergo prolapse surgery in the United States each year, with one-third to one-half including a posterior wall prolapse repair.(32) Prolapse of the posterior vaginal wall may be secondary to the presence of rectocele, sigmoidocele, enterocele, or a combination of these. This section will focus on the current understanding of the posterior vaginal anatomy, pathophysiology and anatomic defects which contribute to posterior vaginal wall prolapse, and will update the previous ICI report regarding outcomes after surgical repair of rectocele.

Anatomy of the Posterior Vaginal Wall

The vagina is made up of fibromuscular tissue extending as a tube from the abdominal cavity to the perineal body. Support of the posterior vaginal wall includes a complex interaction of the vaginal tube, connective tissue support, and muscular support of the pelvic floor.

The connective tissue support of the vagina can be divided into three levels based on work by DeLancey.(178) All three levels require evaluation when considering the surgical management of the posterior vaginal compartment. Level I includes the apical portion of the posterior vagina supported primarily by the cardinal-uterosacral ligaments, originating at the sacrum and inserting onto the posterior cervix and upper vagina.(372) Level II includes support to the mid-section of the vagina, which is provided by the endopelvic fascia, attaching the lateral posterior vaginal wall to the aponeurosis of the levator ani muscles. The fibres of the endopelvic connective tissue extend from the lateral edge of the vaginal tube to the pelvic sidewall. The proximal half of the posterior vagina is supported by endopelvic attachment to the arcus tendinous fasciae pelvis.

Finally, Level III includes the distal support of the posterior vaginal wall and is primarily provided by the perineal body. This level of support has strong attachments to the levator ani complex and is thus less susceptible to pelvic pressure transmission that may cause prolapse: it imparts a physical barrier between the vagina and rectum.

The puborectalis muscle provides a sling of support, enclosing the genital hiatus. Typically, the puborectalis is in a state of chronic contraction and the anterior and posterior vaginal walls are in direct apposition. In normal defaecation, there would be no increased pressure or stress placed on the endopelvic fascial attachments, as the puborectalis muscle relaxes and any increased pressure on the posterior vaginal wall is equilibrated by the opposing anterior vaginal wall.

The rectovaginal space is the potential space between the vaginal tube and the rectum. It consists of areolar tissue, and allows the vagina and rectum to function independently. Histological studies have noted that there is no specific layer of “fascia” between these two structures.(373)

Disruption of this complex interplay of bony, muscular, and connective tissue support can result in posterior vaginal wall prolapse resulting in both physical discomfort as well as negative impact on a woman’s functioning.

Surgical Repair of Posterior Vaginal Prolapse

Posterior vaginal prolapse can be associated with a bothersome vaginal bulge as well as emotional, sexual, and defaecatory dysfunction. Surgical treatment should be primarily driven by patient symptoms and bother. Goals include restoration or maintenance of normal anatomy, bowel function, and/or sexual function. Of note, many patients may present with both defaecatory symptoms as well as posterior vaginal prolapse leading to the assumption that the prolapse is causing the problems. However, data are conflicting regarding the efficacy of posterior vaginal repair on improving defae-

catory symptoms and the association is incompletely understood. (374,375)

Types of surgical repair for posterior vaginal prolapse include midline plication (native tissue), site specific technique (native tissue), graft/mesh augmentation of midline or site-specific repairs, transanal repair, ventral rectopexy, and sacral colpopexy in which mesh is extended to the distal portion of the posterior vaginal wall and/or perineum.

1. MIDLINE PLICATION (TRADITIONAL POSTERIOR COLPORRHAPHY)

Midline plication of the fibromuscularis in the posterior compartment, or posterior colporrhaphy, was introduced in the 19th century. Plication in the midline decreases the width of the posterior vagina wall, creates a shelf of support, theoretically increasing the strength of the fibromuscularis layer. Reported anatomical “success rates” of this technique range from 76-96% (Table 20).

The vaginal epithelium of the posterior vaginal wall is incised in the midline and flaps are created by dissecting the vaginal epithelium off the underlying fibromuscularis layer. Plication of the fibromuscularis then starts proximally towards the hymen. Dyspareunia rates range from 5-45% in the literature.

Of note, midline plication may include plication of the levator ani muscles as well. This can help to close the genital hiatus, although it is not a normal anatomical position of the levator muscles. This may overly constrict the vaginal calibre and cause post-operative pain and dyspareunia.(376-378) Thus, in general levator plication has fallen out of favour especially in sexually active women.

2. SITE-SPECIFIC POSTERIOR VAGINAL REPAIR

This technique is similar to the traditional posterior colporrhaphy, except for the plication step. After the epithelium is dissected off of the underlying connective tissue, discrete defects in the connective tissue are identified by the surgeon by placing a finger in the rectum. Any identified discrete breaks in the connective tissue are then approximated and closed using interrupted sutures. If there is remaining laxity after the site-specific repair, a midline plication can then be performed over the site-specific repairs. Levator plication is not performed. The mean anatomic success rate is 83% (range 56-100%) with 18% post-operatively needing vaginal digitation to defecate and 18% experiencing post-operative dyspareunia (Table 21).

Abramov et al retrospectively compared the midline fascial plication and discrete site specific repair for rectoceles.(385) They noted a significantly higher recurrence rate of rectoceles following the discrete site-specific repair 32% as compared to 13% following the

midline fascial plication (P=0.015). The correction of the rectovaginal fascia defect that allows entrapment of faeces on straining in significant rectoceles may be too large to be repaired with the discrete approach (386) and appears to be corrected by the more robust midline fascial plication.

3. GRAFT (ABSORBABLE) OR MESH (PERMANENT) AUGMENTATION OF POSTERIOR VAGINAL REPAIR

Graft or mesh can be used in the rectovaginal space. This is often combined with either a midline colporrhaphy or site-specific repair. Although there is variation in the surgical technique typically, after creating vaginal flaps, the dissection is extended laterally on both sides to the pelvic sidewall. A midline colporrhaphy or site-specific repair is then typically performed. The graft or mesh is then placed over the repair and anchored along the sidewall. The vaginal epithelium is then closed over the graft or mesh. Of note, commercial transvaginal mesh kits are no longer widely available.

There are four comparative studies suggesting no difference in anatomical and quality of life outcomes when using synthetic absorbable mesh or biological graft compared to native tissue transvaginal repair, including three randomised trials and one retrospective cohort study.(392-394,415) Graft-augmented repair outcomes are presented in Table 22**.**

Paraiso et al compared three techniques for rectocele repair in a prospective randomised trial.(391) Patients were randomised to receive either a traditional repair (N=37), a site specific repair (N=37) or a site-specific repair augmented with porcine small intestine mucosa (N=32). All patients had Stage II or greater posterior vaginal wall prolapse at baseline. The objective anatomical failure rate was highest in the graft augmented group (12/26) at 1 year which was statistically significantly worse than the site-specific group (6/27) and traditional repair (4/28). There was no significant difference in subjective symptoms (worsening prolapse or colorectal symptoms) or dyspareunia between the three groups. No graft exposures were reported.

Sung et al conducted a double blind, multicentre randomised trial comparing native tissue repair (70) versus native tissue with porcine small intestine submucosal (SIS) graft (67) for symptomatic stage 2 rectocele.(392) The native tissue repair involved either a midline plication or site specific repair at the surgeon's discretion, with the majority undergoing site-specific repair. In the graft group the native tissue repair was augmented with porcine SIS overlay. At one year, there was no difference between the groups in objective and subjective success rates or in resolution of defaecatory symptoms. Post-operative dyspareunia rates were not significantly

different at 7% in the native tissue group and 12.5% graft group. No graft exposures were reported.

Grimes et al conducted a retrospective review of 193 posterior repairs performed between 2001-2008 from the Kaiser Permanente San Diego Pelvic Floor Database.(394) 124 (64%) native tissue (including 38% traditional colporrhaphy and 62% site-specific repair) and 69 (36%) graft augmentation procedures were included. Minimum follow up was approximately 12 months. Graft augmentation was at the discretion of the surgeon and included noncross-linked cadaveric dermis, cross-linked porcine dermis, and noncross-linked porcine dermis. Anatomical success was similar between native tissue vs. graft (Bp <-1, 86% vs. 80%). Post-operative splinting and incomplete evacuation was greater in the graft group compared to native tissue (splinting, 85% vs. 68%; p=0.04).

There was one comparative study evaluating patient-reported outcomes after native-tissue versus nonabsorbable mesh augmentation for isolated primary rectocele by Madsen et al.(395) The authors used prospective data from the Swedish National Register for Gynaecological Surgery, including 3988 women who underwent primary operation for rectocele between 2006-2014. 3908 women had a native-tissue repair and 80 had nonabsorbable mesh. No concurrent procedures were included and follow up was 12 months. The authors found no difference in vaginal bulge sensation (78% vs. 90% “cure” for native tissue vs. mesh), or feeling satisfied/very satisfied (74% vs. 70% native tissue vs. mesh). There was no statistically significant difference for de novo dyspareunia (33% vs. 10% for native tissue vs. mesh). Reoperation rate was 1.1% in both groups.

Glazener et al (396) conducted two pragmatic, parallel-group multicentre randomised trials (PROSPECT) in 35 centres in the UK. Women were randomised to native tissue (N=430) vs synthetic mesh augmentation (N=435), or native tissue (N=367) vs biological graft augmentation (N=368). Women were followed for 2 years. Prolapse severity symptoms, quality of life and serious adverse events was not different between groups. The cumulative number of women who had a synthetic mesh complication at 2 years was 12%.

More recently Nussler et al interrogated the Danish surgical database and evaluated those undergoing traditional posterior colporrhaphy (n=433) and permanent polypropylene mesh (n=193) for recurrent isolated rectocele at I year. Those undergoing permanent mesh had significantly greater stage ¾ prolapse than the native tissue group however the awareness of bulge (OR 2.1 95% CI 1.03-4.35) and patient satisfaction (OR = 2.4; CI 1.2-4.97) remained superior in the mesh group. Patient reported complications and reoperation at 12 months remained similar in both groups.(397)

4. VENTRAL RECTOPEXY

For rectal prolapse both perineal and abdominal procedures are described. While the transanal Delorme’s procedure has been performed for many years Level three evidence suggests that perineal approaches seem to be associated with a higher post-operative faecal incontinence and recurrence rate and therefore an abdominal procedure is preferred by most surgeons.(398-400) In the search to reduce this high rate, laparoscopic ventral mesh rectopexy (LVMR) was introduced (401) and mobilises just the anterior aspect of the rectum, and thereby the risk for autonomic nerve damage and associated dysmotility with impaired evacuation is minimised. The dissection is followed by a mesh suspension of the distal rectum to the sacral promontory, correcting the descent of the rectum and reinforcing the rectovaginal septum. Although no high quality comparative research exists so far, VMR is being progressively performed internationally and proposed as the treatment of choice for rectal prolapse.(402)

To date, only one small randomised controlled trial (RCT) Emile et al compared LVMR with Delorme’s operation (n= 25 vs. 25) for ERP with mean follow-up of 18 ± 5 months (range, 9-30).(403) Baseline characteristics differed from the literature with a low mean age (39.7 years) and a high percentage of males (38%). The trial demonstrated no difference between the groups in recurrent prolapse (16% Delorme’s, 8% LVMR) or difference in change in Wexner continence or constipation scores post-operatively. The Delorme’s procedure had a shorter operating time and longer admission stay than the LVMR. With a larger sample size, the non-significantly higher recurrent rectal prolapse rate after the Delorme procedure may become significant.

The vast majority of the current literature regarding LVMR comprises observational studies and often differ in patient selection and outcome measures. This heterogeneity makes it difficult to interpret the results. Most studies lack a systematic approach and follow-up is usually short.

Emile et al have however performed a systematic review of LVMR and found a complication rate of 12% and a recurrence rate of 3% with a median follow up of 23 months. There was a 79% improvement of faecal incontinence and a 71% improvement in constipation.(404)

There is currently no evidence that robotic ventral mesh rectopexy has any benefit over laparoscopy.

4.1. Recurrence

Since the first description of LVMR, recurrence rates for external rectal prolapse (ERP) range between 1.5 to 15.4% (Table 23). Most recurrences are seen within 36 months’ post-operatively, but not all studies demonstrate this time interval. Studies including all rectal

Table 22. Graft-augmented (absorbable) posterior vaginal repair (does not include synthetic mesh)

prolapse syndromes as an indication for LVRM, report a recurrence rate of 2.6 to 14.3% Only three trials evaluated IRP as the indication for LVRM with recurrence ranging from 5.3 to 7.1%. Recurrence rates following RVMR are generally comparable to LVMR series (Table **23).**

4.2. Functional Outcome

4.2.1. External rectal prolapse

External Rectal Prolapse (ERP) is considered a definitive indication for LVMR.(405) Functional outcome in rectal prolapse surgery is usually assessed with validated faecal incontinence and constipation scores. The LVMR articles included in this guideline either used the Cleveland Clinic Constipation Score (CCCS, range 0-30), (406) Obstructed Defaecation Syndrome (ODS) Score (range 0-31),(407) Fecal Incontinence Severity Index (FISI, range 0-61),(408) or the Cleveland Clinic Incontinence Score (CCIS, range 0-30).(409) For all four grading systems, a decrease in score correlates with an improvement of symptoms. A median improvement in CCCS ranged from 4.8-11 points with between 52-84% reporting a general reduction of obstructed defaecation complaints is noted following LVMR (Table 24). Post-operatively 50-93% of patients reported a reduction in faecal incontinence and an improved median FISI ranged from 12 to 36 points**.** New-onset complaints are described in 4.8 to 17.6% of patients for obstructed defaecation and in 1.5 to 3.2% of patients for faecal incontinence (Table 24). The only robotic VMR study including patients with an ERP showed a mean CCCS gain of 3.2 points.(410)

4.2.2. Internal rectal prolapse

In general, for an Internal Rectal Prolapse (IRP) Oxford Grade 1 and 2 (recto-rectal intussusception) pelvic floor physiotherapy is indicated.(411) Significant functional symptoms in combination with an Oxford Grade 3 or 4 IRP (recto-anal intussusception) failing to conservative therapy, could be an indication for VMR.(405) Studies including patients with a symptomatic grade 3 or 4 IRP describe a median reduction of CCCS (range 3.1-9.0 points) and a reduction in obstructed defaecation complaints (range 55-86% of patients) Post-operatively between 20-92% reported a reduction in faecal incontinence with a median improved FISI ranging from 16 to 25 points as seen in Table 24. No, *de novo* faecal incontinence was described.

Median gain of CCIS was non-significantly equivalent between the two techniques. Functional results following RVMR are comparable to the literature on LVMR for various indications (Table **22)**.

5. VENTRAL MESH RECTOPEXY MORBIDITY

Multiple studies have been performed to assess the safety of LVMR. At present, thirty studies report a post-operative complication rate between 0-23.4% (Table 25). The vast majority of those complications were minor, as classified according to the Clavien-Dindo (CD) classification. Major complications following VMR are described from 0-7.7% with a mortality rate of 0-1.1%. In recent years, there was serious controversy about the use of permanent mesh in pelvic floor surgery. In 2015 Evans et al combined data collated from prospective databases in five hospitals (2203 patients) and described an overall mesh erosion rate of 2% (42 synthetic, three biological) after a median of 23 months.(412)

Currently 34 observation studies (range median follow-up 3-74 months) mention mesh-related morbidity following LVMR with mesh complication rates from 0-6.7% and mesh erosion percentages between 0-3.7%.(403, 412-430) Five studies (range median follow-up 3-24 months) evaluated robotic VMR and the rate of synthetic mesh-related complications was 0%.(410, 431-434) Based on these figures, it appears that the concerns about mesh complications following a transvaginal mesh procedure are not applicable to the VMR.

6. BIOLOGICAL GRAFT RECTOPEXY

In 2008 and 2011 the US Food and Drug Administration (FDA) published official warnings for the use of mesh in POP surgery.(435) Although similar figures following an abdominal approach have never been described, an aversion to synthetic mesh in POP surgery was created. In the search for an alternative, biological meshes became more popular. To date, erosion rates and functional outcome following VRM for synthetic and biological mesh are comparable.(436) The material characteristics of a biological mesh could in theory result in a higher recurrence rate. Currently, recurrence rates are quite comparable. One report, however, noted a high recurrence rate of 14% after 20 months of follow-up.(437) Ogilvie et al published the only (case-matched) study comparing biological with synthetic mesh for LVMR (n= 29 vs 29).(420) No significant difference in mesh-related morbidity, functional outcome and recurrence after a median follow-up of 15.4 months was found. One article comparing LVMR with RVMR (34 vs 17) using biological mesh showed no mesh-related morbidity or recurrences in either cohort after 12 months.(438) Functional outcome was approximately equivalent between the two groups. McLean et al found, in a cohort study of 224 LVMR's with biological mesh, a complication rate of 11%, recurrence rate of 11% and a mesh related morbidity of 0.45%.(439)

The use of a biological mesh for LVMR appeared to be safer in a systemic review performed by Balla et al.(440)

7. RECTOCELE AS AN INDICATION FOR VENTRAL MESH RECTOPEXY

Rectocele has been described as an indication for VMR. (413,416,417,419,441) As early as 2008 a Dutch group retrospectively reported on 16 women undergoing LVMR for obstructed defaecation syndrome. Many had an enterocoele or rectocele preoperatively with 25% also having internal rectal prolapse.(442) The mean operating time was 199 minutes and the mesh was secured to the anterior rectum and posterior vagina. Post-operative complications included two ileus, one of which required reoperation, one wound infection, 1 neurological injury to left leg, two incisional hernia and one infected mesh that was removed. The obstructed defaecation score was not significantly different post-operatively and in fact deteriorated in 75%. The authors reported the LVMR to be a feasible approach in selected patients, without identifying the group.

In 2011 Wong et al (441) reported a retrospective case series on ventral rectopexy (n=38) for complex rectocele (defined as one or more of: rectocele greater than 3cm diameter on imaging, associated enterocele or internal rectal prolapse), with 12 months' review.

The surgical technique was unorthodox for ventral rectopexy with "mesh secured to pelvic floor musculature on either side of the rectum, taking care not to place the sutures directly into the rectal wall". This single leaf procedure was performed in (14/38) and closely resembles a single leaf sacral colpopexy. The majority (24/38) actually underwent a classical dual leaf sacral colpopexy.(443) The authors not surprisingly reported a significant reduction in vaginal prolapse symptoms, (45 to 5%) and dyspareunia (27 to 10%) results that have been well recognised in level one data on sacral colpopexy.(444) There was no difference in post-operative scores for obstructed defaecation syndrome, Cleveland clinic incontinence score or Gastrointestinal quality of life score.

Formijne Jonkers et al retrospectively reported on 233 patients undergoing LVMR and who completed postal validated bowel function questionnaires.(413) Indications for surgery were divided into three groups. Group one included external rectal prolapse (15%), group two internal rectal prolapse and or rectocele (68%) and group three internal rectal prolapse or rectocele and enterocele (17%). Sixty-four percent (n=150) completed the questionnaires which demonstrated significant improvement in faecal incontinence and constipation scores post-operatively in all three subgroups. Unfortunately, it is not possible to determine how many of patients in groups two and three are included due to rectocele and how many due to internal rectal prolapse. Furthermore, the study methodology results in an overestimation of impact of the surgery. No attempt was made in the study methodology to account for the 36% that failed to respond and then persisted in including 233 patients in the post-operative review. These oversights in the study methodology served to overestimate the impact of the intervention. Thus, it is not possible to discern from this report if the LVMR is effective for rectocele.

Lauretta et al retrospectively described a modified laparoscopic ventral rectopexy for 30 women with external or internal prolapse and 26 for some degree of rectocele.(417) At surgery the mesh was secured to both the anterior rectum and posterior vaginal wall. Pre- and post-operatively rectocele and internal prolapse were defined at proctography. At a median review of 14 months one patient had a suture erosion and one a recurrent rectal prolapse. Excellent functional outcomes were reported with constipation significantly improved in 93%, a significant reduction in the Altomare obstructed defaecation score and preoperative incontinence improved after the procedure in all patients affected. Unfortunately, no post-operative vaginal prolapse assessment or report of defaecography findings were reported and the reader is unable to determine if the functional outcomes reported are due to correction of the internal and or rectal prolapse or the possible correction of a rectocele.

A French group prospectively evaluated 33 patients undergoing a traditional LVMR for external rectal prolapse (n=20), rectocele and internal rectal prolapse (n=10), and rectocele (n=3).(419) At median review of 42 months constipation was improved in 72% (13/18) and two patients (7%) presented de novo constipation. The patients' Wexner score and quality of life improved significantly post-operatively and two patients developed recurrent rectocele (7%). Despite there being no pre or post-operative vaginal prolapse assessment recorded and that only three patients with rectocele alone were included, the authors concluded LVMR was an effective and safe treatment for external rectal prolapse and or rectocele.

Horisberger et al (416) retrospectively evaluated 27 women undergoing LVMR for complex pelvic floor conditions including symptomatic rectocele (79%), enterocele (64%) and grade 1-2 rectal prolapse (43%). At 22 months significantly improved constipation scores and quality of life scores on the SF-12 questionnaire were demonstrated without improvement in Wexner Incontinence score. Over 50% of preoperatively sexually active women reported a deterioration in sexual function and no post-operative assessment of vaginal prolapse was reported. Again, it is impossible to determine if the improvement in constipation scores are due to treatment of grade 1-2 rectal prolapse or correction of the rectocele.

Due to the significant heterogeneity of the included conditions the reader is unable to determine if the changes reported are due to correction of external and or internal rectal prolapse or due to correction of the rectocele. No trial has demonstrated that the LVMR or modifications employed are successful in correcting rectocele. One trial demonstrated that a procedure that more closely resembles a sacral colpopexy than ventral rectopexy, was successful in correcting vaginal prolapse symptoms with little impact upon functional bowel symptoms.

8. COMBINED VAGINAL AND RECTAL PROLAPSE

Logically women with rectal prolapse may also suffer vaginal prolapse and or bladder dysfunction. As early as 2007 Lim et al (445) retrospectively reported on 29 women undergoing open combined mesh sacral colpopexy, ventral rectopexy and urinary continence surgery performed by urogynaecologist and colorectal surgeons working together for combined pelvic floor dysfunction. The authors demonstrated significant improvement in the validated Pelvic Floor Distress Inventory and in all three subscales including vaginal, urinary and rectal related symptoms. Three patients (10%) required reoperation, one for removal of mesh and two for recurrent vaginal prolapse.

More recently Van Iersel et al prospectively describe 51 patients undergoing robotic ventral rectopexy, sacral colpopexy and urinary continence surgery as required performed in collaboration between colorectal and urogynaecology surgeons for combined vaginal and rectal prolapse.(436) They demonstrated a significant improvement not only in faecal incontinence (Pescatori incontinence scale 4 vs 3, p=0.002) and constipation (73.3%, p<0.0005) but also in the Urinary Distress Inventory (27.8 vs 22.2; p<0.0005) and on sexual function (Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire score 31.8 vs 35.9; p = 0.002. Quality of life for bowel and bladder function (p < 0.0005) was also observed. Anatomical vaginal reconstruction was demonstrated by the simplified POP quantification p< 0.0005). One patient (2%) developed mesh erosion and a single recurrent rectocele was observed.

9. PROLAPSE SURGERY AND COEXISTENT BOWEL SYMPTOMS

Women with vaginal prolapse frequently have coexistent bowel dysfunction including obstructed defaecation, constipation and faecal incontinence. The prevalence of associated bowel symptoms in women with vaginal prolapse was recently reviewed by the International Urogynaecology Consultation and reported obstructed defaecation in 53% (33-95%), constipation 40% (10-83%) and faecal incontinence in 19% (12-69%).(446)

We were unable to identify an evidence-based pathway for the management of pelvic organ prolapse and associated bowel symp-

toms. So utilising the wide clinical and academic experience of the committee we established using the Delphi process clinical guidance on the management of women with vaginal prolapse and associated bowel symptoms as seen in Figure 4. As the success rate of posterior colporrhaphy in those with rectocele and impaired defaecation is over 80% as described above the algorithm points to those entering the standard pathway for vaginal prolapse. Those with obstructed defaecation without significant rectocele and those with faecal incontinence are referred to colorectal colleagues who will differentiate between those with neurological causes that typically would undergo sacral neuromodulation and those with high grade rectal prolapse who maybe considered for ventral rectopexy/resection. Finally, those with constipation are actively managed to minimise straining as constipation is an acknowledged risk factor for the development and possible recurrence of vaginal prolapse.

Table 23. Recurrence rates following LVMR and RVMR with synthetic mesh

Laparoscopic studies	n	FU (median)	Recurrence	Type of recurrence	Presentation of recurrence (months)

maybe suitable for combined surgery for vaginal and rectal prolapse.

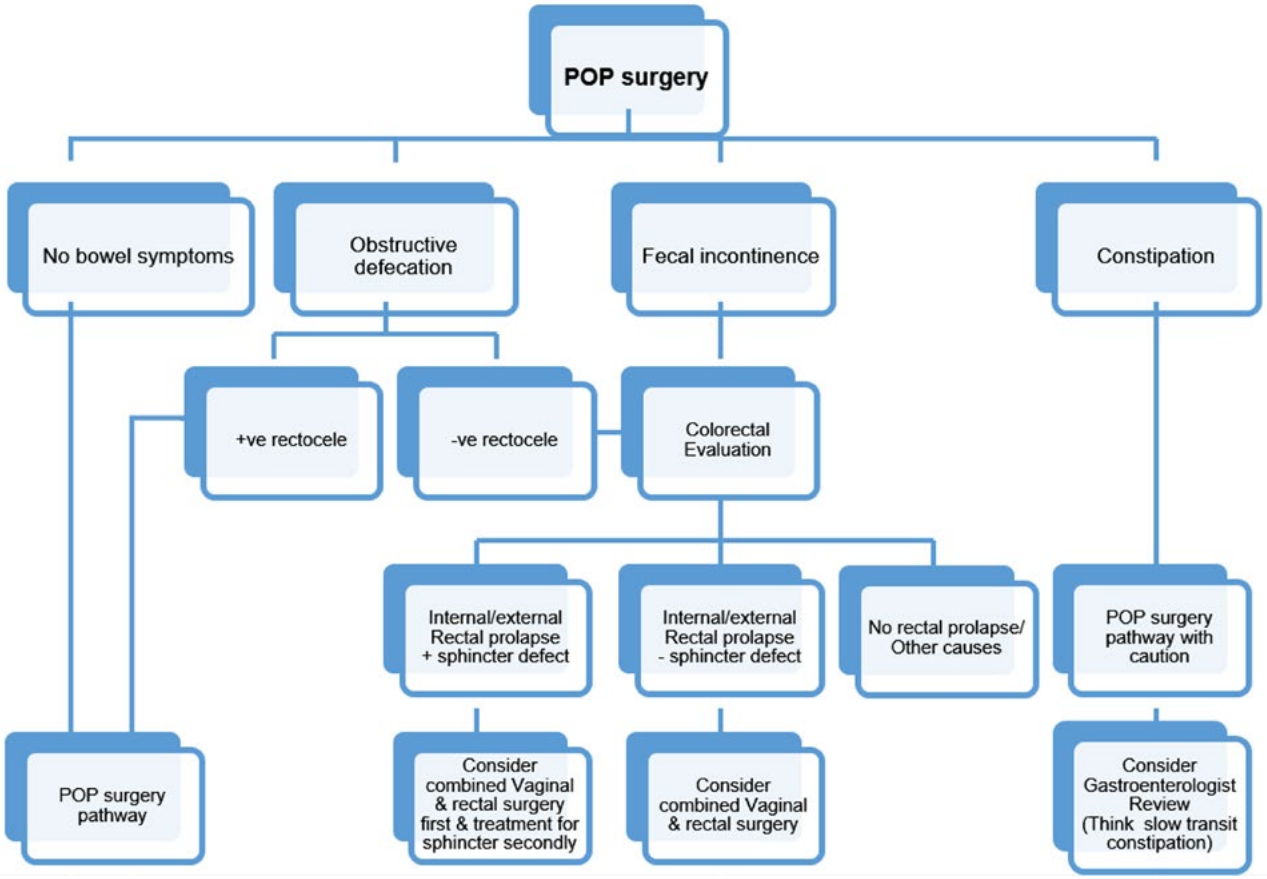

Figure 4. Prolapse surgery pathway and coexistent bowel symptoms.

CONCLUSION

Level one and two evidence suggest midline plication posterior repair without levatorplasty has superior objective outcomes as compared to site-specific posterior repair. (GoR B)

Higher dyspareunia rate is reported when levatorplasty is performed. (GoR C)

Transvaginal approach is superior to the transanal approach for repair of posterior wall prolapse. (GoR A)

To date no study has shown any benefit to graft or mesh overlay or augmentation of a suture repair for posterior vaginal wall prolapse. (GoR B)

While modified abdominal sacrocolpopexy results have been reported, data on how these results would compare to traditional transvaginal repair of posterior vaginal wall prolapse is lacking.

The data comparing Delorme's procedure and VMR for external rectal prolapse are conflicting with a single RCT demonstrating no statistical difference, while level 3 data is supportive of VMR performed laparoscopically or robotically, with low rates of recurrent rectal prolapse and improved rates of faecal incontinence and constipation. (GoR D)

VMR appears superior to other abdominal rectopexies (posterior mesh rectopexy, Ripstein, Orr-Loygue) with different rectal mobilisations to treat ERP in terms of functional outcome. (GoE C)

LoE 3 supports ventral rectopexy for Oxford grade 3-4 internal rectal prolapse. The data is not conclusive regarding graft material or route of surgery. (GoR C)

No data demonstrates ventral rectopexy with or without graft attachment to the posterior vaginal wall is effective in management of rectocele. (GoR D)

Limited level three evidence suggest that patients with combined rectal and vaginal prolapse benefit from colorectal surgeons and urogynaecologist collaborating closely. (GoR C)

VII. SURGERY FOR PELVIC ORGAN PROLAPSE AND BLADDER FUNCTION

Patients with POP often present with bladder symptoms like urinary incontinence or voiding difficulties: In women with stage II POP about 55% have concurrent SUI. This prevalence decreases with increasing POP stages to 33% in women with stage IV POP (458) and proves that preoperatively, many women with advanced POP do not experience SUI. However, if the prolapse is reduced

digitally or with the help of a pessary, sponge holder or speculum, SUI might be demonstrated in 10 to 80%.(459-462) This type of SUI, which is demonstrable with the prolapse reduced in otherwise continent women, is termed occult, masked or latent SUI. The importance of this finding remains ambiguous (463): the test itself is not optimal (463) as it does not necessarily mimic prolapse surgery and may obstruct or put undue tension on the urethra. Although different techniques to reduce the prolapse have been described, a gold-standard has not been established.(462,463) Neither the speculum nor the pessary test to reduce the prolapse had acceptable positive predictive values to identify women in need of a concomitant continence procedure. The negative predictive values however were 92.5% (95%CI 90.3–1.00) and 91.1% (95%CI 88.5–99.7), respectively. Therefore, women with preoperatively negative tests for occult SUI are at low risk to develop SUI postoperatively.(462,464) After POP surgery, women might experience new SUI because the operation for POP unkinked the previously obstructed urethra.(465,466) The term de novo stress urinary incontinence is used to describe SUI that develops following surgical correction of the prolapse, amongst women who were continent prior to surgery.

If women remained continent during pessary insertion for 2 months prior to POP surgery, most of them (84%) continued to be continent postoperatively.(467) The number needed to treat was 11. The authors concluded that overtreatment was avoided by this longer-term pessary test.(467) Such an “extended pessary trial” might be very helpful counselling women regarding concomitant continence procedures.(468) A further method to expose occult SUI was described by Song et al.(469) They performed a standard 1-hour-pad-test after pessary fitting. After vaginal POP repair 22/45 women (49%) had new SUI compared to only 30/161 (19%) women who did not have occult SUI preoperatively. The cut-off point was calculated at 1.9 g.(469)

In a secondary analysis of the CARE trial the authors revealed that a more distal preoperative POPQ-point Ba was associated with a higher incidence of postoperative de novo SUI.(470)

One third of women with stage II or more POP experience difficulties emptying the bladder.(458) Reducing the prolapse during preoperative urodynamics may restore normal voiding function.(471) Voiding difficulties might disappear postoperatively because the obstruction caused by the prolapse has been corrected.(471) In contrast, they might develop because of kinking of the urethra due the surgical technique.

Urinary symptoms belong to the patient-centred outcome measures after POP surgery. Accordingly, bladder symptoms including persistent or de novo stress and urge urinary incontinence as well as voiding symptoms should be discussed with the patient when counselling for a POP operation. Should women with or without accompanying SUI and POP receive an additional continence procedure when the prolapse is repaired? Which prolapse operation would be best to prevent de novo or persisting symptomatic postoperative SUI? This section of the chapter assesses the available evidence regarding the effect of POP surgery on bladder function including stress urinary incontinence, overactive bladder and voiding dysfunction. Fig. 5 summarises data from randomised, prospective and retrospective studies. They were included if they clearly described preoperative examinations including testing for occult SUI and adequately analysed data to fit the categories of stress incontinent women and continent women with and without occult SUI.

Postoperative SUI rates after POP surgery with and without continence procedures based on preoperative SUI symptoms and presence of occult SUI. *(AC=anterior colporrhaphy, VR= vaginal repairs, AMesh=anterior mesh, TVT=tension-free vaginal tape, TVT-O=tension-free vaginal tape-transobturator, TOT=transobturator tape, MUS=mid-urethral sling, UP=urethropexy, SCP=sacrocolpopexy, SHP=sacrohysteropexy)*

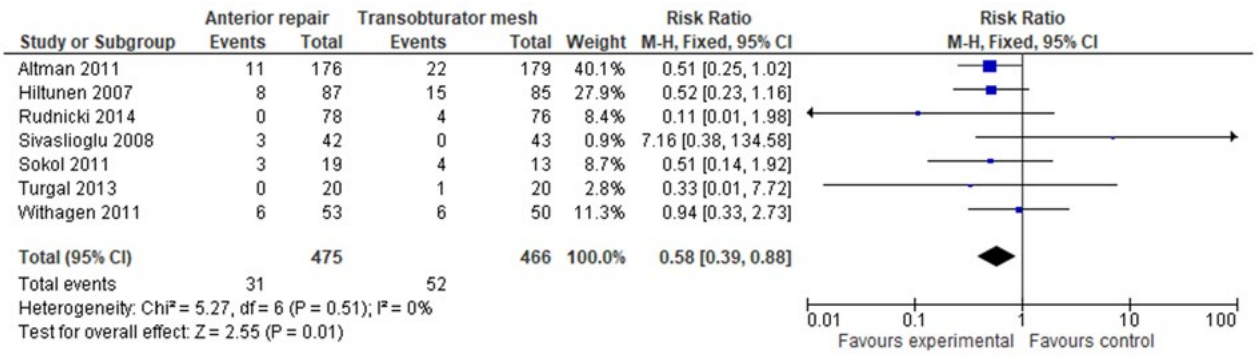

Figure 6. De novo SUI: Forrest plot of seven RCT´s comparing anterior repair and transoburator mesh repairs.

1. CONTINENT WOMEN UNDERGOING POP SURGERY

In women undergoing POP surgery without preoperative SUI symptoms but unclear occult SUI testing, de novo SUI was detected after vaginal POP repairs in 37/550 (7%) women in nine randomised controlled trials (RCT) (125,173,472-478) and in 13/189 women (7%) in 6 non-RCTs (459, 462, 479-482). After armed anterior mesh procedures the de novo SUI rate was significantly higher at 14% (212/1475; p=0.0045, chi-square; OR 2.31, 95% CI 1.68 to 3.19) with a rate of 16% (110/708) in nine RCT arms, (125, 173, 472-476, 483, 484) and 13% (102/767) in 12 prospective or retrospective trials.(485-493)

Seven RCT´s directly compared anterior colporrhaphy and transobturator mesh procedures (mesh kits or self-fashioned) in continent women and reported 12-months results.(125,173,472-475,494) Anterior repair significantly decreased the risk of de novo SUI (RR 0.58, 95%CI 0.39, 0.88; Fig. 6).

The 3-year follow-up results of two RCTs (132,473) corroborate the 12 months findings: 24/144 (17%) versus 13/145 (9%) women developed SUI after anterior mesh versus native tissue repair (RR 1.88, 95%CI 1.01-3.49).(121,132,494) Similar rates of de novo SUI occurred if the anterior compartment prolapse was repaired using a polypropylene transobturator mesh in 2/96 (2%) or a porcine dermis graft 1% (1/94).(163)

New SUI was significantly more common after sacrospinous fixation and vaginal repairs compared with abdominal sacral colpopexy (8/24, 33% versus 2/22, 9% in a single RCT),(66) however, in the sacral colpopexy group some women received paravaginal repairs which may be effective in limiting de novo SUI postoperatively. One trial considered concomitant sacrospinous fixation as a risk factor for de novo OAB.(495)

Although the risk of developing SUI after POP surgery without a concomitant continence procedures is not higher for continent women without occult SUI (357/2072; 17%) (163,459,463,467,469,477,478,480-482,484,496-504) compared to POP surgery with a continence procedure (60/299; 20%), (463,484,498,505,506) there are differences between surgical approaches as displayed in Fig. 5. Sacrocolpopexy alone significantly increases the risk for de novo SUI (100/312; 32%) compared with vaginal repairs (215/1443, 15%; OR 2.92, 95%CI 0.47-1.11) and vaginal anterior mesh procedures (42/317, 13%; OR z3.34, 95%CI 2.22-5.03).

Summarising all studies assessing de novo SUI rates in continent women with negative testing for occult SUI who underwent sacrocolpopexy or sacrohysteropexy, 100/312 (32%) developed SUI (Fig. 5) (463, 499, 503-505) compared to 31/151 (21%) with an additional urethropexy (OR 1.98; 95 % CI: 1.25 to 3.13).

In the large multicentre randomised controlled CARE trial (Colpopexy and urinary reduction efforts), preoperatively continent women were randomly allocated to undergo sacral colpopexy with (n=157) or without Burch colposuspension (n=165). Brubaker et al demonstrated at 2 years that an additional Burch colposuspension significantly reduced the risk for de novo SUI. Subjective SUI was reported by 38/147 (26%) after additional Burch colposuspension and by 63/155 women (41%) after sacrocolpopexy alone. However, objective testing yielded similar findings in the two groups: 11/116 (9%) and 9/134 women (7%), respectively, demonstrated SUI. The study was terminated prematurely because of the high postoperative SUI rate in women who did not receive concomitant Burch colposuspension and as result of early termination was underpowered. Unfortunately, surgery was only standardised for colposuspension but neither for the paravaginal repair nor for sacral colpopexy with significant variations in use of suture type and graft materials.(67,507) After a follow up of 8 years, Costantini et al in another smaller RCT reported contrary results with 9/31 women (29%) developing SUI after additional Burch colposuspension compared to 5/31 (16%) after sacrocolpopexy alone.(502, 505) A meta-analysis using a random-effects model summarises these two RCT´s with results after more than 12 months (505, 507) According to this model, continent women do not benefit from prophylactic Burch colposuspension when undergoing sacral colpopexy (RR 1.41, 95%CI 0.24-8.21)

De novo SUI is clearly disappointing to women and a validated risk calculator has been developed “The Model Predicting De Novo Stress Urinary Incontinence in Women Undergoing Pelvic Organ Prolapse Surgery” (https://riskcalc.org/FemalePelvicMedicineandReconstructiveSurgery) . It is based on the OPUS and CUPIDO randomised controlled trials evaluating vaginal surgery with or without a mid-urethral sling in women with and without SUI and POP. The model takes into account age, vaginal birth, BMI, diabetes, OAB and preoperative stress test.(508,509) On external validation the accuracy of this model in predicting de novo SUI after prolapse surgery was only slightly higher than that achieved with flipping a

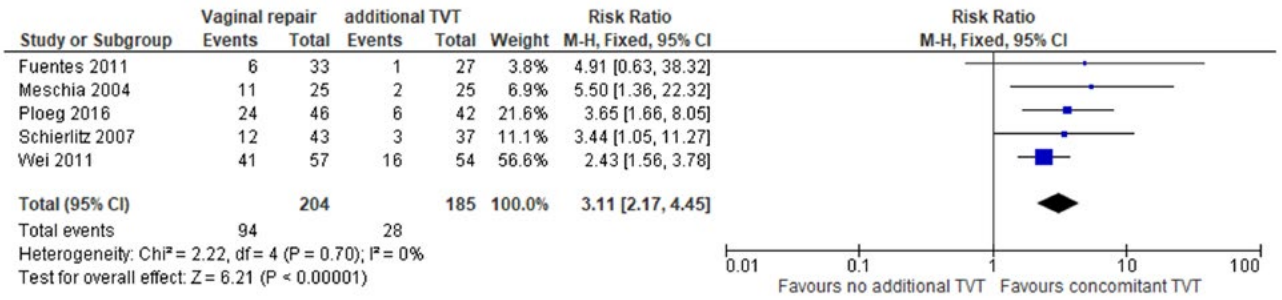

Figure 7: An additional mid-urethral sling at the time of vaginal prolapse repairs in women with occult SUI significantly reduces the risk of new postoperative symptomatic SUI.

coin with a concordance). an index of 0.57; 95% CI 0.46-0.67, P=.048).(509)

2. WOMEN WITH POP AND OCCULT SUI

Women with preoperative occult SUI benefit from the addition of continence surgery to their POP surgery. Five randomised trials assessed postoperative SUI rates in women who were symptomatically dry preoperatively but had a positive stress test with the prolapse reduced.(510-514) With a mid-urethral sling in addition to vaginal prolapse repairs, significantly fewer women complained of SUI (28/185, 15% versus 94/204, 46%; chi-square P<0.001). The meta-analysis of these five trials calculated that a concomitant MUS significantly increased postoperative SUI rates (RR 3.11, 95%CI 2.17-4.45; Fig. 7).

If non-randomised studies are included, the meta-analyses corroborate these findings: In general, a concomitant continence procedure (463, 467, 481, 482, 497, 498, 504, 506, 510, 512-521) improves postoperative SUI rates in women with POP and occult SUI compared to POP surgery alone (459, 463, 469, 482, 498, 510, 512-515, 522) (OR 5.1, 95%CI 3.97 to 6.60; Fig. 4). A concomitant urethropexy (463, 481, 506) at the time of sacrocolpopexy decreases the risk of postoperative SUI (OR 0.14, 95%CI 0.06-0.34) which is also true for a concomitant MUS (504, 521) (OR 0.07, 95%CI 0.03-0.16).

2.1. Women with SUI and POP

Colombo et al (105) compared Burch colposuspension and anterior repair for the treatment of women with anterior vaginal wall prolapse and SUI. While women benefited more from Burch colposuspension with regards to SUI (cure of SUI 30/35, 86% versus 17/33, 52%), anterior repair better corrected the anterior prolapse (cure of cystocele 23/35 versus 32/33).(105) Most urogynaecologists would deem a Burch colposuspension an operation for SUI and not necessarily for anterior vaginal wall prolapse and an anterior repair would be considered for POP rather than for SUI.

Two randomised trials compared vaginal POP repairs with and without an additional MUS in incontinent women.(523,524) As expected, the concurrent continence procedure significantly reduced postoperative SUI rates (RR 0.30, 95%CI 0.19, 0.48). Whether a mid-urethral tape (TVT) is inserted concomitantly or after three months did not result in significantly different success rates based on an “on-treatment” analysis of Borstad et al (83/87, 95% versus 47/53, 89% three months later).(524) Twenty-seven/94 (29%) women were cured of SUI after prolapse surgery alone and did not receive a TVT three months later.(524) As a concomitant MUS represents an additional risk and may not be necessary in a significant number of women, a staged procedure might be considered and adequate counselling appears paramount.

Overall, in women with POP and SUI, compared to POP surgery without a continence procedure, (486,488,489,497,499,512,515,524-528) a concomitant continence procedure increases postoperative SUI cure rates (105,487,490,491,497,506,512,515,524,528-534) (OR 5.49, 95% CI 4.31-7.00; Fig. 5). This was particularly evident for vaginal native tissue repairs with or without MUS (44% versus 12%; OR 5.95, 95% CI 3.99-8.87) and anterior vaginal mesh procedures with or without MUS (45% versus 5%; OR 17.2, 95%CI 9.97-29.75).

In the meta-analysis including non-randomised studies (Fig. 5), concomitant Burch colposuspension or urethropexy at the time or sacrocolpopexy did not significantly reduce postoperative SUI rates in women with POP and SUI (15/48, 31% versus 42/179, 23%; OR 1.48, 95%CI 0.73-2.99). This also applied to MUS and sacrocolpopexy (38/182, 22%; OR 1.65, 95%CI 0.78-3.52).(532-535) One retrospective trial assessed the effect of fascial sling, retropubic or transobturator mid-urethral tapes inserted at the time of abdominal sacral colpopexy (536): The transobturator sling was inferior with an SUI cure rate of 67% in comparison to 84% and 83%, respectively.

It remains unclear why an additional urethropexy at the time of sacrocolpopexy proved beneficial in continent women and not in women with POP and SUI. Based upon the available evidence Fig. 8 represents a decision flow analysis of women undergoing POP surgery with and without SUI.

3. OVERACTIVE BLADDER SYMPTOMS

OAB symptoms may be associated with POP (458) and prolapse surgery may cure or improve OAB but it may also result in new OAB symptoms. The Cochrane review on the surgical management of POP in women with or without incontinence (494) calculated that de novo overactive bladder symptoms developed in 71 of 221 women (32%) undergoing prolapse surgery.

The reported cumulative rate of de novo OAB in women who underwent a transobturator anterior mesh procedure in non-RCTs is 13% (90/712), (483,486-488,491,527,531,537,538) whereas it is 10% (7/71) in the few studies reporting data after anterior repair with or without a mid-urethral tape.(510,539) After sacrocolpopexy with Burch colposuspension de novo OAB occurred in 12/83 (14%) (505, 532) and 2/60 (3%) after sacrocolpopexy with a MUS.(532)

OAB seems to resolve in approximately half of women after any POP operation (259/525, 49%).(495, 514, 527, 533, 539, 540) In a large prospective Finish cohort (n=2933: 81% native tissue repair, 12% vaginal mesh, 7% abdominal mesh with those undergoing concomitant continence surgery excluded) preoperative OAB was identified in 40% and decreased to 18% at 2 years. Reduction in preoperative OAB was more apparent after anterior/apical interventions than posterior compartment surgeries. Preoperative medical treatment of OAB was utilised in 3.3% and vaginal or systemic oestrogen in 82%. De novo OAB occurred in 1-3% and the study methodology did not allow for analysis of associated treatments of OAB symptoms.(541)

Overall, there is wide variation in the rate of de novo OAB (2-32%) after prolapse surgery which may be impacted by undisclosed rates of treatment instigated.

4. URINARY VOIDING DYSFUNCTION

The Cochrane review (494) noted new voiding dysfunction in 57 of 456 (12%) women in seven randomised trials with various prolapse surgeries with or without continence procedures. (105,125,474,505,528,533,542) However, significant heterogeneity exists in defining and reporting urinary voiding problems so a meaningful meta-analysis was not able to be performed and most voiding difficulties are transient.

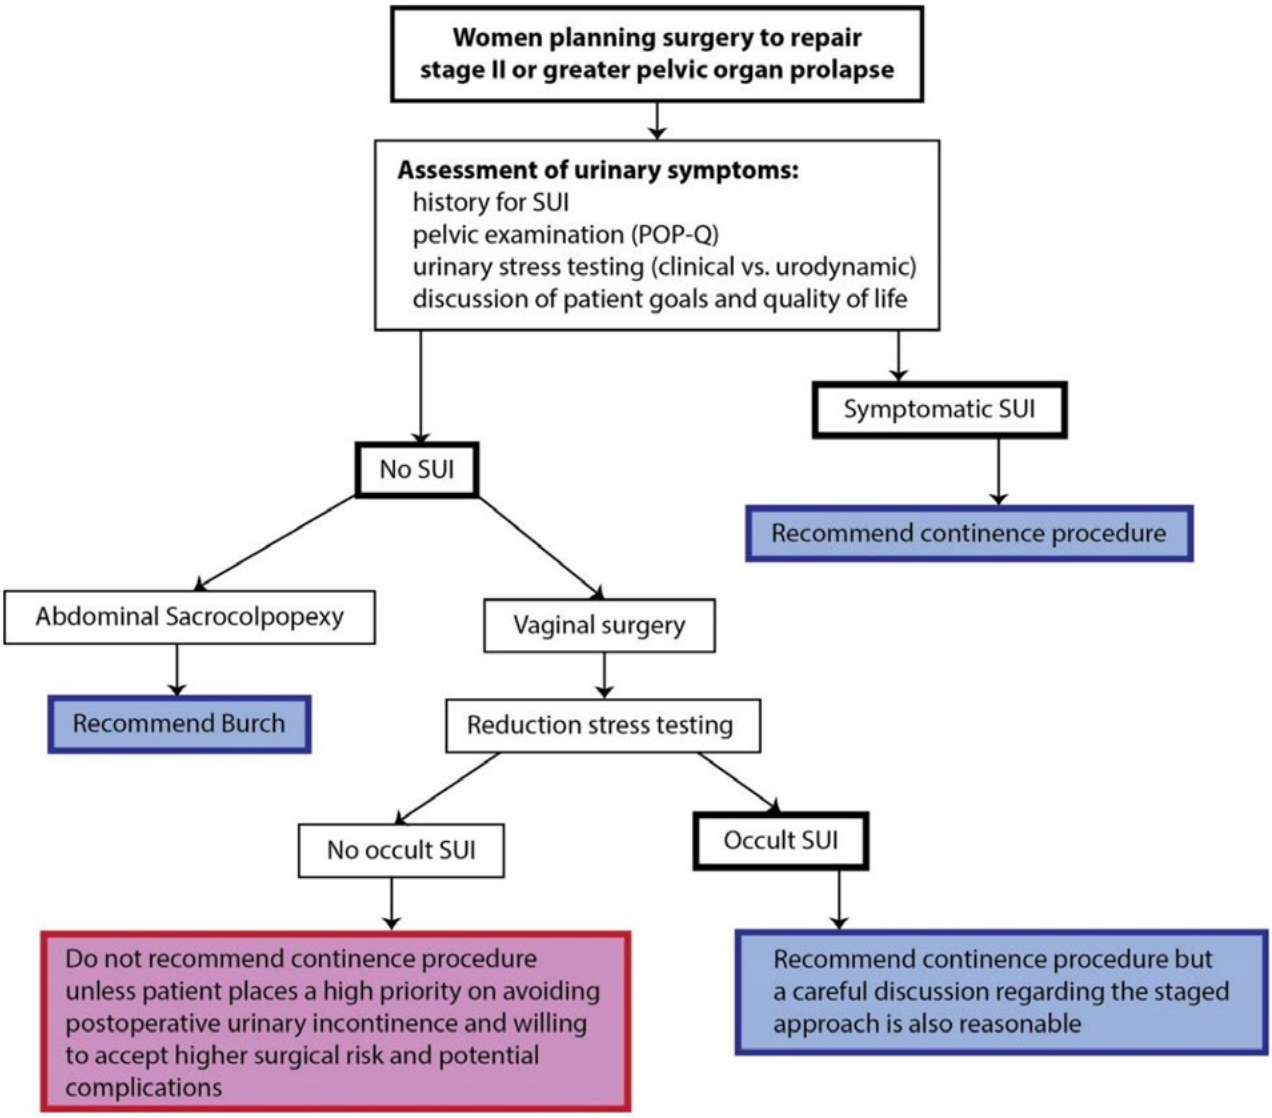

Figure 8. Decision making flow chart for women undergoing prolapse surgery with and without SUI.

After anterior repair, voiding dysfunction ranges from 0% to 37%. (105,150,156,173,510,543)

Anterior repair with or without concomitant vaginal POP surgery resulted in postvoid residuals exceeding 150 ml in 27/126 (21%) in an RCT comparing transurethral and suprapubic catheterisation. (543) After anterior mesh repair, voiding difficulties occur between 5% and 42%.(66,173,487,544-547)

One study looked at postoperative urinary retention defined as the need to discharge the patient with an indwelling catheter because of a failed trial of void.(545) Voiding dysfunction ranged from 34% (10/29) after isolated anterior mesh repair to 42% (30/71) cases after combined anterior and posterior repairs. After isolated posterior repair 8/42 (19%) developed urinary retention. At the 3-months follow up, there were no more voiding complaints.(545)

If there are postoperative voiding problems with residuals exceeding 150 ml, clean intermittent catheterisation is superior to an indwelling catheter for three days with regards to bacteriuria, urinary tract infection and length of required catheterisation according to one RCT(548) and intermittent transurethral catheterisation is equivalent to a suprapubic catheter regime.(543) Insertion of a suprapubic catheter however resulted in more related complications like loss and blockage of the catheter and haematuria.(543) Another RCT (549) reported on the duration of postoperative urethral catheterisation between two and four days after anterior repair and found no differences in voiding dysfunction. This was confirmed by an RCT comparing two and five days of indwelling catheter placement. Longer hospital stay and more urinary tract infections were associated with the five days protocol.(550) Patients do not seem to benefit from postoperative urethral catheterisation beyond two days.(549,550)

Whether preoperative voiding dysfunction resolves after POP repair is rarely adequately described. Lo et al reported that 37/380 women (10%) continued to have voiding dysfunction after native tissue vaginal POP surgery whereas it developed in only 1%. Expectedly, concomitant MUS increased the risk of postoperative voiding dysfunction (OR 3.12, 95 % CI 1.79 - 5.46, $p < 0.001$) (551). Similarly, voiding dysfunction improved in most women after vaginal mesh repairs (40% preop versus 1% postop).(552)

CONCLUSIONS

- Continent women with negative testing for occult SUI do not require a concurrent prophylactic continence procedure. (GoR B)
- In continent women with negative occult SUI testing undergoing sacrocolpopexy, an additional Burch colposuspension may reduce postoperative SUI. (GoR C)
- Anterior mesh repair increases the risk for SUI as compared to anterior repair without mesh in continent women. (GoR B)
- Continent women with occult SUI benefit from POP surgery with concomitant continence procedures as compared to POP surgery without continence intervention. (GoR B)
- In women with POP and SUI, a concomitant continence procedure increases postoperative SUI cure rates. (GoR A)
- Preoperative OAB (40%) resolves in approximately 50% post prolapse surgery although the impact of concomitant non- surgical treatment on this date has not been clarified. (GoR C)
- The rate of de novo OAB varies widely (2-32%). (GoR C)
- Rates of Urinary retention following POP surgery varies from 0-34% and is nearly always temporary. (GoR C)
- Pre-operative urinary retention resolves in as many as 90% post prolapse surgery. (GoR C)

VIII. PELVIC ORGAN PROLAPSE SURGERY AND SEXUAL FUNCTION

The prevalence of sexual dysfunction in patients with pelvic organ prolapse (POP) and other pelvic floor disorders is high, approximately 64%.(553) Therefore, changes to sexual function (SF) are important to women considering prolapse surgery. When women with POP were asked to prioritise the importance of outcomes after surgery, they ranked improvement in sexual function just below resolution of bulge symptoms and improvement in physical function.(554) Other qualitative studies in a urogynaecologic population show that worsening sexual function after surgery is viewed by women as a severe adverse event.(555)

Prior reviews have shown that overall sexual function either improves or remains unchanged after POP surgery.(556-558) Dyspareunia can be reported in clinical trials in a variety of ways, in that it can be due pain with intercourse prior to surgery, postoperative, persistent, or de novo. Many randomised trials on POP surgery report overall sexual function based on validated sexual function questionnaires and dyspareunia, but there is a lack of data on sexual function domains such as: sexual desire, arousal, lubrication, and orgasm. It is not clear how POP surgeries affect these other domains of sexual function and further research in this area is warranted.

It is important to assess sexual function in patients undergoing reconstructive surgery for prolapse in general practice and in research trials. According to the IUGA-ICS Joint Report on the Terminology and Assessment of Sexual Health of Women with Pelvic Floor Disorders, trials should report both on preoperative AND postoperative outcomes for: sexual activity, dyspareunia, and validated sexual function questionnaire scores.(559) Few randomised POP studies report on all these measures, and the overall quality of sexual function outcome reporting is low (Table 26-29).

To measure sexual function, validated questionnaires on sexual function are necessary. Some validated quality of life and symptom questionnaires are inclusive of sexual function, but there are several sexual function questionnaires that are specific to a urogynaecologic patient population. They include the Pelvic Organ Prolapse/ Incontinence Sexual Questionnaire (PISQ), PISQ-12 short form, and PISQ-IR.(560) The PISQ-12 is the most commonly used sexual function questionnaire in prolapse randomised trials. The Female Sexual Function Index (FSFI) is another questionnaire that is commonly used in clinical research on female sexual function, and is commonly utilised, but is not specific to women with prolapse.(561) Unfortunately, in nearly all of the trials that report sexual function post-surgical intervention the primary outcome is not sexual function and as such the trials are frequently under-powered to assess

this outcome. So meta-analysis of data is required to obtain meaningful sexual function results and this is performed understanding that definitions of dyspareunia and evaluation of sexual function may vary creating challenges in data interpretation.

1. SEXUAL FUNCTION AFTER PROLAPSE SURGERY WITH NATIVE TISSUE REPAIRS

Overall, sexual function usually improves or remains unchanged after prolapse surgery with native tissue repairs. Since many vaginal pelvic reconstructive surgeries utilise a combination of apical suspension native tissue repairs and repairs in other vaginal compartments, it is difficult to separate these repairs individually to analyse effects of sexual function. The most level I data in the prolapse surgical literature involves comparing transvaginal synthetic mesh to a variety of native tissue repairs, most commonly in the anterior compartment.

There are several RCTs that look at sexual function in women after sacrospinous ligament fixations (SSLF), and all show an improvement in overall sexual function scores based on PISQ-12 scores. (216, 217, 562) Similar to this, surgical trials for uterosacral ligaments suspensions show improvement in overall sexual function, as all PISQ-12 scores increased postoperatively.(216,217,323)

Posterior colporrhaphy/repairs previously involved levator-ani plication which is associated with high rates of dyspareunia.(377) However, modern posterior repairs avoid this step while still plicating the rectovaginal muscularis. Two randomised trials look specifically at posterior repairs, and although total postoperative dyspareunia ranges from 20-27%, this is still lower than dyspareunia preoperatively in the same patient population.(392,393) It would be more important to examine the rate of de novo dyspareunia in the these RCTs, but neither trials report on this. Another RCT comparing women undergoing posterior repairs with standard postoperative recovery to women with posterior repairs using postoperative vaginal dilators, showed a de novo dyspareunia rate in the control group to be 3.8% at 6 months.(563) As for overall sexual function scores, one RCT reported PISQ-12 scores remained similar while the other reported significant improvement after posterior repairs.(392,393)

2. SEXUAL FUNCTION AFTER PROLAPSE SURGERY WITH MESH

Although transvaginal synthetic mesh has been controversial and banned in several countries internationally, significant quality data is available regarding changes in sexual function. Meta-analysis of sexual function outcomes from 16 RCTs with 24 publications evaluating 3243 women with follow-up ranging from 6-84 months, comparing transvaginal mesh and native tissue repairs are summarised in Table 26. While, based on 16 studies included, the rates of dyspareunia (11.2 versus 9.9%, RR 1.13 95%CI 0.84, 1.51 P=0.42) and de novo dyspareunia (7.1 versus 6.5% RR 1.1 95%CI 0.68,1.77 p=0.61) were similar between the groups post intervention, the sexual function outcomes based upon PISQ scores were significantly higher in the non-mesh group than after the transvaginal mesh interventions as seen in Forrest plot Figure 9. These results suggest that while the rate of dyspareunia, new and or persisting is similar after vaginal repair with or without transvaginal mesh that sexuality and sexual function more generally as measured in PISQ is better after vaginal repairs without mesh than in those with transvaginal mesh. Risk factors for pelvic pain and dyspareunia after TV mesh surgery includes younger age, fibromyalgia, poorer physical health, and somatisation.(564)

Details on 10 RCTs evaluating sexual function in 1462 women comparing vaginal biological grafts to native tissue repairs are listed in Table 27. There was no difference between biological grafts and native tissue repairs in the rates of dyspareunia (11.4 versus 10% RR 1.1 95% Ci 0.7,1.6 p=0.68) and de novo dyspareunia (2.7 versus 3.0% RR 0.9 95% CI 0.2,5.2 p=0.9). In four RCT's comparing anterior colporrhaphy to porcine skin graft or porcine small intestine submucosa mesh, no differences were found in dyspareunia and improvement on PISQ-12 scores.(156,565-567)

For mesh in the posterior compartment specifically, fewer RCT's were performed comparing native tissue repair to mesh repair. Paraiso et al compared three techniques (posterior colporrhaphy, site-specific repair and use of porcine small intestine sub mucosa). (393) No differences in sexual outcome were found between the groups and PISQ scores improved after surgery in all three groups.

3. SEXUAL FUNCTION AFTER PROLAPSE SURGERY WITH SACROCOLPOPEXY

Meta-analysis of three RCTs evaluating 325 women comparing abdominal sacrocolpopexy to native tissue repairs are listed in Table 28 and demonstrated a non-significantly lower rate of dyspareunia (17.5 versus 28.6% RR 0.61 95% CI 0.3, 1.4 p=0.23) and de novo dyspareunia (4.8 versus 8.1%, RR 0.6 95% CI 0.1, 3.3 p=0.66) after sacrocolpopexy as compared to native tissue repairs.

Table 29 is a meta-analysis of data on sexual function from 5 RCTs evaluating 514 women ranging from 6 to 48 months between transvaginal mesh and sacrocolpopexy for apical prolapse. The results demonstrate a higher rate of dyspareunia (30 versus 14% RR 2.1 95% CI 1.1, 4.2 p=0.04) and a non-significantly higher rate de novo dyspareunia (19 versus 7% RR 2.95 95% CI 0.82, 10.6 p=0.1) following transvaginal mesh as compared to sacrocolpopexy.

Culligan and Salamon et al reported laparoscopic sacrocolpopexy procedures have a positive impact on sexual function. In this trial comparing mesh to biologic grafts, laparoscopic sacrocolpopexy with mesh showed dyspareunia decreased from 51% preoperatively to 20% postoperatively.(568, 569) Another trial by Maher et al, concluded that sexual function remains similar after sacrocolpopexy, although dyspareunia rates tend to decrease.(66,570) De novo dyspareunia ranges 5-8%.(66,569,571)

CONCLUSION

- While synthetic transvaginal mesh and non-mesh vaginal repairs have similar rates of de novo and total dyspareunia the transvaginal mesh repair has poorer sexual function as measured by PISQ when compared to non-mesh repairs. (GoR B)
- Synthetic transvaginal mesh has higher rate of total dyspareunia when compared to sacrocolpopexy (GoR B)

- When comparing vaginal biologic grafts to vaginal native tissue repairs, there are similar decreases in postoperative dyspareunia and similar changes in sexual function (GoR B)
- Sexual activity preoperatively in patients undergoing POP reconstructive surgery ranges 42-65%, while postoperative sexual activity ranges 32-62%. (GoR C)
- De novo dyspareunia rates for native tissue vaginal repair and sacrocolpopexy range from 2-8% (GoR C)
- Total dyspareunia rates generally decrease following native tissue repairs and sacrocolpopexy from 15-30% preoperatively to 8-20% postoperatively (GoR C)
- It is essential to use validated questionnaires measuring sexual function in women before and after prolapse surgery. We also recommend reporting sexual activity and dyspareunia rates de novo, pre-, and post-intervention in all patients. (GoR C)

IX. COMPLICATIONS AND METHODS OF PREVENTION

While pelvic reconstructive surgery for genital prolapse, with or without mesh, results in improved prolapse related symptoms and quality of life in most cases (595) (Level 1) complications are inevitable.

A national Scottish database cohort study has been done between 1997 and 2016 on 18 986 women underwent a first single prolapse procedure, 1279 (7%) of which used mesh.(596,597) Compared with non-mesh repair, mesh repair of anterior compartment prolapse was associated with a similar risk of immediate complications (aRR 0.93 [95%CI 0.49-1.79]); an increased risk of further incontinence (aIRR 3.20 [2.06-4.96]) and prolapse surgery (1.69 [1.29-2.20]); and a substantially increased risk of later complications (3.15 [2.46-4.04]). Compared with non-mesh repair, mesh repair of posterior compartment prolapse was associated with a similarly increased risk of repeat prolapse surgery and later complications. No difference in any outcome was observed between vaginal and, separately, abdominal mesh repair of vaginal vault prolapse compared with vaginal non-mesh repair.

Many countries (US, UK, Australia, France) have prohibited access to vaginal meshes due to an unfavourable risk/benefit ratio and a high incidence of mesh-related complications.

On April 16, 2019, the FDA ordered all manufacturers of surgical mesh intended for transvaginal repair of vaginal prolapse to immediately stop selling and distributing their products.(598) The FDA has determined that the manufacturers have not demonstrated reasonable assurance of safety and effectiveness for these devices, which is the premarket standard that now applies to them since the agency reclassified them into class III (high risk) in 2016. Women who have received transvaginal mesh for the surgical repair of pelvic organ prolapse should continue with their follow-up care. There is no need to take additional action if they are satisfied with their surgery and are not having any complications or symptoms. They should notify their health care provider if they have complications or symptoms, including persistent vaginal bleeding or discharge, pelvic or groin pain, or pain with sex.

In 2011, the IUGA (International Urogynecological Association) and the ICS (International Continence Society) published a specific classification of complications related to pelvic reconstructive surgery using prostheses.(80) That classification has been developed to encompass to all possible physical complications involving the use of a prosthesis or graft in a female pelvic floor surgical procedure. Both insertion complications (e.g. trocar related) and healing abnormalities are covered. Whilst this creates a large number of possible complication scenarios, appropriate organisation has still been possible by category (C), time (T) and site (S). A key advantage of a standardised classification is that all parties involved in female pelvic floor surgery will be referring to the same clinical issue. It has been shown in several studies that this classification can significantly add to clarity in reporting mesh related complications,(141, 599, 600) even if training is necessary to optimise inter-observer reliability,(601) which has been criticised by others. (602-604)

Other classification, such as Clavien-Dindo classification, has also been used. (137) In a French multicenter randomised controlled trial on 262 women with cystocele stage ≥2, without previous prolapse surgery, laparoscopic mesh sacropexy (LS) and transvaginal mesh repair (TVM) were compared on the rate of complications ≥ grade II according to the modified Clavien-Dindo classification at one-year. The rate of complications ≥ grade II was lower after LS than after TVM, but did not meet statistical significance (17% vs 26%, treatment difference 8.6% [95%CI -1.5 to 18]; p=0.088). The rate of complications of grade III or higher was nonetheless significantly lower after LS (LS=0.8%, TVM=9.4%, treatment difference 8.6% [95%CI 3.4%; 15%]; p=0.001).

Using the same complication classification after transvaginal mesh repair for prolapse Barski et al (605) performed a systematic review and reported much higher rates of complications than reported above for native tissue POP repairs. Eleven randomised controlled and nine prospective studies from 2008 to 2013 with 2,289 patients (most POP-Q ≥ II, median follow-up 12 months) were included. The total complication rate was 27% in anterior, 20% in posterior, and 40% in combined mesh repair group. Complications of at least Clavien-Dindo grade 3 (requiring surgical, endoscopic or radiological intervention) occurred in 8% anterior, 3.5% posterior, and 13% of combined mesh repairs. No differences were found for reoperation rates for POP in mesh repairs as compared to non-mesh repairs (2 versus 3%).

1. REOPERATION AFTER VAGINAL SURGERY

Mairesse et al have recently published a retrospective population-based cohort study of all French surgical procedures for prolapse from 2008 to 2014.(248) A total of 310,938 patients were studied. Rates of death, admission to intensive care unit, readmission for early (30-day) complications, and reoperation for recurrent prolapse were 0.07%, 0.45%, 2.5% and 4.4%, respectively. Concomitant hysterectomy at the first surgery was associated with a significantly lower risk of reoperation for recurrence (HR 95%CI = 0.51 [0.49-0.53]. The most frequent reasons for early readmission were local infection (32.8%), haemorrhage (21.4%) and pain (17.2%). Risk factors for complications were obesity, low surgical volumes hospital and associated incontinence surgery.

Table 30 shows the reoperation rates after vaginal polypropylene mesh surgery versus native tissue repair for specific (linked to the mesh) complications from randomised controlled trials. The mean rate of reoperation for mesh-related complications was 6.6%, mainly for vaginal mesh exposure. The rate of reoperation for prolapse was similar in both the transvaginal mesh group and native tissue repair, 23/871 (2.6%) vs 33/861 (3.8%) (p=0.16) (Level 1), but follow-up was less than 36 months in the majority of trials.(119, 121, 122, 129, 131, 132, 173, 472, 474, 575, 577, 578, 606, 607)

In a retrospective study of 524 Prolift mesh, with a median follow-up of 38 months (range, 15-63), global reoperation rate was 11.6%, including surgery for urinary incontinence (6.9%), mesh-related complications (3.6%), and prolapse recurrence (3%) (Level 4).(608)

To estimate the risk of repeat surgery for recurrent prolapse or mesh removal after vaginal mesh versus native tissue repair for anterior vaginal wall prolapse, Jonsson Funk et al had utilised longitudinal, healthcare claims from 2005 to 2010 to identify women ≥18 years who underwent an anterior colporrhaphy with or without concurrent vaginal mesh. They identified 27,809 anterior prolapse surgeries with 49,658 person-years of follow-up. Of those, 6,871 (24.7%) included vaginal mesh. The 5-year cumulative risk of any repeat surgery was significantly higher for vaginal mesh versus na-

tive tissue (15.2 % vs 9.8 %, p<0.0001) with a 5-year risk of mesh revision/removal of 5.9%. The 5-year risk of surgery for recurrent prolapse was similar between vaginal mesh and native tissue groups (10.4 % vs 9.3 %, p=0.70) (Level 3). The use of mesh for anterior prolapse was associated with an increased risk of any repeat surgery, which was driven by surgery for mesh removal.(609)

In a study based on prospectively collected data from the Swedish National Register for Gynaecological Surgery, including 6247 anterior colporrhaphy and 356 non-absorbable mesh, reoperation rate within 12 months was higher in the mesh group, OR = 6.87 (CI 3.68-12.80) (Level 3).(610)

In a retrospective study based on 445 patients (including 43.5% for pelvic organ prolapse) with complications whom underwent mesh removal laparoscopically, via groin dissection and/or transvaginally in three tertiary referral centres in the US.(611) In patients who had POP mesh removal, 42.3% had an anterior TVM, 30.6% had a posterior TVM, 14% had both anterior and posterior TVMs, and 13.1% underwent sacrocolpopexy mesh removal. Complications encountered during mesh revision/removal surgery were: two ureteral injuries during anterior vaginal wall mesh removal, and two rectal injuries during posterior vaginal wall mesh removal.

In the recent French multicentre randomised controlled trial Prospere, on 262 women with cystocele stage ≥2, without previous prolapse surgery, the total reoperation rate was lower after laparoscopic mesh sacrocolpopexy (LS) compared to transvaginal mesh repair (TVM), but did not meet statistical significance (LS=4.7%, TVM=10.9%, treatment difference 6.3% [95%CI -0.4 to 13.3]; p=0.060).(137) (Level 2).

In the UK Prospect study, a pragmatic, parallel-group, multicentre, randomised controlled trials, on 1348 women, serious adverse events such as infection, urinary retention, or dyspareunia or other pain, excluding mesh complications, occurred with similar frequency in the different groups (vaginal standard repair alone, mesh augmentation and graft augmentation) over 1 year (mesh trial: 31/430 [7%] with standard repair vs 34/435 [8%] with mesh, RR 1.08, 95%CI 0.68 to 1.72; p=0.73; graft trial: 23/367 [6%] with standard repair vs 36/368 [10%] with graft, RR 1.57, 0.95 to 2.59; p=0.08). The cumulative number of women with a mesh complication over 2 years in women actually exposed to synthetic mesh was 51 (12%) of 434.(396)(Level 2)

2. REOPERATION AFTER ABDOMINAL SURGERY

Several techniques have been described (with the use of non-absorbable sutures and with or without mesh placement) concerning the treatment of pelvic organ prolapse (POP) by abdominal route: sacrocolpopexy (SCP), sacrocervicopexy (SCerP), sacrohysteropexy, anterior abdominal wall hysteropexy, uterosacral hysteropexy and uterosacral ligament suspension (USLS) . These procedures can be performed by an open laparotomy, a laparoscopy or a robotic-assisted laparoscopic approach (614) and lateral suspension.(615) Data are lacking concerning comparative studies between these different procedures and between abdominal and vaginal procedures. However, in 2020, sacrocolpo/cervico/hysteropexy was the most evaluated procedure and this procedure was considered to be the standard treatment of POP via the abdominal route.

Rates of anatomical recurrence following laparoscopic sacral colpopexy or hysteropexy range from 4 to 18% at 12-14 months of follow-up (Level 2). Mean rates of reoperation for prolapse recurrence and for de novo stress urinary incontinence after open abdominal sacral colpopexy are 2% and 5%, respectively (Level 3).(46,156,326,616-619)

Population-based cohort studies observed similar rates of reintervention following abdominal and vaginal POP surgeries, with or without the use of a mesh (597,620) (Level 3). Nevertheless, RCTs observed that the total reoperation rate was lower after laparoscopic mesh sacropexy compared to transvaginal mesh repair.(137,570)(Level 2)

RCTs observed similar reoperation rates following open or laparoscopic route for sacral colpopexy (339,621)(Level 3).

Table 18 demonstrates that the total reoperation rate for laparoscopic sacral colpopexy is 5.1%, with 2.1% representing complications and 2.9% representing reoperations for prolapse.

Higher recurrence rates (up to 60% at 6 years follow-up) have been reported in some retrospective series.(622)

The rate of reoperation for recurrences after laparoscopic sacrocolpopexy is significantly higher with the use of porcine dermis grafts in comparison to polypropylene mesh.(623) (Level 3)

3. VAGINAL MESH EXPOSURE

According to AUGS/IUGA,(614) only the term “mesh exposure” with a description of where that exposure is located (e.g., “vaginal mesh exposure” or “rectal mesh exposure”) should be used.

3.1. Prevalence of vaginal mesh exposure after vaginal mesh surgery

It is difficult to know the exact rate of vaginal mesh exposure, as the definition of exposure is variable between studies and meshes used are different. Table 31 shows the rate of exposures after vaginal polypropylene mesh surgery in the 14 currently available randomised controlled trials, mainly with different kinds of four-arm trans-obturator meshes. In these trials, the mean rate of exposure was 12%, and the mean rate of reoperation for vaginal mesh exposure was 6% (Level 1).

According to the available literature, polypropylene collagen-coated mesh does not seem to give any advantage in comparison to classic non-absorbable mesh regarding the vaginal mesh exposure rate (Level 1)(132,135,624,625). Furthermore, vaginal mesh exposure has also been reported as high as 6.9% with the use of biological implant,(626) even if others have found low rates using biological implants, between 0 to 1.4%.(627,628)

Partially absorbable meshes are also associated with a risk of vaginal mesh exposure. In a RCT conducted in 163 women comparing native tissue surgery and partially absorbable mesh vaginal surgery, the prevalence of vaginal mesh exposure was 6%.(613)

In recent series, ultra-light weight meshes (<30gr/m²) used with trans-obturator arms (OPUR) (Enikeev et al, Urologia, 2020) or anterior sacrospinous fixation were associated with a low rate of mesh exposure (1%) at medium-term review (Level 4).(135) However, a comparative retrospective series showed very low but similar rates of mesh exposure following UPHOLD (ultra-lightmesh) and PROLIFT (non ultra-light mesh) placement (1/330 (0.3%) vs 17/2258 (0.7%), respectively; p=0.72) (Level 3) (Kato et al, Int J Urol, 2021).

Furthermore, several case series have reported a low rate of vaginal mesh exposure after anterior-apical single incision techniques, from 0 to 3.4% (Level 4), (134,135,629-632) which was significantly lower in comparison to trans-obturator meshes,(633) although there is no available RCT showing that these rates are due to the technique, rather than to the surgeons experience or the lightweight mesh.

A recent RCT has compared vaginal hysteropexy using light-mesh and vaginal hysterectomy with uterosacral ligament suspension on 175 postmenopausal women at 9 clinical sites in the US between 2013 and 2015, and followed up to 3-year for 97% of the initial population.(136) While vaginal mesh exposure was higher in the mesh group (8% vs 0%), other complications were higher in the non-mesh group (ureteral kinking 7% vs 0%, granulation tissue after 12 weeks 11% vs 1%, and suture exposure after 12 weeks 21% vs 3%).

Although there is a lack of evidence supporting the use of posterior mesh vaginally for rectocele or enterocele repair,(595) a few studies have reported a low vaginal mesh exposure rate in the posterior compartment, between 2 to 3.8%.(634,635)

Data is becoming available of long-term rates of mesh exposure. Letouzey et al, who used the Gynemesh® on 63 patients with a mean follow-up of 6.5 years, the vaginal mesh exposure rate was 16% (10/63), all of which underwent surgical correction.(636) In the study by Heinonen et al, who used the Prolift® mesh on 140 patients with a mean follow-up of 7 years, the vaginal mesh exposure rate was 23% (32/140), even though most of these were small (less than 1cm in 25/36) and asymptomatic (24/32).(637) In comparison Meyer et al, who used the Prolift® mesh as well, on 48/208 patients with a mean follow-up of 7 years (range 5.8 to 8.1), the vaginal mesh exposure rate was 6% (3/48).(638)

3.2. Prevalence of vaginal mesh exposure after abdominal surgery

Vaginal mesh exposure rate following laparoscopic sacral colpopexy or hysteropexy is 2% (mean, range 1-7%) (Table 20) (Level 2). Vaginal mesh exposure rates were comparable regardless the surgical approach (open, laparoscopic, robot-assisted) (Level 2).(639,640) The risk of vaginal mesh exposure is significantly increased if hysterectomy is performed concomitantly (8.6%), in comparison to sacral colpopexy for post-hysterectomy prolapse (2.2%) (p<0.05) (641) (Level 2) or if permanent sutures are utilised (330,642). In contrast a recent RCT reported no difference in the rate of mesh exposure when comparing permanent and absorbable sutures at 12 months however the rate of mesh exposure was high at 6% in both groups and maybe explained by all undergoing concomitant hysterectomy.(643)

3.3. Risk factors of vaginal mesh exposure

Maher et al, have shown a non-significant increased rates of vaginal mesh exposure and reoperation for vaginal mesh exposure after vaginal mesh surgery in comparison to laparoscopic sacrocolpopexy (13% vs 2%, p=0.07 and 9% vs 2%, p=0.11, respectively). (324)(Level 2) However, that was not the primary endpoint of the study, and that study was underpowered for this parameter.

Younger age, higher parity, premenopausal status, diabetes mellitus, smoking, concomitant hysterectomy and surgery performed by a junior surgeon are significant risk factors for vaginal mesh exposure after female pelvic floor reconstructive surgery (Level 3).(644)

Concerning vaginal mesh surgery, obesity (BMI>30 kg/m², OR=10.1) has been shown by some authors to be an independent risk factor for vaginal mesh exposure.(645) However, others have reported no difference in the rate of mesh exposure related to BMI, in a study on 200 patients with advanced pelvic organ prolapse treated by vaginal sacrospinous ligament fixation with anterior mesh repair as primary surgery with an exposure rate of 4.1% at a mean follow-up of 36 months.(646) Furthermore, a recent paper on 201 patients with a mean mesh exposure rate of 8.5% at a mean follow-up of 14 months has reported that the BMI may negatively correlate with exposure rates (12.9% for BMI less than 25 kg/m, 9.5% for BMI of 25 to 29.9 kg/m, 3.1% for BMI of 30 to 34.9 kg/m, and 0% for BMI greater than or equal to 35 kg/m).(647)

Smoking has also been shown to be an independent risk factor for mesh exposure after vaginal mesh surgery [OR=3.1 to 3.7].(648-651) With regard to sacrocolpopexy, smoking [OR=5.2; 95%CI 1.7-16] is also an independent risk factor for vaginal mesh exposure. (253)

Current data on the impact of ageing on mesh complications are conflicting and no conclusion can be drawn.(253,257,645,652-654) In a recent study of 217 patients who underwent vaginal sacrospinous ligament fixation with anterior mesh repair for primary prolapse surgery, outcome measures were observed in cohorts of two age groups (<75 years and ≥75 years), with a mean follow-up of 34 and 36 months respectively. Although older women had significant-

ly more preoperative comorbidities, perioperative complications showed no difference between the two groups.(263) On the other hand, in a case-control study comparing mesh exposure requiring surgical revision (n=48) and controls who had no mesh exposures (n=48), the adjusted odds ratio of being one year older was 0.96 (95% CI 0.92-1.0) among women with mesh exposure.(650) Overall, it has been shown that although the absolute risk of death is low, elderly women have a higher risk of mortality and morbidity following urogynaecology surgery.(655) Among 264,340 women, increasing age was associated with a higher mortality risk per 1000 women (<60 years, 0.1; 60-69 years, 0.5 [OR 3.4; 95% CI 1.7-6.9]; 70-79 years, 0.9 [OR 4.9; 95% CI 2.2-10.9]; >80 years, 2.8 [OR 13.6; 95% CI 5.9-31.4]; P<.01) and a higher risk of complications per 1000 women (<60 years, 140; 60-69 years, 130; 70-79 years, 160; >80 years, 200 [OR 1.4; 95% CI 1.3-1.5]; P<.01). Furthermore, elderly women 80 years and over who underwent obliterative procedures had a lower risk of complications compared with those who underwent reconstructive procedures (17 vs 24.7%, P<.01).(655)

Sexual activity has been reported to be a risk factor for vaginal mesh exposure after vaginal mesh surgery(636,654)(Level 3). However, this could simply reflect that those who are sexually active are more likely to identify a mesh exposure than those who are not.

A bleeding complication at the time of mesh implantation (excessive bleeding >500, post-operative haematoma requiring drainage or embolisation) has also been shown to be an independent risk factor for mesh exposure requiring reoperation after vaginal mesh surgery [OR=7.25, 95% CI 1.47-35.66].(650)

Parity greater than two has also been shown to be an independent risk factor for mesh exposure after vaginal mesh surgery [OR=2.64, 95% CI 1.07-6.51].(649)

No study has shown that the following are significantly associated with mesh exposure: diabetes mellitus, corticosteroid use, immunosuppressive therapy, previous pelvic irradiation, history of previous mesh exposure, vaginal atrophy. However, many studies have shown that in other surgical specialties poorly controlled diabetes mellitus is a risk factor for post-operative infection. One study has reported that somatic inflammatory disease (mainly rheumatoid arthritis) is independent risk factor for mesh exposure after vaginal mesh surgery [25% (3/12) vs 7.6% (20/264), OR 5.11, 95% CI 1.17-22.23].(649) Somatic inflammatory disease (rheumatoid arthritis, Sjögren´s disease, lupus erythematosus) may by themselves influence wound healing but treatment is often accompanied by immunosuppressant medications which may prolong wound healing.

3.4. Treatment of vaginal mesh exposure after vaginal mesh surgery

Vaginal mesh exposure, both after vaginal mesh surgery or sacrocolpopexy is usually associated with vaginal discharge, and sometimes pain, dyspareunia, vaginal infection, and rarely abscess or cellulitis.(656,657)(Level 3). The choice of treatment has to take into account the type of mesh implanted (need to obtain previous surgical records), clinical symptoms, location and size of exposure. All cases with abscess or cellulitis need an immediate reoperation to remove the maximum (if possible, all) of the foreign material.

In cases of mesh exposure after vaginal mesh surgery, if there is no abscess or cellulitis, medical treatment is usually undertaken using local oestrogens and/or local antiseptic. However, medical treatment efficacy is low at 28% (Table 31) (Level 3).(234,651,657-662)

After failure of medical treatment, a reoperation under local or general anaesthesia is generally performed, in order to remove the exposed portion of the mesh and to close the vaginal epithelium. Although technically difficult in some cases, mesh excision was safe with resolution of almost all presenting symptoms.(140,665) Conversely, for others, recurrence was reported in up to 29% of patients with no change or worsening symptoms (recurrent discharge, persistent pelvic pain).(666) Furthermore, up to 62% of treated patients could require multiple surgical procedures.(667,668) Efficacy of surgical excision for vaginal mesh exposure after vaginal mesh surgery is 91% and summarised Table 32

A model to compare medical treatment and surgical excision has favoured surgical excision over conservative treatment in the initial management of mesh exposure following vaginal prolapse repair with synthetic mesh. However, in this model, the difference in Quality Adjusted Life Year (QALYs) between strategies was less than the Minimally Important Difference (MID). Therefore, the strategies are likely similar overall. Individual patient characteristics may ultimately drive clinical decision-making for this surgical complication. (670,671)

Furthermore, spontaneous evolution of asymptomatic (no vaginal discharge, no sexual problems) and small (≤1cm²) mesh exposure in the long-term could be without specific complications, allowing expectant management (Level 4).(672,673)

Table 31. Efficacy of medical treatment for vaginal mesh exposure after vaginal mesh surgery.

Hansen,(666)	Different mesh kits	2/3
Wong, 2013 (668)	Different mesh kits	18/20
Firoozi, 2012 (140)	Different mesh kits (Prolift, Apogee/Perigee, Avaulta)	20/23
Total		**93/102 (91.2%)**

Abbreviation: PP: polypropylene, TVM: trans-vaginal mesh

In a study cohort consisting of 847 patients, Wong et al have reported 53 (6.2%) vaginal exposures after both vaginal (34/393, 8.7%) and abdominal surgery (19/454, 4%). Concerning treatment, permanent mesh exposures resolved most often after surgical excision (18/20, 90%) compared with office excision (6/14, 43%), vaginal oestrogen (6/33, 18%), or expectant management (1/3, 33%) (P<.001) (Level 3).(668)

According to AUGS/IUGA,(614) the different surgical procedures for mesh related complication should be classified as follow:

- Mesh Revision: Either no mesh is removed (e.g., dissecting and primarily closing vaginal epithelium), or a small edge of mesh is removed such that the structural integrity of the implant is left intact.
- Partial Vaginal Mesh Excision: A segment/component of the mesh is removed or transected, such that the structural integrity of the implant is altered.
- Complete Vaginal Mesh Excision: The entirety of the mesh that is in contact with the vagina is excised.
- Extra-vaginal Mesh Excision: Removal of segments or components of mesh beyond, or not in contact with, the vagina
- Total Mesh Excision: The surgical goal is the removal of 100% of the implant.

A new joint position statement on the management of mesh-related complications for both exposure and pain/dyspareunia has been published by AUGS and IUGA.(674)

3.5. Treatment of vaginal mesh exposure after abdominal surgery

In cases of vaginal mesh exposure after sacrocolpopexy, most authors report reoperation by the vaginal approach as first line, (262,330,616,675) because of the risk of spondylodiscitis and of the very low success rate of medical treatment (<15%). (253,262,676,677)

However, some authors reported good success rate (10/28 (35%) following vaginal oestrogen and/or antibiotics +/- trimming of the mesh in the office for vaginal mesh exposure after sacral colpopexy using polypropylene mesh.(678)(Level 4) Then if recurrence occurs after vaginal mesh excision, or in case of associated pelvic infection, total mesh removal by laparoscopy or laparotomy has been described. (679,680)(Level 4)

The success (resolution of vaginal mesh exposure) rate of partial mesh removal (resection of the exposed/extruded) portion of the mesh is high (80-90%) but additional surgical revision is sometimes required.(678)(Level 4) The outcome (improved or cured pelvic pain) following partial or complete removal of the mesh, ranged from 50 to 100% in observational series.(681)

4. VISCERAL (BLADDER, RECTUM) MESH EXPOSURE

There was no visceral mesh exposure reported in the randomised controlled trials after vaginal mesh surgeries, but follow-up was short. Late bladder or ureteric and rectal exposure have been reported after vaginal surgery (Level 4).(637,682,683)

In a large Japanese retrospective cohort study on 2648 patients who underwent transvaginal mesh prolapse surgery between 2006 and 2017, the rates of vaginal, bladder, ureter and rectal exposure were 0.68%, 0.38%, 0.08% and 0.15%, respectively.(684)

Visceral (bladder, rectum) mesh exposure have been reported rarely (< 0.1%) following sacral colpopexy or hysteropexy (OS, LS, RALS) (Level 4).(685,686)

Concerning non-mesh vaginal surgery, a recent study on 91 litigations in the US (687) has shown that the leading allegation of malpractice was negligence of surgery, whereas the most common complication was urinary tract injury (26%), followed by the need for additional surgery (24%), and new postoperative urinary symptoms (24%).

5. INFECTIOUS COMPLICATION

There is no clear definition of bacterial colonisation around a mesh or mesh infection. Consequently, the rate of infection is currently unknown.(685) Some studies have reported up to 80% bacterial mesh colonisation.(688,689) However, the rate of relevant clinical infection (abscess, cellulitis, spondylodiscitis) does not seem to be more than 1%, after both sacrocolpopexy (Level 4) (690-693), or vaginal mesh surgery (Level 4).(694-696)

In a cohort of 684 polypropylene mesh implanted vaginally (TVM procedure), the rates of pelvic abscess and cellulitis have been reported to occur in only 0.29% and 0.15%, respectively.(697) (Level 4).

One case of Actinomyces infection appearing five years after trocar-guided transvaginal mesh prolapse repair was recently reported.(698)

Severe pelvic infection has also been described after native tissue repair, including total colpocleisis.(699)

A recent study compared rates of perioperative complications of native tissue versus vaginal mesh repairs, using the National Surgical

Quality Improvement Program (NSQIP) database on 10 657 vaginal reconstructive procedures without mesh and 959 mesh-based repairs. Procedures with mesh had a higher rate of organ surgical site infection (SSI) (0.52% vs 0.17%, P = 0.02).(700)

More recently, Veit-Rubin et al. have shown that abnormal vaginal microbiome could be associated with vaginal mesh complications (701). They have shown that the presence of Veillonella spp. could be associated with mesh contraction, but they were not able to identify vaginal microbiotic dysbiosis as a factor associated with exposure.

Spondylitis had been reported rarely following laparoscopic sacral colpopexy or hysteropexy. The prevalence of this complication ranges from 0.1 to 0.2% (see Table 20). Cases of spondylodiscitis have been reported following laparoscopic sacral colpopexy with tacks, but also with sutures and it is impossible to determine with certainty whether it is the mesh material itself, the sacral colpopexy system, the vaginal fixation system or the exposure which was the cause of, or promoted, the spondylitis (probably multifactorial in origin).

Pelvic abscess has also been reported rarely following sacral colpo/hysteropexy.

A retrospective comparative series (Level 4) observed a very good agreement between MRI findings (loculated collection or tracking abscess or sinus tract or osteomyelitis) and surgical findings for mesh infection.(702,703) However, this series included only 11 cases of mesh infection.

6. PELVIC PAIN

6.1. Pelvic pain after vaginal surgery (with/without mesh, including mesh contraction)

The aetiology of chronic pelvic pain after vaginal mesh placement is variable, and the most significant causes include pelvic floor muscle spasm, pudendal neuralgia, and infection.(704) Obturator muscles laceration with consequent oedema provoked by the mesh arm could also explain pain. In such cases, Magnetic Resonance Imaging (MRI) will look for obturator muscle hyper-intensity consistent with muscular oedema and pain could be helped by oral corticosteroids.(705) The rate of polypropylene mesh-related pain reported ranges between 4 and 11% according to the definition used (Level 3) (119, 121, 173, 474, 606, 660, 661, 697). In the 2011 American FDA report regarding transvaginal mesh, vaginal pain and dyspareunia were the most common adverse events reported and vaginal pain and dyspareunia were also the most common indications for reoperation following transvaginal mesh in the report by Tijdink et al.(625) These reports contrast with the common perception in the literature that mesh exposure is the commonest complication associated with transvaginal meshes and requires ongoing evaluation.

Mesh contraction is also a possible aetiology. Feiner et al defined mesh contraction as an adverse outcome following armed polypropylene mesh repair in which patients experience vaginal pain with movement and dyspareunia and on examination have localised areas of prominent, tense and tender mesh under the vaginal epithelium.(706) Mesh contraction assessed on ultrasound examination after anterior vaginal mesh repair may correlate with de novo OAB symptoms and vaginal pain. Of 103 patients who underwent Prolift anterior™ implantation, after 6 months' follow-up, mesh contraction occurred in 19.4% of patients presenting with de novo OAB symptoms, and 22.3% of patients reporting post-operative vaginal pain (Level 4).(633)

Pain before surgery has been shown to be a predictive factor for pain after surgery, with an OR of 3.2 (95% CI 1.2-8.4), in a prospective observational cohort study on 284 patients with a post-operative pain rate of 13% (35/275) (Level 3).(651) Preoperative dyspareunia has also be shown by multivariable regression to be the only factor associated with postoperative dyspareunia (adjusted odds ratio 7.8, 95% CI 4.2–14.4.)(702)

Local pain around the mesh site could initially be treated conservatively with local injection using a combined steroid and local anaesthetic agent, as for groin pain after TVT,(707) but there is no evidence for vaginal mesh.

Although technically difficult in some cases, some authors have reported that purely transvaginal mesh excision appears to be safe with resolution of almost all presenting symptomatic, including pelvic pain(140), even if mesh removal was performed for painful mesh contraction, with a symptoms resolution rate of 77.9 to 93% (14/15) (Level 4).(708) Contrarily, others have reported unsatisfactory outcomes after mesh removal. On 58 women who underwent mesh excision for multiple complaints, including pelvic pain in 22%, re-excision of residual mesh was necessary in 27 women (29%), and only 14 women (24%) were treated successfully, with complete resolution of all presenting symptoms.(709)

6.2. Pelvic pain after abdominal surgery

Pelvic or back pain is a rare condition (ranging from 1 to 2%) following laparoscopic sacral colpopexy or hysteropexy (Level 2)(686) however, most did not assess lumbar/back pain before and after surgery and high rates of lower back pain are reported in the general population.(710) Maher et al have reported a reoperation rate for mesh contraction significantly greater after vaginal mesh surgery than after laparoscopic sacral colpopexy (7% vs 0%, p=0.05).(324) (Level 2). Other Complications

Other rare but severe complications have been described after pelvic organ prolapse surgery, such as massive haemorrhage after a trans-obturator mesh procedure, major vessel injury during sacral colpopexy, trocar hernia, bowel obstruction, urinary retention, ureteric complications and thrombo-embolism.

Post-operative haemorrhage or hematoma have been reported after native tissue repair, in 0.9% and 2.5% respectively.(711) In that study of 438 patients who underwent anterior and posterior colporrhaphy, associated with sacrospinous fixation for level I defects in 269 patients and hysterectomy in 255 cases, gluteal hematomas occurred more commonly after sacrospinous fixation (p = 0.019) (Level 3), while concomitant hysterectomy was not associated with more complications. A recent study has determined comparative rates of perioperative complications of native tissue versus vaginal mesh repairs, using the National Surgical Quality Improvement Program (NSQIP) database on 10 657 vaginal reconstructive procedures without mesh and 959 mesh-based repairs. Procedures with mesh had a higher rate of perioperative bleeding requiring transfusion than native tissue repair (2.3% vs 0.49%, P < 0.001).(700)

Post-operative urinary retention has been described after both native tissue repair and vaginal mesh surgery. Urinary retention could be defined as a post-void residual over 150 ml more than 48 h after catheter removal.(712) Posterior colporrhaphy has been shown to give more transient urinary retention than mid-urethral sling, in 32% vs 15% (P = 0.03), with longer bladder catheterisation (3.2±0.9 vs

1.8±0.4 days; P = 0.007), probably related to post-operative pain (Level 3).(713) Of 94 patients who underwent trans-obturator mesh (n=32) or anterior-apical mesh anchored to the sacrospinous ligament (n=62), with normal preoperative uroflowmetry and without concomitant mid-urethral sling, urinary retention occurred more frequently after the second technique [(17 (27 %) vs 2 (6.25 %), OR 5.7, 95% CI 1.2-26.3, p = 0.027] (Level 3), with a trend towards more frequent hospital discharge with self-catheterisation [8 % (5) vs 3 % (1)]. This phenomenon could be explained by more injury to pelvic splanchnic nerves during the dissection of the sacrospinous ligament.(712)

Post-operative ureteric complications have also been described after both native tissue repair and vaginal mesh surgery. In a retrospective chart review of 983 women who underwent uterosacral colpopexy for uterovaginal and post-hysterectomy vault prolapse, the overall adverse event rate was 31.2% (95%CI, 29.2-38.6), which included 4.5% (95%CI, 3.4-6.0) of ureteric kinking requiring suture removal (Level 3).(303) Ureteric kinking has also been reported with vaginal mesh surgery, and could be related to the traction of peri-ureteral tissue by the mesh arm.(154) In a study cohort consisted of 1,282 patients receiving 1,484 implants (847 synthetic mesh and 637 biologic grafts), Wong et al. have reported 59 (0.6%) ureteric injuries resulted from ureteric kinking during seven uterosacral ligament vaginal suspensions, one ureteric kinking during anterior implant placement, and one ureteric transection during sacrocolpopexy (Level 3).(668)

Concerning postoperative venous thrombo-embolism (within 30 days after surgery), in large POP surgery series (database), the prevalence ranged from 0.1% (on 13,023 women who have undergone reconstructive pelvic surgery (POP surgery or sling for USI) (714) to 0.4% (on 26,103 women who have undergone POP surgery).(715) Women with obesity, an increased length of stay, or ASA score of 3 or higher are at an increased risk for developing thrombo-embolism after undergoing surgery for POP (multivariate analysis) (Level 3).

Concerning laparoscopic sacral colpopexy, conversion to the open approach is rarely considered as a complication. However, conversion rates range from 0.7 to 11% (mean 3%), according to the surgeons' experience (Level 3).(341,686,716)

Mean bladder injury rate ranges from 0.6 to 2% during open or laparoscopic or robot-assisted sacral colpopexy or hysteropexy (Level 2).(685,686) Bladder injury may occur due to trocar placement, tissue dissection or suture placement. Injuries have been managed by immediate repair and extended duration of indwelling catheter. Mean bowel injury rate ranges from 0.07 to 1% (Level 2).(685,686)

Peri-operative blood loss is decreased using laparoscopic approach when compare to open approach (Level of evidence 2). However, blood losses amounts are limited (150-200ml) and the requirement of transfusion is rare (<1%), whatever the surgical route. Laparoscopic approach is associated with a decrease in the transfusion rate (multivariate analysis), when compared to open approach (Level 3). (717) Concomitant hysterectomy may increase blood loss.

Laparoscopic approach is associated with a decrease in the wound disruption, when compared to open approach (Level 3) (Linder et al, J Urol, 2018).

Obstructed defaecation is rarely reported (2-2.5%) following sacral colpopexy.(686) Small bowel obstruction (1.2%), and port site hernia (0.2%) have been reported following sacrocolpo/hysteropexy (Level 4).(686)

Vascular injuries are rare complications (<1%) of sacral colpopexy. (718) Some cases are due to anatomical variations of the internal iliac veins in the presacral area

Very rare complications (<0.1%) of sacral colpopexy include vascular injuries due to anatomical variations of the internal iliac veins in the presacral area.(719)

Corneal abrasions have been rarely reported during pelvic reconstructive surgery.(720) In this series, the prevalence of corneal abrasions was 2% following sacral colpopexy and 0.3% following vaginal surgery (p=0.04) (Level 3). However, the mean operative duration in the laparoscopic group was 312 min in this series. Furthermore, corneal abrasions did not occur in any patient with a total operating time less than 227 min. The amount of Trendelenburg was not recorded.

Fatalities occurred after vaginal surgery, open or laparoscopic sacrocolpopexy/hysteropexy. Concerning abdominal surgery, mortality rates ranged from 0.05 to 0.1 % (no difference between open and laparoscopic approach).(685)

7. METHODS OF PREVENTION

7.1. Methods of Prevention for both vaginal and abdominal approaches

Although there is no specific study in prolapse surgery, to demonstrate that cessation of smoking prior to surgery will decrease the post-operative complication rate (healing problems) in many other surgical specialties these data exist (Level 2). In a randomised controlled study on the effects of smoking cessation before surgery, including groin hernia repair using mesh, continued smoking up until the operation significantly increased the risk of acquiring post-operative complications compared to those who stopped smoking four weeks before the operation.(721)

Reducing bleeding during surgery is important as both excessive bleeding >500 ml and post-operative hematoma requiring drainage or embolisation are independent risk factors for mesh exposure requiring reoperation after vaginal mesh surgery [OR 7.25, 95% CI 1.47-35.66].(650)

Many studies have shown, in other surgical specialties, that poorly controlled diabetes mellitus is a risk factor for post-operative infection.

7.1.1. Oestrogen therapy

Vaginal oestrogen application before and/or after pelvic organ prolapse surgery has been shown to improve the vaginal maturation index and increased vaginal epithelial thickness. However, no study has shown that the use of pre and/or post-operative application of oestrogen was associated with a decrease in vaginal mesh exposure rates (Level 3).(722)

Furthermore, a retrospective cohort study conducted on 363 women who underwent sacral colpopexy, counter-intuitively observed that pre-menopausal women were at higher risk for mesh exposure than postmenopausal women (RR 4.5 95% CI 1.9-10.9 p=0.01). (678)

Two RCTs evaluated role of preoperative vaginal oestrogen in postmenopausal women undergoing POP surgery. The first trial confirmed RCT (LOTUS) (723) confirmed a larger trial was feasible and Marschalek reported a double blinded RCT and demonstrated that preoperative oestrogen reduced postoperative complications (p=0.045) and antibiotic use (p = 0.003). Surgeons blinded to treatment allocation, were unable to identify any difference in tissue perfusion, atrophy, consistency or dissection difficulty.(724)

7.1.2. Bowel preparation

One single-blind randomised trial has evaluated mechanical bowel preparation before reconstructive vaginal prolapse surgery (apical suspension and posterior colporrhaphy). Bowel preparation consisted of a clear liquid diet and two self-administered saline enemas the day before surgery (n=75). The patients in the control group are a normal diet (n=75). The bowel preparation group was less likely to report "complete" satisfaction compared with the control group (OR 0.11, 95% CI 0.04-0.35; P<.001) (Level 2). Abdominal fullness and cramping, fatigue, anal irritation, and hunger pains were greater in the bowel preparation group (all P<.01). Finally, preoperative bowel preparation conferred no benefit regarding surgeons' intraoperative assessment of the operative field (primary endpoint) (Level 2).(725)

Bowel preparation prior to sacral colpopexy is not routinely used in most series. One RCT assessed post-operative constipation (measured by the Patient Assessment of Constipation Symptoms (PAC-SYM)) following bowel preparation prior to sacral colpopexy. (726) In intervention group, the bowel preparation consisted of written and verbal instructions to be on a clear liquid diet the afternoon prior to surgery and i-to consume one bottle of magnesium citrate the day before surgery. No differences were noted on ITT (Level 2). Surgeons were more likely to rate the complexity of the case as "more difficult than average" (54.4% vs 40.1%, p =0.027) in those without a bowel preparation. However, the prevalence of peri-operative and postoperative complications was similar in both groups.

7.1.3. Antibiotic / Cranberries prophylaxis

There is no specific study on the use of antibiotic prophylaxis at the time of mesh reconstructive surgery for prolapse. However, most of studies report their use during pelvic organ prolapse surgery. (121,173) There are no data on the need to identify a urinary tract infection in the preoperative period nor to perform a vaginal bacteriological test or to use antiseptic or antibiotic meshes. Prolonged post-operative bladder catheterisation increases the risk of lower urinary tract infection (Level 3).(727)

One randomised double-blind placebo-controlled trial has been done to evaluate whether cranberries are able to prevent postoperative urinary bacteriuria in patients undergoing pelvic surgery and receiving transurethral catheterisation. 272 women were enrolled and have received 36 mg cranberry (proanthocyanidins, PAC) or placebo once daily for 10 days. Authors have shown that immediate postoperative prophylaxis with PAC does not reduce the risk of postoperative bacteriuria in patients receiving short-term transurethral catheterisation after pelvic surgery.(728)

7.1.4. Mesh implantation and visceral injury

Although there is no comparative study, most of authors would consider the use of mesh after a rectal injury during dissection as a contraindication to mesh insertion, due to a perceived higher risk of mesh infection and subsequent recto-vaginal fistula(729) (Level 4).

In the anterior compartment, a small series of five cases of recognised intra-operative bladder injury (out of 704 Trans-Vaginal Mesh procedures) has shown that mesh surgery was feasible without subsequent complications after appropriate bladder repair.(729) (Level 4) These data are limited and further evaluation is required.

7.1.5. Concomitant surgery for stress urinary incontinence

In a prospective longitudinal cohort study using a surgical registry on 1873 women in 13 French public hospitals, Fritel et al. have recently reported that the incidence of serious complications 6 months after the surgical procedure was higher when concomitant mid-urethral sling (MUS) was performed: 1.7% (0.0-3.8%) after vaginal native tissue repair, 2.8% (0.9-4.6%) after transvaginal mesh, 1.0% (0.1-1.9%) after laparoscopy with mesh, and 7.0% (2.8-11.3%) after prolapse surgery with MUS. (620)

7.1.6. Convalescence recommendations

There are substantial variations in activity restrictions placed on post-operative patients. In France, mean recommended time until recommencement of sexual intercourse is four weeks following pelvic organ surgery. Mean recommended lifting restrictions range from four to six weeks.(730)

In a RCT, 95 women were randomized. (n=45 liberal, n=50 restricted activity recommendations) Satisfaction and short-term anatomical outcomes were similar in both groups 3 months after prolapse surgery.(731) Post-operative complications were not reported in this RCT. "Restricted activity recommendations "was defined as follows " You should not lift anything heavier than 10 pounds for 12 weeks after surgery; you should avoid high impact activities such as running, aerobics, and sit-ups for 12 weeks after surgery". In both groups, it was advised to not have sexual intercourse for at least 6 weeks after surgery.

8. PREVENTION METHODS FOR VAGINAL MESH SURGERY

8.1. Learning curve

The data regarding the impact of the learning curve for transvaginal meshes on the incidence of post-operative complications is conflicting. Some authors have reported that learning has a significant effect on the complication rate(651,732-734) while others did not. (488,735) For de Tayrac et al, 113 patients underwent bilateral anterior sacrospinous ligament suspension associated with anterior mesh, the risk of major complications (ureteric complications, vaginal infections, sciatic pain) was reduced by approximately 30% every ten procedures (HR = 0.71, 95% CI: 0.53–0.95) (Level 3).(732) For Mowat et al, gynaecologists performing procedures approximately once a month or less were found to have higher rates of adverse outcomes in urogynaecology (RR 1.4, 95% CI 1.2-1.6), with higher rates of reoperation for mesh complications after mid-urethral sling procedures (RR 1.4, 95% CI 1.2-1.5).(734)

8.2. Concomitant hysterectomy

Although several studies did not find any differences,(233,657) most of the studies have shown an increased rate of vaginal mesh exposure with concomitant vaginal hysterectomy.(234,262,652,653,736-738) Meta-analysis demonstrates that the addition of hysterectomy to a transvaginal mesh surgery significantly (p<0.001) increases the risk of mesh exposure from 5.2% (43/824) without hysterectomy as compared to 18.9% (125/6620) with hysterectomy (P<.001) (Level 2) (Table 33).

8.3. Vaginal sutures

Three studies have evaluated the type of sutures used for closure of the vaginal skin. The first two studies have matched women under-

Table 33. Comparison mesh exposure rate at transvaginal polypropylene mesh surgery with and without hysterectomy.

Author	Year	Number	Review months	Surgical technique	"Mesh exposure hysterectomy n/N (%)"	"Mesh exposure no hysterectomy n/N (%)"	p value

Abbreviation: PP: polypropylene, IVS: posterior intravaginal slingplasty

going POP surgery with vaginal closure with multi-filament sutures with a cohort in which 2.0 monofilament sutures were used. In the first study, the multifilament suture group had significantly higher rates of offensive discharge (p<0.001), vaginal bleeding (p<0.001) and vaginal pain (p=0.004) (Level 3). They were more likely to receive medical advice (0.007). However, patients in the multifilament group were no more likely to suffer from a UTI (p=1.000) or to be readmitted post-operatively (p=1.000).(742) In the second study, offensive vaginal discharge was also more common in the multifilament group (24% vs 12%; p=0.04) (Level 3). However, there was no increased requirement to seek advice from a health professional (33% vs. 25%; p = 0.27) or to require antibiotics. Vaginal bleeding (10% vs. 5%; p = 0.28) and urinary infection (2% vs. 5%; p = 0.44) were statistically no more common in the multifilament group (Level 3).(743) The third study has compared non-coated monofilament with triclosan-coated (antiseptic properties) monofilament sutures. Surgical site infections occurred in 3/78 (3.8%) in the first group versus 1/72 in the second group (1.4%), with no statistically significant difference (P=0.62) (Level 3).(744)

8.4. Vaginal packing

Only one double-blind randomised study of 190 women undergoing vaginal hysterectomy and/or pelvic floor repair has evaluated the effect of vaginal packing following pelvic floor surgery with regard to post-operative pain, bleeding and infection. No statistically significant differences in the post-operative pain scores or secondary outcome measures were demonstrated. Incidence of haematoma formation (14.8 % no pack, 7.3 % pack, p = 0.204) was not statistically significant (Level 2). There were three clinically significant complications in the no pack group and none in the pack group. There is no evidence to suggest that packing increases pain scores or post-operative morbidity. A trend towards increased haematoma and significant complications was seen in the no pack group. Unfortunately, duration of inpatient stay was not recorded in that study. As vaginal packing does no harm and may be of some benefit, authors argued that packing should be recommended as routine clinical practice for vaginal surgery.(745)

Another prospective study has been done on 63 consecutive women undergoing elective vaginal surgery for POP in whom vaginal packs were inserted after surgery, and weighed before insertion and at the time of removal the day after surgery. There was a statistically significant increase in pack weight of 6.7g (p<0.01). Five percent of the patients had a bleed of more than 25g into the pack. Removal of the pack was associated with minor discomfort. Complications in the post-operative period were low with 11% of patients seen in the first 6 weeks with bleeding or discharge. Authors have concluded that packs are probably not required for controlling post-operative blood loss in the majority of patients.(746)

9. PREVENTION METHODS FOR ABDOMINAL SACRAL COLPOPEXY

9.1. Learning curve

The prevalence of conversion to laparotomy, intra- and post-operative complications and early recurrence, seemed to be associated with the experience of the surgeon (learning curve). The surgical “proficiency” was achieved after 55-84 cases for laparoscopic or robot-assisted laparoscopic sacral-colpopexy/hysteropexy.(747-749) (Level 3) However, the incidence of severe complications does not seem to be related to the learning curve.(341,342)

In a comparative retrospective series, the rate of complications/re-intervention was not associated with the specialty of the surgeon (urologist or gynaecologist).(750) A recent RCT compared ETHIBOND (polyester) and absorbable VICRYL polyglactin) sutures for vaginal mesh attachment during sacral cervicopexy.(642) In this

study, 150 women were randomized. Primary outcome was the correction of POP; no difference was observed at 12 months follow-up (100% in both groups) however mesh exposure rate was non significantly higher at 4% following the permanent suture as compared to no exposures in the absorbable suture group.

9.2. Choice of surgical route for sacrocolpopexy

Most complications following sacral colpopexy occur irrespective of entry route. Most RCT's observed that laparoscopic sacral colpopexy is as effective as the open abdominal procedure, with a reduced rate of intraoperative bleeding, hospitalisation and wound complications.(337,338) Robotic sacral colpopexy (RSC) and laparoscopic procedure had similar operative times, short-term anatomic cure rates, and length of hospital stay (335,348) (Level 2) however the robotic approach had longer operating time, greater pain and higher costs than LSC.(348, 384, 639) The learning curve to reduce complications occurs around 55-70 procedures and is similar for laparoscopic and robotic approach are similar.(747-749)

Robot-assistance did not seem to be associated with a decrease risk in complications/reoperation rates when compared to the classical laparoscopic approach (751) especially concerning vaginal exposure rates and complications. (351)

The laparoscopic and robotic approaches are associated with a decrease in blood loss and shorter length of hospital stay, when compared to open route (Level 2).(639,685) However, overall complications rates are comparable in either approach.

9.3. Choose the right mesh for abdominal surgery

In a retrospective comparative study of open abdominal sacral colpopexy, Quiroz et al have shown that the short-term mesh-related complication rate was significantly higher with polypropylene than with porcine dermis [24/102 vs 12/134, p=0.003] (357)(Level 3), however the prolapse recurrence rate using porcine dermis was higher [7/93 vs 0/105, p = 0.004]. Another study comparing fascia lata and polypropylene meshes with five-year review, has shown a long-term increased recurrence rate, but with no differences in the rate of complication.(352)(Level 2) Concerning LSC, in a prospective comparative non randomised study, Deprest et al have shown that recurrences at the level of anterior and apical compartment occur significantly more often when using a biograft, in comparison to polypropylene, 21% vs 3%, p<0.01 and 36% vs 19%, p <0.05, respectively (Level 3).(358) Partially absorbable composite meshes (polyglactin + polypropylene) also seems to increase the risk of short-term recurrences (Level 4).(752)

The rate of mesh exposure 7-years following sacral colpopexy was high at 10% in the E-Care paper a finding that maybe related to graft and suture choice. More than 50% cases a multi-filament mesh was utilised, 50% used permanent sutures and 36% had concomitant hysterectomy all factors associated with high rate of mesh exposure.(327) Long-term rates of mesh exposure of 3% or less have been reported 5-years following laparoscopic sacrocolpopexy when monofilament microporous graft and delayed absorbable sutures are utilised.(331,640)

The risk of vaginal mesh exposure seems to be higher with the use of polytetrafluoroethylene than with polypropylene meshes at ASC (15% vs 0%, p=0.03) (Level 4) (619)[38] and 19% vs 5% (Level 2).(253) Similar results were observed with the use of silicon-coated polyester (19% vs 0%, p<0.05) (Level 4).(753)

A retrospective series (n=105) compared at 2 years follow-up, the outcomes of laparoscopic sacrocolpopexy either with polyvinylidene fluoride (PVDF) or hybrid polypropylene containing a resorbable polyglecaprone (PP+PG) mesh.(754) There were no differences in complications/reoperation rates, patient satisfaction and anatomical outcomes after LSCP either with PVDF or PP+PG mesh.

Another series (n=136) compared the surgical, anatomical, and functional outcomes of sacrocolpopexy using polyvinylidene fluoride (PVDF) mesh versus using the standard polypropylene mesh. (755) Postoperative anatomical correction was not significantly different between the two groups. The PVDF group showed superior results in term of storage symptoms (PVDF=0% versus PP=8.2%; p=0.02) and lower rate of sexual dysfunction (PVDF=0% versus PP=16,4%; p=0.001). Only 1 patient in PP group and 2 in PVDF group (p=0.47) presented a mesh exposure. There was no statistical difference in PGI-I scores (PP=1.5±1.0 vs PVDF=1.8±0.5; p=0.40).

Consensus Statement of the European Urology Association (EAU) and the European Urogynaecological Association on the Use of Implanted Materials for Treating Pelvic Organ Prolapse (756) and the European Commission's SCENIHR report on the use of surgical meshes (SCENIHR 2015) supported the use of polypropylene or polyester meshes for sacral colpopexy/hysteropexy.

For now, no comparative study was conducted on ultra-lightweight polypropylene mesh versus classical polypropylene meshes.

9.4. Choose the right fixation technique to the promontory, vaginal wall and levator ani

Most of authors perform a direct fixation to the vaginal wall using absorbable or non-absorbable sutures, and to the promontory using non-absorbable sutures (Level 3).(333,752,757,758)

Fewer authors use staples for the mesh fixation, both to the vaginal wall and to the levator ani muscle,(341) or tackers to the promontory.(66,324,337) Spondylitis has been reported after both tackers (759) and sutures (333,336,757) are utilised to secure the graft to the promontory. Whatever the fixation material use for the vaginal wall, the main method of preventing the occurrence of vaginal mesh exposure seems to avoid breaching the vaginal epithelium (Level 4).(760)

The rate of vaginal suture exposure was 7% in a long-term cohort series (when using polyester sutures). Use of permanent polyester (Ethibond) suture was strongly associated with an increased risk of vaginal suture erosion (OR 10.82 95%CI 2.54– 46.10 p =0.001; comparative use of PDS suture) when compared to slowly dissolvable, polydioxanone, monofilament sutures (PDS) (Level 3).(330)

This effect estimate was not changed by adjustment for other potentially relevant factors, including patient age and use of concomitant procedures. Furthermore a retrospective comparative series observed that the use of delayed-absorbable monofilament sutures for suturing the mesh to the vagina was not associated with an increased risk of failure in patients undergoing sacral colpopexy.(761)

In a RCT conducted in 204 patients undergoing sacrocolpopexy associated with total hysterectomy, absorbable (PDS) and non absorbable (GORE-TEX)) sutures were assessed for the polypropylene mesh attachment to the vagina; the primary outcome was vaginal mesh/suture exposure rate at 12 months-follow-up.(643) The vaginal mesh/permanent suture exposure was comparable in both groups (5%, vs 7%,RR 0.73; 95%CI 0.24-2.22) and much higher than the 2.1% reported in over 5000 trials reported above and may reflect the concomitant performance of hysterectomy in the cohort.

Composite success rate was comparable in both groups (93% vs 95%; p=0.43). Recently, a German group randomly compared absorbable vicryl (n=940 and non-absorbable ethibond sutures (n=96) at sacrocolpopexy for vault prolapse. At 6 months there were no mesh exposures and equivalent objective and subjective outcomes. There were three (3%) suture exposures in the permanent suture group and none in the vicryl sutures group.(762)

Alternative techniques of fixation may be anchors or glue, but limited data have been published concerning these techniques of suturing.

At short term follow-up, a limited sample sized RCT showed that the use of delayed absorbable anchors was associated with a decrease in the operative duration when compared to sutures for mesh vaginal attachment during robotic assisted sacral colpopexy (12 min vs 21 min, p<.001) (Level 2). However, the overall duration of the procedure, complication rates and PROs were comparable in the two groups (Level 3).(763)

At medium term follow-up (36 months), it was reported that the use of glue mesh fixation to the vagina was feasible and associated with good objective and subjective success rates following sacrocolpopexy.(Level 4)(764) However, one case of vaginal mesh exposure and 7 cases of “mesh shrinkage” have been reported in this series that involved 70 women.

9.5. Concomitant hysterectomy

The risk of vaginal mesh exposure is significantly increased in cases of sacrocolpopexy associated with concomitant total hysterectomy (8.6%), in comparison to 2.2% in those with previous hysterectomy , 1.5% at sacral hysteropexy and 1.7% subtotal hysterectomy. (641)(Level 4).

Previous hysterectomy was associated with an increased prevalence of serious complication when compared to concomitant hysterectomy, in a recent series conducted in more than 800 patients. (378)

9.6. Peritoneal closure

Reoperation rate related to the absence of peritoneal closure remains debated. Most of authors close the peritoneum after a sacrocolpopexy, both after open (262,675,765) and laparoscopic approach.(324,333,758) A recent review of 450 cases of laparoscopic and robotic sacrocolpopexy demonstrated a 1.8% rate of post-operative ileus or small bowel obstruction that were equally distributed between those with mesh that was and was not reperitionealised. (766)

In the largest series concerning sacral colpopexy/hysteropexy (n=178 with 35months review) without peritoneal closure,(767) a total of 77 complications were observed in 49 patients, ranging from one to six complications per patient. Five (3%) serious complications were unanimously or possibly thought to be possibly related to nonperitonealisation (ileus due to mesh adhesions or enterovaginal fistula requiring surgical intervention).

CONCLUSION

Pelvic organ prolapse reconstructive surgery is associated with rare but potentially severe complication, whatever the surgical approach and the use of mesh.

Preoperatively, patients should be informed that a mesh is considered a permanent implant; removal of mesh or correction of mesh-related complications may involve subsequent surgeries. Furthermore, complete removal of mesh may not be possible and additional surgeries may not fully correct some complications. Patients must also be informed of conservative and alternative surgical techniques.

Proposed Recommendations to Reduce the Rate of Complications

GoR A

Patients should be informed that transvaginal meshes have a higher reoperation rate than native tissue vaginal repairs.

GoR B

Concerning vaginal surgery:

Bowel preparation prior to surgery is not recommended.

If a synthetic mesh is placed by the vaginal route, it is recommended that a macroporous polypropylene monofilament mesh should be used.

The use of polyester mesh is not recommended.

Cranberies prophylaxis is not recommended.

***Concerning sacral colpopexy*:**

The use silicone-coated polyester, porcine dermis, fascia lata, and polytetrafluoroethylene meshes is not recommended.

It is recommended to avoid total hysterectomy.

GoR C

Whatever the surgical route:

The first cases should be undertaken with the guidance of an experienced surgeon in the relevant technique.

Pre-operative vaginal oestrogen therapy may reduce postoperative complications.

Concerning sacrocolpopexy:

Laparoscopic approach is recommended for sacral colpopexy

The use of polyester (without silicone coating) or monofilament polypropylene meshes is recommended.

Delayed absorbable sutures for securing mesh to vaginal recommended

Concomitant total hysterectomy associated increased risk mesh exposure

Expert Opinion

***Whatever the surgical route*:**

As with any surgery, cessation of smoking preoperatively is recommended.

It is recommended to comply with the prevention of nosocomial infections.

Antibiotic prophylaxis is recommended, regardless of the approach.

Thromboembolic prophylaxis is recommended, regardless of the approach.

It is recommended that preoperative urinary tract infections are identified and treated.

Concerning vaginal surgery:
It is recommended that a non-absorbable synthetic mesh should not be inserted into the rectovaginal septum when a rectal injury occurs.

The placement of a non-absorbable synthetic mesh into the vesicovaginal fascia may be considered after a bladder injury has been repaired if the repair is considered to be satisfactory.

It is possible to perform a hysterectomy in association with the introduction of a non-absorbable synthetic mesh inserted vaginally but this is not recommended routinely.

It is recommended to minimise the excision of vaginal tissue.

Concerning sacrocolpopexy:
It is recommended that the type and commercial name of mesh used in the operative report.

Peritoneal closure is recommended to cover the meshes.

X. RISK FACTORS RECURRENT PROLAPSE

While poor outcomes from prolapse surgery are difficult to succinctly define, knowledge of prognostic variables which could influence the outcome of surgery, along with incidences of failure and complications, are invaluable information for both patient and surgeon. While the remainder of the chapter concentrates on procedural safety and efficacy, in this section we seek to evaluate the impact of non-procedural factors such as patient and surgeon characteristics and peri-operative interventions on prolapse surgery outcomes.

1. PATIENT CHARACTERISTICS

Recurrent prolapse were most commonly reported in the anterior compartment(768,769) although in a10-year multivariate analysis of 374 American women by Denman et al this was not able to be confirmed.(108) They identified prior pelvic organ prolapse or urinary incontinence (POPUI) surgery conferred a hazard ratio of 1.9 (95% CI, 1.1-3.2; P .018) for recurrent prolapse surgery. The abdominal approach was protective against reoperation compared with the vaginal approach (hazard ratio, 0.37; 95% CI, 0.17-0.83; P .02). No association was observed for age, vaginal parity, previous hysterectomy, body mass index, prolapse severity, ethnicity, chronic lung disease, smoking, oestrogen status, surgical indication, or anatomic compartment.

Vergeldt et al completed a comprehensive systematic review evaluating 28 pre-determined risk factors for recurrent prolapse(770) and after screening 7,500 relevant articles only 5 trials fulfilled predefined inclusion criteria(768,771-774) (POP recurrence defined as stage 2 or greater, at least 1 year review, native tissue repairs only and a multivariate analysis reported. The only predictive factor for recurrent prolapse in all five papers was preoperative POP-Q stages III or IV prolapse although in Tegerstedt et al(774) only preoperative stage III, and not IV was a risk factor. Briefly, Weemhoff et al(772) prospectively evaluated 156 women having repair of vaginal repair cystocele. Risk factors for anatomical recurrence were complete avulsion of puborectalis muscle (OR, 2.4; 95% CI, 1.3, 4.7), advanced preoperative stage (OR, 2.0; 95% CI, 1.0, 4.1), family history of prolapse (OR, 2.4; 95% CI, 1.2, 4.9), and sacrospinous ligament fixation (SSLF) (OR, 6.5; 95% CI, 2.0, 21.2). Salvatore identified 36 of an original 360 women who had undergone vaginal prolapse surgery and the only predictive factor for recurrence was initial stage III or IV prolapse (OR 2.4, 1.1–5.1 95% CI).(771)

Diez-Itza et al (768) reported on a retrospective cohort of 134 women five years after prolapse surgery and while 42 (31.3%) had anatomical recurrence of the prolapse (grade≥II), only 10 (7.4%) had prolapse related symptoms. Advanced preoperative prolapse (grade III–IV) of any compartment was associated with anatomical failure but not with symptomatic recurrence, (OR 3.93; 95% CI, 1.19–12.97). This study also suggested age under 60 years and weight over 65kg were additional prognostic factors for recurrence. Poor levator muscle contraction strength was not a risk factor for recurrent prolapse.

In a prospective observational study of 389 patients, age less than 60 years (OR 3.2; 95% CI, 1.6-6.4) and POP-Q stages III and IV, (OR 2.7; 95% CI, 1.3-5.3) were associated with greater risk for recurrent prolapse at 1 year.(773) No other prognostic variables were identified in this prospective observational study. Specifically, there was no difference in outcomes between the four surgeons, all described as Urogynaecologist. Concomitant Burch or sling for stress incontinence protected against recurrent anterior wall prolapse, but increased the risk of a posterior wall prolapse.

Diminished levator strength and wide genital hiatus are possible risk factors for recurrent prolapse. The data on levator muscle strength is conflicting. Diez-Itza et al (768) demonstrated in multivariate analysis that decreased levator strength was not predictive of recurrent prolapse. However, in univariate analysis of 358 women 5 months after prolapse surgery, Vakili et al demonstrated diminished levator strength was associated with recurrent prolapse (35.8% versus 0%; P = .017) as was a genital hiatus 5 cm or greater (44.2% vs 27.8%; P = .034). Increasing levator contraction strength was associated with a decreased reoperation rate for pelvic floor disorders.(775) The theory of an enlarged genital hiatus being a risk factor for recurrent prolapse is supported by the retrospective univariate analysis by Medina et al (776) which demonstrated a correlation for recurrent anterior compartment prolapse and genital hiatus measurement greater than 5cm. The rate of post-operative anterior vaginal wall prolapse was greater in patients with a wide genital hiatus compared with those with a normal genital hiatus (34.3% vs 10% respectively; OR 4.7 95% CI 1.0– 24.1).

As noted above Weemhoff confirmed after multivariate analysis that complete avulsion of the puborectalis muscle (USS confirmed) was a risk factor for objective recurrence of cystocele (OR, 2.3; 95% CI, 1.1, 4.8).(772)

Diez-Itza 2020 prospectively evaluated 455 women one year after undergoing anterior colporrhaphy surgery for anterior compartment prolapse and after multivariate analysis determined that levator ani defects (OR 1.96), levator hiatal area >25cm^2 (OR 2.51) stage 3 (OR 2.34) and stage 4 prolapse (OR 4.47) were independent risk factors for recurrence.

Alternatively, a variety of authors evaluating women with cystoceles did not identify LAM defects as being predictive of failure after multivariate analysis.

Wong et al 2013 evaluated 209 women, 2.2 years (range 3 months to 5.6 years) after a variety of anterior transvaginal mesh procedures. Levator avulsion was not a risk factor for symptomatic prolapse, POP-Q stage 2 prolapse, descent of Point Ba on examination, or mean bladder descent on ultrasound. (777) Vergeldt et al , in an evaluation of 287 women undergoing anterior colporrhaphy, after multivariate analysis levator defects were not an independent risk factor for recurrent prolapse OR 1.37 (0.8 to 2.34).(778)

Wong et al 2020 reported on 154 Chinese women with Stage 3-4 prolapse 2-years following native tissue repair and 5-years after vaginal and abdominal mesh procedures and found LAM defect was not a risk factor for recurrent prolapse after multivariate analysis.(779)

A South American group retrospectively evaluated 134 women 16 months after laparoscopic sacral colpopexy and reported LAM defect (OR 0.99 95% CI 0.098-10.1) or ballooning on pelvic floor USS (OR 1.1 95% CI 0.99-1.2) were not risk factors for recurrent prolapse after multivariate analysis.(780)

Similarly, Norwegian group reported only preoperative stage 3 or greater POP (OR 2.8 95% CI 1.4-5.3) was an independent risk factor for recurrent prolapse 1-year after Manchester repair (n=189) performed for anterior compartment prolapse. LAM defect was not an independent risk factor (OR 1.7 95% CI 0.9-3.2).(200)

The data from multivariate analysis is inconsistent in determining if pre-operative levator ani defects are a risk factor for recurrent prolapse.

While women with a positive family history are two to three times more likely to develop prolapse than women without a positive family history,(781,782) the evidence from multivariate analysis is conflicting in regard to recurrent prolapse.(768,772) It has also been demonstrated that women with reduced type 1 collagen and increased collagenolytic activity in vaginal tissue are predisposed to prolapse.(783,784) In a preliminary study, Khaja et al was not able to demonstrate a relationship between quality or type of collagen and outcome of anterior colporrhaphy.(785) Further evaluation of these risk factors is warranted.

2. SURGEON CHARACTERISTICS

2.1. Surgeon experience

The experience of the surgeon was not identified as an increased risk of vaginal prolapse recurrence following prolapse surgery in a multivariate analysis undertaken by Diez-Itza et al.(768) A systematic review by Mowat et al of low versus high volume surgery (low defined as < than 12 procedures/year) found a higher rates of complications for of all gynaecology procedures for low versus high volume surgeons. In the urogynaecology group, a single study reported that the LVS group had a higher rate of any complication (RR 1.4 95% CI 1.2-1.6). The evidence is of moderate to very low quality.(734)

Surgeon surgical volume was assessed in a retrospective analysis of all 5,488 vaginal mesh POP procedures performed by 368 surgeons in Ontario Canada, from 2002 to 2013. At 10-year review, the hazard of reoperation for complications was lower for patients of high-volume (>14 cases per annum) surgeons (3.0%, 145/3,001] compared with non- high-volume surgeons (4.8%, 73/2,447), adjusted hazards ratio 0.59, 95% CI 0.40–0.86). In multivariable modelling, younger age, concomitant hysterectomy, blood transfusion, and increased medical comorbidity were all also associated with reoperation. Patients of high-volume surgeons were less likely to have a concurrent hysterectomy (32.5% versus 37.7%) and had a shorter post-operative stay in the hospital (median 2.0 versus 3 days).(786) Overall, 1 in 20 women required a second surgery for a transvaginal mesh complication, after 10 years of follow-up and this risk was reduced by 41% for patients of high volume surgeons.

2.2. Surgeon learning curve

For total vaginal mesh (TVM) repair for POP, a significant surgeon learning curve was demonstrated in a multivariate analysis by Long et al.(787) Women operated on during the surgeons first 50 cases were 11.93 times (95% CI: 1.79–240.1) more likely than subsequent women to develop a stage 2 POP-Q recurrence. A further retrospective study of 138 SSLF procedures also identified lower surgeon experience (< 20 cases) as a significant risk factor for recurrence (OR 2.7 95% CI 1.1 to 6.8) as compared to surgeon having performed > 20 cases.(788)

LSC requires the attaining of laparoscopic suturing and knot tying skills. Claerhout et al observed that LSC operative duration decreased rapidly during the first 30 procedures and reached steady state after 90 cases. However, complication rates remained unchanged throughout this learning curve series. Using a cumulative sum approach, they hypothesized that adequate learning occurred after 60 cases (Level 4).(341) Akladios et al also observed that LSC operation duration decreased after 25 procedures.(342) The complication rates were also low throughout this series and were not affected by learning curve. However, this study analysed the learning curve of a senior urogynaecology surgeon who was initiated into this technique, and not the learning curve of a trainee. Kantartzis et al analysed the learning curves of the first 180 LSC done by 4 attending Urogynaecologist and observed that there was no significant difference in the rate of overall complications regardless of the number of prior procedures performed (Level 4).(789) Mustafa et al (2012) observed that LSC operative time decreased considerably following the first 15 cases (Level 4).(343)

However, since complication rates associated with LSC are low, the published series cannot assess the effect of under-experience since the number of cases is few in each series. Furthermore, the complication rates are probably limited because of the supervision by a ‘senior surgeon’ during this learning curve. Prior training in laparoscopic suturing coincided with a short learning process for the phases requiring suturing.(747) The most time-consuming step is the dissection of the vault, for which it took the trainee 31 procedures to achieve an operation time comparable to that of the teacher.(747)

Protagonist of robotic approach to sacral colpopexy often cite quicker learning compared to laparoscopic approach as a significant advantage to robotic technique. Recent reviews do not support this view with reduction in operating time and complications very similar to that reported above for laparoscopic approach. An American group reported operating time of RSC plateaued after 60 cases and peri-operative complications stabilized after 84 cases.(748) Almost identically a Dutch group reported operating time reduction of

25% was achieved after 28 cases and perioperative complications stabilised at 78 cases.(749)

Similarly, Morgan et al (790) used multivariate analysis to look at the effect of surgeon case volume on use of apical colpopexy and cystoscopy and in the rate of intraoperative complications during hysterectomy for prolapse. Vaginal hysterectomy was undertaken for 78% of cases. Low (≤10 cases), intermediate (1 1–49 cases)-, and high (≥50 cases)-volume surgeon groups over a 4-year period were established a priori. High-volume (OR, 0.42; 95% CI, 0.30-0.61) and low-volume (OR, 0.32; 95% CI, 0.15-0.66) surgeons were less likely than intermediate-volume surgeons to have intraoperative complications during vaginal hysterectomy for prolapse. The difference between high- and low-volume surgeons was not statistically significant (OR, 0.77; 95% CI, 0.5-1.2). The finding that intermediate-volume surgeons have the highest rates of intraoperative complications suggests a nonlinear relationship between surgeon volume and avoidance of injury. The low volume surgeons however were far more likely to have a second experienced surgeon present for the case which could account for this. High volume surgeons were more likely to perform concomitant colpopexy and cystoscopy than intermediate or low volume surgeons.

A retrospective surgical database study by Sung et al(791) demonstrated that for urogynaecological procedures low volume (<8 case per year) and intermediate volume (8-18 cases per year) had significantly higher rates of intraoperative complications (RR 1.36 and 1.24 respectively) than high volume surgeons (>18 cases per year). This was from the Nationwide Inpatient sample in the USA which represents a 20% stratified sample of US hospitals between 1998 and 2003.

2.3. Physiotherapy

Pelvic floor muscle training (PFMT) is often recommended for women undergoing surgery for pelvic organ prolapse despite little evidence in the literature to support its routine use.

Jarvis et al(792) randomised 60 women undergoing surgery for prolapse or incontinence and reported an improvement in urinary symptoms and quality of life in the women who received pre and post-operative pelvic floor muscle training (Jarvis et al). Follow up was only to 3 months post operatively and the differences in outcomes could be explained by the fact that the treatment group underwent continence surgery (10/23, 44%) twice as frequently as the control group (6/27 22%).

In another Australian RCT by Frawley et al, (793) 51 women were allocated prolapse or continence surgery with and without supervised pre and post-operative pelvic floor exercises. No differences were detected at 1 year between the groups in Urogenital Distress Inventory (UDI) and the Incontinence Impact Questionnaire (IIQ) scores. Neither of the above trials reported effect on prolapse symptoms or need for retreatment.

Pauls reported no benefit in a recent RCT (n=25 each group) comparing native tissue prolapse surgery with and without structured PFMT (1 preoperative and 5 post-operative visits with expert pelvic floor therapist) at 6-month review on a variety of outcomes including validated pelvic floor questionnaires and POP-Q staging. Quality of life and prolapsed, urinary and sexual function scores were improved equally in both groups reflecting the effect of the surgery and not the addition of a PFMT program.

In a slightly larger (n=28 in each group) multi-centre RCT, McClurg et al (794) compared prolapse surgery with and without structured PFMT (1 preoperative, one phone call in week one and five post-operative visits with a dedicated pelvic floor physiotherapist over a 12-week period). At 6-month review of the whole available cohort no differences were detected between the two groups. Participant retention was problematic with less than 50% completing questionnaires and less than 20% completed examination at 12 months. At 12-month review at a single study site the treatment group had improved outcomes on the POP-SS and SF-12 scores. Unfortunately,

Table 34. Risk factors for recurrent prolapse

Outcomes	Multivariate evidence	Risk quantification	GoE
Patient factors			
Age	<60 yrs.	OR 3.2-4.1(768, 773)	GoE B

Abbreviation: PP: polypropylene, IVS: posterior intravaginal slingplasty

the 12-month results do not include eligible participants from other sites which detracts from the validity of the trial.

In the largest randomised trial to date by Barber et al,(297) 374 women undergoing surgery to treat both apical vaginal prolapse and stress urinary incontinence were recruited and two-year follow-up rate was 84.5%. The intervention group underwent pelvic floor assessment and taught PFMT 2 to 4 weeks pre-op and were re-assessed four times post operatively up to 12 weeks. Importantly this trial did include prolapse specific follow up assessment as well as urinary symptoms using UDI. No difference was found between behavioural therapy and pelvic floor muscle training and control group for urinary scores at 6 months [treatment difference −6.7 (95% CI −19.7, 6.2)], or prolapse scores at 24 months [treatment difference −8.0(95% CI −22.1, 6.1)] or anatomic success at 24 months. This trial differs from those by Frawley and Jarvis in that those supervising and teaching the behavioral package and PFMT were not interventional physiotherapists, but trained and certified clinicians.

Durate et al most recently randomised 95 women undergoing prolapse surgery to surgery with perioperative structured PFE (4 preoperative and 7 postoperative physiotherapy visits) and without PFE. At 90 days there was no discernible benefit in prolapse symptoms, quality of life, sexual function or pelvic floor muscle strength. (795)

These findings do not support the routine use of PFMT programs for women undergoing repair for pelvic organ prolapse. Table 34 summarises data relating to possible risk factors for recurrent prolapse and the Grade of evidence supporting the finding

XI. ECONOMICS OF PROLAPSE SURGERY

Despite the high prevalence and frequency of surgery for pelvic organ prolapse (POP), there is insufficient information on the costs of medical care for this condition. POP is a common pathology in middle-aged women, affecting approximately 50% of women over 50,(7) with an estimated global prevalence of 2.9% in women older than 20 in USA.(796) A study in USA estimated that the direct costs of POP surgery were substantial, amounting to $1,012 million (95% confidence interval $755, 1,251 million) for a total of 226,000 patient surgical procedures during 1997.(797) A European study showed that the number (rate) of admissions for POP surgery was 36,679 (1.14 per 1,000 women) in France and 28,959 (1.13 per 1,000 women) in England in the year 2005. The total costs were €144,236,557, €83,067,825 and €81,030,907 in German, France and England respectively, which were considered to be substantial, and required more attention in order to decrease the burden on the countries studied.(798) In addition, direct costs must be added to the indirect costs resulting from the loss of productivity and wages as well as the intangible costs arising from the deterioration of the quality of life. Mestre et al (799) reviewed that 50% women who consulted for urogynaecological problems are still active in the society and 60% of them reported some type of sexual dysfunction.

In the current situation of progressive aging population, a significant increase in the prevalence of POP is to be expected. In USA, a study estimated that there will be an increase in the number of women with symptomatic POP between 2010 and 2050 from 46% (3.2 to 4.9 million women) to 200% (from 3.3 to 9.2 million women). (800) This will lead to an increase in demand for treatment as well as the need for economic resources.

Traditionally, Gynaecologists have based their decisions regarding treatment options upon the success rate, patient satisfaction, peri-operative morbidities and complications. With rising health care costs and in a setting of finite resources, it is now imperative that clinicians should include the financial costs of surgical interventions as a vital part of their decision-making process. Hullfish et al designed a study to compare the relative cost-effectiveness of treatment decision alternatives for post-hysterectomy POP.(801) The authors used a Markov decision analysis model to assess and compare the relative cost-effectiveness of expectant management, use of a ring pessary and vaginal reconstructive surgery (VRS) and open or robotic sacral colpopexy to obtain months of quality adjusted life (OALY) over 1 year. Laparoscopy for prolapse surgery and vaginal mesh kits were excluded as the authors do not utilise those two procedures at their institutions and colpocleisis was also excluded as the baseline cases desired preservation of coital function. Only two decision alternatives were found to be cost-effective: pessary use and VRS. Pessary use achieved 10.4 OALY at a cost of $10,000 per patient. This cost included all events for patients initially assigned to pessary use including costs for those patients who eventually underwent surgeries within the 12-month time frame. The VRS alternative obtained 11.4 QALY at $15,000 per patient. Each of the other alternatives achieved fewer OALY at greater cost. National Institute for Health and Case Excellence (NICE) had updated guidelines on management of POP in 2019, commenting that a time horizon of at least 5 years would be required to capture all important differences in costs and outcomes between surgery and pessary.(802) Even though pessary has lower intervention costs when compared with surgery, when taking into account the whole sequelae of events the cost differential will be reduced. At the same time, even though surgery has a high risk of complications that may require intensive care and may incur high costs, the women's individual choices and quality of life should be the main outcome of interest. In the analysis "Vaginal Pessaries for Pelvic Organ Prolapse or Stress Urinary Incontinence: A Health Technology Assessment",(803) the authors did the first known analysis estimating the cost-effectiveness of treatment sequences for POP (Pessary -> PFMT -> Surgery, PFMT -> pessary -> surgery, PFMT-> surgery, Pessary -> surgery, surgery), accounting for the complexities of treating these chronic conditions through a stepped care approach (a sequence of interventions followed after the current treatment proves ineffective). The time horizon was 10 years, which is useful when evaluating conservative treatments as they have a large discontinuations rate over time. They concluded that there was high degree of certainty that pessaries were cost-effective in a population with POP. When the treatment sequence of pessaries and surgery was compared with surgery alone, the pessaries treatment sequence dominated surgery alone in the cohort with POP, and in the cohort with SUI pessaries had an incremental cost-effectiveness ratio (ICER) of $1,033 per QALY gained.

There are several surgical techniques and materials used in the treatment of POP. For anterior, the cost-effectiveness of surgical management options (including mesh and non-mesh procedures) were evaluated. Over the last decade both clinical efficacy and cost-efficiency of the mid-urethral sling in incontinence surgery has been demonstrated. Transvaginal mesh kits have been introduced to prolapse surgery in an attempt to replicate this benefit for the community. A study on the analysis of the cost-effectiveness of traditional anterior colporrhaphy (AC), non-kit mesh and commercial mesh kits for anterior vaginal prolapse repair showed that commercial mesh-kits are not cost-effective.(804) The authors included the

estimated cost of managing recurrent prolapse and extrusions in the analytic model after performing a meta-analysis of 18 papers relating to anterior compartment repair to determine operating and admission time, recurrence rate and mesh extrusion rate for the three groups. The cost of non-kit mesh was $3,380, AC was $3,461 and mesh kits $4,678. Non-kit mesh repair is cost-effective, compared with AC, if extrusion rates remain below 25%. One-way cost sensitivity analysis demonstrates that when the reoperation rate for AC reached 28%, the commercial mesh kits became cost-effective. The balance of the costs of AC and non-mesh kits depends significantly on recurrence and extrusion rates could be erosion or exposure. Two-way cost sensitivity analysis demonstrated that if the re-operation rate of AC is below 20%, AC is more cost-effective even if the extrusion rate is 0%. When the reoperation rate of AC is 30% the non-mesh kit repair is the most effective operation if the extrusion rate is less than 25%.

At the same time Jacklin et al also used a decision-analytic Markov model to compare the cost effectiveness of anterior repair augmented with synthetic mesh against non-mesh anterior repair (805) and concluded that anterior augmented repair with mesh was relatively less cost-effective. Under base case assumption at five years, the incremental cost-effectiveness ratio (ICER) for mesh-augmented anterior repairs was £15 million per OALY. This was mostly due to the extra costs associated with the price of the mesh and treatment of mesh erosion. Glazener et al (587) evaluated the cost-effectiveness of surgical options for the management of anterior and / or posterior vaginal wall prolapse in the United Kingdom. The economic analysis was conducted alongside RCTs and supplemented with modelling. The first analysis was conducted alongside an RCT in women who were having their first (primary) anterior or posterior prolapse repair (n= 1,348). The interventions included standard repair, synthetic mesh, and biological graft. The secondary analysis was conducted alongside an RCT in women who were having their secondary anterior or posterior prolapse repair (n= 154). The analysis was conducted from NHS perspective and included a range of direct cost including intervention procedure costs (mesh cost, staff time in theatre, cost of drugs in theatre, cost of catheterisation, cost of vaginal packing, theatre overheads), inpatient and follow up secondary care costs (including new prolapse and incontinence procedures, other related readmissions, further prolapse related surgery, outpatient visits) and costs of primary care services relating to the index prolapse surgery (including physiotherapy, GP nurse, GP doctor, shelf pessary, ring pessary, incontinence drugs, oestrogen, intermittent catheter, absorbent pads, other drug treatments). For the outcome of primary anterior and / or posterior repair, incremental costs were £363 (95% CI, £32 to £758) and £565 (95% CI, £180 to £950) for synthetic mesh and biological graft Vs standard respectively. Incremental OALY were 0.071 (95% CI, 0.004 to 0.145) and 0.039 (95% CI, 0.041 to 0.120) for mesh and graft Vs standard respectively. A Markov decision model extrapolating trial results over 5 years showed standard repair had the highest probability of cost-effectiveness, but results were surrounded by considerable uncertainty. For secondary repair, there were no statistically significant differences between the randomised groups in any outcome measures, but the sample size was too small to be conclusive. The conclusions made were: in women who were having primary repairs, there was evidence of no benefit from the use of synthetic mesh or biological graft compared with standard repair. The secondary trials were two small to provide conclusive results. The NICE guidelines (802) committee acknowledged the existing UK-based economic evidence which showed that mesh was potentially cost-ineffective when compared with a non-mesh procedure in women with primary anterior POP. The guideline economic analysis with a 15-year time horizon demonstrated that anterior colporrhaphy (without mesh) was the dominant procedure (that is, it resulted in lower costs and higher OALYs) when compared with anterior colporrhaphy with biological graft / synthetic partially absorbable mesh / non absorbable mesh. The cost ineffectiveness of mesh was attributed to a higher rate of mesh complications including mesh extrusion / erosion and pain, and high costs associated with managing mesh complications. The probability of anterior colporrhaphy (without mesh) being cost effective was 0.69 at a NICE's lower cost-effectiveness threshold of £20,000 per OALY. Sensitivity analysis indicated the risk of mesh complications including mesh extrusion and pain would need to be very low for the mesh to be considered cost-effective. The committee also suggested that for women with a recurrent anterior POP with adequate apical support or when an abdominal approach is contraindicated, synthetic polypropylene or biological mesh placement could be considered as an option. In such cases, the benefits of synthetic or biological mesh placement will potentially outweigh the costs associated with the higher risk of mesh complications.

It is now recognised that women with advanced prolapse require adequate apical support to ensure durability of a simultaneous anterior and / or posterior correction.(806) Options for correcting apical prolapse include: sacral colpopexy (ASC) which can be performed via a laparotomy or laparoscopically including robotically assisted laparoscopy, sacrospinous ligament fixation (SSLF), uterosacral ligament suspension, McCall's culdoplasty and levator myorrhaphy. A Cochrane meta-analysis of level 1 data comparing abdominal sacrocolpopexy (ASC) with sacrospinous fixation (SSLF) showed that ASC was superior in terms of recurrent vault prolapse, post-operative stress urinary incontinence (SUI) and post-operative dyspareunia. However, the downside of ASC includes longer operating time, longer recovery time, and increased inpatient cost. Ohno et al used a decision analytic model to compare ASC to SSLF using TreeAge Pro (2013). Results showed that ASC is more expensive than SSLF ($13,988 vs $11,950) but is more effective (QALY 1.53 vs 1.45) and is cost-effective (ICER $24,574 / OALY) at 2 years (807). The additional costs incurred with ASC are justifiable owing to the improved outcome associated with ASC. However, if the cost of SSLF further decreases, or if the post-operative outcomes after SSLF improve, then ASC is no longer cost-effective. Limitations of the study include the lack of incorporation of the peri-operative complications like mesh erosion, wound complications etc. Evaluations extending the analysis to longer than two years are required.

Lua (808) also assessed the costs of sacrospinous ligament fixation (SSF), abdominal sacrocolpopexy (ASC), laparoscopic sacrocolpopexy (LSC), in women with apical prolapse in USA. The resource use estimates were based on the retrospective observational cohort study, commercial claims and encounter database (SSF, n=17,459); (ASC, n=6,126); (LSC, n=10,708). The mean total costs per women were $13,916 for SSF, $15,716 for ASC, and $16,838 for LSC. SSF was found to be more cost saving when compared with both ASC and LSC. Two cost-minimisation studies have evaluated the relative inpatient cost of robotic sacral colpopexy (RCS), laparoscopic sacral colpopexy (LSC) and ASC (809,810) with both findings that the ASC was the least costly inpatient option. Patel reviewed 15 cases, 5 each of ASC, LSC, RSC performed in USA in 2008 (Patel et al, 2009). Results showed that ASC was the least expensive at $13,419, LSC at $19,308 and RSC the most expensive at $24,161. Importantly, in this model there were no differences in length of stay and all procedures had long operating times, with the robotic procedure being over 2hr quicker than the laparoscopic procedures, which does not reflect common practice in the literature. Judd et al., using a decision model, estimated the hospital cost of ASC at $5,792, LSC at $7,353 and RSC at $8,508 (ex-

cluding the cost of the robotic system). In this model, RSC and LSC became cost equivalent only when the robotic operating time was reduced to 149 min, robotic disposables were reduced to $2,132 or laparoscopic disposables were increased to $3,413. Both models of analysis only included inpatient care and may not reflect other benefits of the minimally invasive approach such as quicker recovery and possibly faster return to work. Paraiso et al. performed an RCT comparing RSC (38) and LSC (40) for vault prolapse and reported the robotic group incurred significantly greater costs than the laparoscopic group (mean differences +$1,936; 95% CI $417-$3,454; P=0.008).(384) Importantly, in this study the authors were experienced laparoscopic surgeons who had also completed the learning phase of the RSC. At that same time; Anger et al (811) also randomised 78 women into laparoscopic and robotic group. The RSC group had higher initial hospital costs ($19,616 compared with $11,573, p<0.001) and over six weeks, hospital costs remained higher for RSC ($20,898 compared with $12,170, p<0.001). When costs of robot purchase and maintenance had been excluded, the difference would not be significant. Therefore, primary cost difference between RSC and LSC resulted from robot maintenance and purchase costs.

Maher and Connelly reported a cost minimisation analysis of an RCT comparing total vaginal mesh (TVM n=55) and LSC (n=53) in the management of vault prolapse at two years.(812) Opportunity costs, defined as the economic costs to the women associated with recovery time were added to define the total economic cost. Mean total economic costs were significantly lower in the LSC group compared with the TVM ($4,013.07, 95% CI 3,107.77-4,918.37). Labour costs were significantly greater for the LSC, reflecting that the operating time was twice as long as that of the TVM procedure. These higher labour costs were offset by lower consumable, inpatient, opportunity and reoperation costs for the LSC compared with the TVM. One-way cost analysis for the LSC and TVM demonstrates that cost equivalence would be achieved once the consumable cost reduced to zero, or the reoperation rate was zero in the TVM group or the operating time of the LSC was 130 min longer than that of the TVM. By using similar decision analysis model, Richardson et al compared the cost-effectiveness of three strategies for the use of a mid-urethral sling to prevent occult urinary incontinence in patients under-going abdominal sacral colpopexy.(813) They concluded that universal concomitant mid-urethral sling is the most cost-effective prophylaxis strategy for occult stress urinary incontinence undergoing ASC. Corracedo (814) compared the cost-effectiveness of laparoscopic sacrocolpopexy (LS) and transvaginal mesh (TVM) in women with POP in Spain. He made the conclusion that the mean total costs per woman were €5,985.7 (95% CI, €5,613.1 to €6,358.3) for LS and €6,534.3 (95% CI, €6,290.4 to €6778.3) for TVM. Based on the above costs, LS is cost saving when compared with TVM. Ehlert (815) assessed the costs associated with robotic sacrocolpopexy (RSC) when compared with transvaginal mesh repair (TVM) in women (n=226) the required surgical repair of POP in USA. In women who were also undergoing concomitant hysterectomy, the mean total costs per women were $12,483 for RSC and $9,676 for RSC and $6,719 for TVM. Based on the above costs, TVM is cost saving procedure. This was mainly due to lower surgical supplies costs and also shorter operating time. Husby (816) assessed the costs associated with Manchester-Fothergill procedure against uterosacral ligament suspension (with vaginal hysterectomy) in Denmark when considering only the primary operation, the mean total costs per woman over 20 months were €3,514 for uterosacral ligament suspension (with hysterectomy) and €2,318 for Manchster-Fothergill procedure is less expensive when compared with uterosacral ligament suspension (with hysterectomy) in women with apical POP. This was due to greater reoperations costs post uterosacral ligament suspension. The NICE committee (802) commented that the existing economic evidence for apical POP was non UK based and was too heterogenous. As a result, the committee could not draw any conclusion from it. Although, it was noted that laparoscopic procedure is less invasive, quicker to perform, and is associated with a shorter recovery, not all surgeons are trained in its use and it is not available in all centres.

According to NICE guidelines,(802) the existing economic evidence pertaining to posterior surgery was limited to one UK study (587) with the study population comprised of women with anterior and / or posterior POP. The probability of standard repair being cost-effective was 0.5 at any willingness-to-pay value per OALY. This supports that non-mesh repair is more favourable cost-effectiveness when compared with mesh repair.

An interesting retrospective study in 2016 studied the trends and factors influencing inpatient prolapse surgical cost and length of stay in United States.(817) This retrospective cross-sectional study along with longitudinal trend analysis from 2001 to 2011 National Inpatient Sample (NIS) included 116,474 subjects who underwent inpatient POP repairs. The NIS is the largest all-payer inpatient care database that is publicly available in USA and provides reliable estimates of average LOS and costs. Unadjusted analysis revealed increase LOS with age of 80 years or older. African American race, uninsured status, lower income and lower surgical volume hospitals (≤75%) all increased cost in the West and public hospitals. African Americans had 1.09 (95% CI, 1.05-1.13, p<0.001) times longer LOS compared with Caucasians, and the uninsured had 1.15 (95% CI, 1.01-1.30, p=0.032) times longer LOS compared with those privately insured. Comorbidities associated with 20% increase in LOS and causes were pulmonary circulation disorders, metastatic cancer, weight loss, coagulopathy, and electrolyte/ fluid imbalance (p<0.001). Congestive heart failure and blood loss / deficiency anaemia lead to 20% longer LOS (p<0.001). In 2001-2011, mean LOS declined from 2.42 days (95% CI, 2.37-2.47) to 1.79 days (95% CI, 1.71-1.87, p<0.001) whereas mean total cost increased from $6,233 (95% CI, $5,859-$6,607) to $9,035 (95% CI, $8,632 -$9,438, p<0.001). The authors concluded that some patient and hospital characteristics are associated with increased inpatient LOS and cost and modifiable factors could be addressed to reduce cost. If medical comorbidity is not modifiable, non-surgical treatment should be considered as an alternative. In addition, some modifiable factors such as pre-operative planning, peri-operative management of medical conditions and high-volume surgical programs will lead to decreased LOS and costs which allow the physicians and hospitals to advocate and plan for necessary health care resources allocation.

Conclusions

- Native tissue vaginal repairs are more cost effective than transvaginal mesh repairs. (GoR B)
- ASC is more expensive than SSLF ($13,988 vs $11,950) but is more effective (QALY 1.53 vs 1.45) and is cost-effective (ICER $24,574 / OALY) at 2 years. (GoR C)
- Mean total economic costs were significantly lower in the LSC group compared with the TVM ($4,013.07, 95% CI 3,107.77-4,918.37). (GoR B)
- Based on inpatient cost alone Robotic approach is more expensive than laparoscopic approach which is more expensive than open approach to sacrocolpopexy. (GoR C)

Future research recommendations

- The surgical management of uterine prolapse needs significant further clarification.
- The surgical management of anterior compartment prolapse including recurrent prolapse needs further clarification.
- The role of potential risk factors for recurrent prolapse needs clarification to aid in informed individual decision making.
- New biomaterials for reconstructive surgery are required.

Summary of Findings

While the above text is significant in the evaluation of the surgical management of POP, the reader should note that no trial to date has reported a single intervention that has demonstrated superior outcomes to any other intervention using validated quality of life pelvic floor questionnaires for vaginal prolapse, bladder or bowel function. This indicates that either the interventions are not significantly different for the patients or that the questionnaires are not sensitive enough to detect change. Notwithstanding this problem, our committee has developed a treatment algorithm for the surgical management of prolapse (Figure 10). The committee recognises the algorithm is a guideline for both patients and clinicians and that patient's treatment is best individualised and recorded in open and transparent consultation and consent. The decisions that informed the algorithm are based on the findings in the report and the recommendations are summarised in Table 28.

The committee notes that prolapse surgery has undergone significant changes over the last four years with the removal of many commercial transvaginal mesh products from the market. Despite extensive criticism and concern raised by the general community regarding our unguarded optimism with the introduction of new surgical techniques and changes to regulatory pathways for new devices, as a group we continue to perform surgeries with little evidence as to their safety and efficacy. For example, many of the newer light weight mesh devices that are currently available have little supportive data and these products require significant further evaluation prior to being introduced into treatment pathways for the surgical management of prolapse.

A second example relates to the anecdotal perception that the performance of sacral colpopexy for uterine prolapse, that includes sacrohysteropexy, or supracervical or total hysterectomy and sacral colpopexy, is increasingly common. The confidence in surgical outcomes relating to sacral colpopexy is largely derived from post hysterectomy prolapse data and there is a paucity of data relating to these interventions. An interesting contradiction is emerging that while there is increasing data to support the performance of sacral colpopexy for post-hysterectomy prolapse, the limited early data available in this review suggest that neither sacrohysteropexy, nor supracervical or total hysterectomy and sacral colpopexy are superior to a variety of vaginal based interventions. The current evidence based algorithm points towards vaginal based native tissue interventions for primary uterine prolapse and reserving sacral colpopexy for post-hysterectomy and recurrent prolapse.

Innovation in the surgical management of pelvic organ prolapse remains vital to improving the outcomes of the women we are privileged to treat. There remains a simple obligation for clinicians and industry to work collaboratively and within the confines of appropriate national and local regulatory oversight to ensure that these new interventions are adequately evaluated prior to the wider introduction to the general market. These simple measures will help ensure that we are able to recapture the confidence of the community we serve.

Table 35 Summarises key finding and relevant GoR for the surgical treatment of pelvic organ prolapse

Table 35 summarises key findings and GoR summary for the POP surgery chapter

Treatment	GoR
Obliterative Surgery	
• Effective low morbidity surgery for women not wishing to retain coital activity	C
• Partial Colpocleisis is preferred over vaginal hysterectomy and total colpocleisis when there is no specific indication for hysterectomy and no interest in preserving coital function.	C
Reconstructive Surgery	
Isolated cystocele:	
• Anterior Colporrhaphy (AC) is generally recommended however permanent synthetic mesh could be considered for recurrent prolapse if women understand the risk/benefit profile	A
• Biological grafts offer no significant advantage over AC	B
Isolated rectocele:	
• Posterior Colporrhaphy (PC) is the procedure of choice	B
• Fascial plication superior to site specific posterior vaginal repair	C
• Levatorplasty associated with high rate of dyspareunia	C
• No evidence demonstrating benefit for synthetic or biological graft	C
• PC reduced prolapse with equal functional outcome compared to transanal approach	B
• No data demonstrates ventral rectopexy ± vaginal graft is effective for rectocele.	D
• Those with combined rectal and vaginal prolapse benefit from colorectal & gynaecologist collaboration	C
Apical prolapse	
• Apical suspension at AC or PC significantly reduces the need for subsequent prolapse surgery	B

Treatment	GoR
Vault prolapse (post hysterectomy)	
• Sacrocolpopexy has significant anatomical and functional advantages when compared with a broad group of vaginal surgery (±mesh)	A
• Vaginal apical suspensions appropriate those not suitable for SC (Delphi)	C
• Transvaginal apical mesh confers no advantage when compared to native tissue repairs	A
• Uterosacral & sacrospinous colpopexy have similar efficacy for apical prolapse	B
• Laparoscopic sacrocolpopexy has advantages over both robotic and open approach however the learning curve with both laparoscopic and robotic approach is significant.	B
Uterine prolapse	
• Relative contraindications to uterine preservation are listed in the Table 6.	C
• Salpingectomy ↓risk of ovarian Ca in women retaining ovaries at the time of hysterectomy	B
• Vaginal hysteropexy is equally effective as vaginal hysterectomy with apical suspension and is associated with reduced blood loss and operating time	B
• Opportunistic salpingectomy which is not able to be performed at vaginal hysteropexy should be included in the shared decision making process (Delphi)	C
• Large database studies demonstrated lower reoperation rates for recurrent prolapse and slightly higher complication rates in the hysterectomy group compared to hysteropexy.	C
• Vaginal hysterectomy with apical suspension has a lower reoperation rate for prolapse than abdominal sacr-hysteropexy	B
• Sacrohysteropexy (SHP) has a similar success rate and reoperation for prolapse when compared to vaginal hysterectomy and USLS, however lower success rates than sacrocolpopexy with total or supracervical hysterectomy.	C
• Sacrocolpoexy with hysterectomy is associated with a high rate of mesh exposure	B
• Supracervical hysterectomy has a lower rate of mesh exposure than hysterectomy & SC	B
• Supracervical hysterectomy has ↑ rate of recurrent POP compared to SC & hysterectomy	C
Prolapse surgery and lower urinary tract functions	
• POP + SUI consider POP and continence surgery	A
• POP + occult SUI consider POP & continence surgery (consider staged procedure)	B
• POP without occult SUI does not require concomitant continence surgery.	B
• Preoperative OAB resolves in approximately 50% post prolapse surgery although the impact of concomitant non- surgical treatment on this date has not been clarified.	D
• The rate of reported denovo OAB varies widely 2-32% with further clarification required.	C
• Rates of Urinary retention following POP surgery varies from 0-34% and is nearly always temporary.	C
• Pre-operative urinary retention resolves in as many as 90% post prolapse surgery	C
Risk factors for recurrent prolapse	
• Age < 60 years	C
• Stage 3 or Stage 4 prolapse	B
• Preoperative widened genital hiatus or levator defects on USS: data are inconclusive	D
• Less experienced surgeons have higher rates of recurrent prolapse after transvaginal surgery	C
• Low volume surgeons have ↑ rate of complications compared to high volume surgeons	B
• Peri-operative physiotheraphy does not reduce rate of recurrent prolapse	A
Prolapse surgery Complications	
• Vaginal mesh repairs have a higher rate of complications than native tissue repairs	A
Concerning vaginal surgery	
• If a synthetic mesh is utilised it is recommended that it be macroporous monofilament polypropylene and hysterectomy avoided	B
• Bowel preparation prior to surgery is not recommended	B
• It is recommended to avoid excessive excision of vaginal skin	C
Concerning sacrocolpopexy	
• A macroporous monofilament polypropylene mesh recommended	B
• Concomitant hysterectomy not recommended	B
• Laparoscopy preferred approach	B
• Delayed absorbable sutures preferenced in securing mesh to vagina	C
• Closure peritoneum recommended (Delphi)	C
Expert Opinion Recommendations	
• Cessation smoking pre-operatively	C
• Comply with prevention of nosocomial infections	C
• Antibiotic and thromboembolic prophylaxis	C
• Treat UTIs preoperatively	C

Treatment	GoR
Prolapse surgery and sexual function	
• Sexual function generally improves or remains unchanged following prolapse surgery	B
• Sexual satisfaction measured with validated PISQ is lower after transvaginal mesh than native tissue vaginal repair while the rates of denovo dyspareunia and total dyspareunia are similar	B
• Synthetic transvaginal mesh has a higher rate of dyspareunia compared to sacrocolpopexy	C
• When comparing vaginal biologic grafts to vaginal native tissue repairs, there are similar decreases in postoperative dyspareunia and similar changes in sexual function	C
• When reporting prolapse surgery outcomes pre and postoperative sexual activity, dyspareunia and use of validated sexual function questionnaire and rate denovo dyspareunia preferrable	C
Cost prolapse surgery	
• Native tissue vaginal repair is more cost effective than transvaginal mesh repairs	B
• ASC is more expensive than SSLF ($13,988 vs $11,950) but is more effective (QALY 1.53 vs 1.45) and is cost-effective (ICER $24,574 / OALY) at 2 years	B
• Inpatient cost and total cost are higher for robotic than laparoscopic sacrocolpopexy	B
• Inpatient cost are higher for laparoscopic than open sacrocolpopexy.	B
Prolapse surgery Rates and Outcomes	
• Significant variation exist in reporting rates and types of surgery performed worldwide	B
• Early evidence of declining Rates of prolapse surgery worldwide requires further evaluation s	B
• Evidence based pathways for surgical treatment of prolapse may reduce variability in surgical interventions (Delphi)	C
Reporting outcomes	
• Anatomical outcomes should include all POP-Q points and staging utilising traditional definition of success. Assessment should be prospective blinded and without any conflict of interest related to intervention	C
• Subjective assessment should be absence of vaginal bulge	C
• Functional outcomes are best reported using valid, reliable and responsive symptom questionnaires and condition specific HRQOL instruments	C
• Prolapse surgery should be defined as primary surgery, and repeat surgery subclassified as primary surgery different site, repeat surgery, complications related to surgery and surgery for non-related conditions.	C

I. INTRODUCTION

1. EVIDENCE ACQUISITION

The unrestricted, fully exploded Medical Subject Heading (MeSH) "interstitial cystitis" (including all related terms as "painful bladder syndrome", "bladder pain syndrome", or different terms such as "chronic interstitial cystitis", etc.) were used to thoroughly search the Pub Med database (https://www.ncbi.nlm.nih.gov/pubmed/) of the United States National Library of Medicine of the National Institutes of Health from the years 2017-2021. Seven hundred fifty-five publications in English or with English abstracts were reviewed.

Focus was on clinical trials, randomized controlled trials, meta-analyses, scientific guidelines, and core clinical journals. The literature update this achieved was added to the previously existing database reflected in the 2017 publication that was established according to a similar protocol. (1)

Rating of the level of evidence and grade of recommendation was performed according to the Oxford Scale. The committee believes that the Oxford system for categorizing levels of evidence is primarily relevant only for the sections on treatment which follow. While the committee's opinions will be expressed where applicable regarding evidence and conclusions for other areas including diagnoses, aetiology, and pathophysiology, use of the Oxford system in this context is more open to interpretation.

2. DEFINITION AND TAXONOMY

The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage". (2) **table 1** Interstitial Cystitis/Bladder Pain Syndrome (IC/BPS) is a clinical diagnosis that relies on symptoms of pain in the bladder and or pelvis and other urinary symptoms like urgency and frequency. It is a physical disorder that is often associated with pervasive and severe psychosocial impacts (3). Therapeutic regimens and clinical trials can be difficult to interpret as up to half of patients tend to improve with time with or without regular follow-up and seemingly unrelated to treatment (4,5).

Based on the evolving consensus that IC/BPS is strongly related to other pain syndromes like Irritable Bowel Syndrome, Fibromyalgia and Chronic Fatigue Syndrome in some patients, the European Society for the Study of Bladder Pain Syndrome (ESSIC) published a comprehensive paper on definition and diagnosis of IC/BPS. (6) IC/BPS was defined as chronic (>6 months) pelvic pain, pressure, or discomfort *perceived to be* related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Confusable diseases as the cause of the symptoms must be excluded. Further documentation and classification might be performed according to findings at cystoscopy with hydrodistension and morphological findings in bladder biopsies. **table 2** The presence of other organ symptoms as well as cognitive, behavioural, emotional, and sexual symptoms should be addressed.

This definition has been broadly accepted although actual wording differs somewhat (7). Because omitting the name "Interstitial Cystitis" might cause serious problems in different health systems by affecting reimbursement and disability determinations, and because worldwide in 2022 the terms interstitial cystitis and bladder pain syndrome are used interchangeably in the world-wide literature, the name "interstitial cystitis/bladder pain syndrome" "IC/BPS" will be the preferred terminology in this updated Consultation. **Interstitial cystitis and bladder pain syndrome are essentially interchangeable as there is no accepted definition that clearly delineates the interstitial cystitis syndrome from bladder pain syndrome. Many studies referred to in this document will denote the syndrome as BPS, IC, or painful bladder syndrome, but are understood to represent the same collection of symptoms.**

Table 1. *2020 International Association for the study of Pain (IASP) Revised Definition of Pain explanatory notes. From Raja SN, Carr DB, Cohen M, Finnerup NB, Flor H, Gibson S, et al. The revised international association for the study of pain definition of pain. Pain 2020, May 23;Publish Ahead of Print(9)*

Pain
An unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage.

Notes
- Pain is always a personal experience that is influenced to varying degrees by biological, psychological, and social factors.
- Pain and nociception are different phenomena. Pain cannot be inferred solely from activity in sensory neurons.
- Through their life experiences, individuals learn the concept of pain.
- A person's report of an experience as pain should be respected.*
- Although pain usually serves an adaptive role, it may have adverse effects on function and social and psychological well-being.
- Verbal description is only one of several behaviors to express pain; inability to communicate does not negate the possibility that a human or a nonhuman animal experiences pain.

Etymology
Middle English, from Anglo-French peine (pain, suffering), from Latin poena (penalty, punishment), in tum from Greek poinē (payment, penalty, recompense). *The Declaration of Montréal, a document developed during the First International Pain Summit on September 3, 2010, states that "Access to pain management is a fundamental human right."

Table 2. ESSIC Classification of Bladder Pain Syndrome. *From van de Merwe JP, Nordling J, Bouchelouche P, Bouchelouche K, Cervigni M, Daha LK, et al. Diagnostic criteria, classification, and nomenclature for painful bladder syndrome/interstitial cystitis: An ESSIC proposal. Eur Urol 2008, Jan;53(1):60-7.*

Historically, definitions of IC have moved from a severe inflammatory bladder disease to a syndrome described primarily by symptoms (7) **table 3**

Table 3. Historical definitions of IC/BPS. *Hanno P, Nordling J, van OA. What is new in bladder pain syndrome/interstitial cystitis? Curr Opin Urol 2008, Jul;18(4):353-8.*

1887 Skene {Skene 1887}: An inflammation that has destroyed the mucous membrane partly or wholly and extended to the muscular parietes.
1915 Hunner: {Hunner 1915}: A peculiar form of bladder ulceration whose diagnosis depends ultimately on its resistance to all ordinary forms of treatment in patients with frequency and bladder symptoms (spasms).
1951 Bourque {Bourque 1951} : Patients who suffer chronically from their bladder; and we mean the ones who are distressed, not only periodically but constantly, having to urinate at all moments of the dav and of the night suffering pains every time they void.
1978 Messing and Stamey {Messing 1978} : Nonspecific and highly subjective symptoms of around-the-clock frequency, urgency, and pain somewhat relieved by voiding when associated with glomerulations upon bladder distention under anesthesia.
1990 Revised NIDDK Criteria: Pain associated with the bladder or urinary urgency, and, glomerulations or Hunner's ulcer on cystoscopy under anesthesia in patients with 9 months or more of symptoms, at least 8 voids per day, 1 void per night, and cystometric bladder capacity less than 350cc. {Gillenwater 1988} {Hanno 1990a}
1997 NIDDK Interstitial Cystitis Database Entry Criteria {Simon 1997a}: Unexplained urgency or frequency (7 or more voids per day), OR pelvic pain of at least 6 months duration in the absence of other definable aetiologies.
2008 European Society for the Study of Bladder Pain Syndrome (ESSIC) {VanDeMerwe 2008a}: Chronic (>6 months) pelvic pain, pressure, or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Confusable diseases as the cause of the symptoms must be excluded.
2014 Multidisciplinary Approach to the Study of Chronic Pelvic Pain (MAPP) {Landis 2014}, National Institutes of Health: Chronic unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms, in the absence of infection or other identifiable causes.
2009/2016 East Asian Guideline {Homma 2009} {Homma 2016}: A disease of the urinary bladder diagnosed by 3 conditions: lower urinary tract symptoms, Hunner lesion or mucosal bleeding after distention, and exclusion of confusable diseases. The characteristic symptom complex (hypersensitive bladder syndrome) includes bladder hypersensitivity, usually associated with urinary frequency, with or without bladder pain.
2011/2015 American Urological Association {Hanno 2011} {Hanno 2015}: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than 6 weeks duration, in the absence of infection or other identifiable causes.
2015 Spanish Urological Association: {Esteban 2015} The unpleasant sensation (pain, pressure, discomfort) perceived in relation to the filling of the bladder and accompanied by at least another symptom of the lower urinary tract, either daytime or nightime, such as increased urinary frequency and in the absence of infection or another identifiable cause.
2016 Canadian Urological Association: {Cox 2016} See American Urological Association guideline
2019 German Guideline: {Bschleipfer 2019} Bladder pain syndrome is a symptom complex in which, in the absence of an infection or another underlying disease, the sufferer experiences chronic bladder-associated pelvic pain, pressure or discomfort, and at least one other specific symptom (e.g., a frequent or persistent urge to urinate. Hunner type, in which Hunner's lesions are clearly visible on cystoscopy. Non-Hunner type, in which no Hunner's lesions are observed during/after bladder filling.
2019 European Association of Urology: {Engeler} Bladder pain syndrome is the occurrence of persistent or recurrent pain perceived in the urinary bladder region, accompanied by at least one other symptom, such as pain worsening with bladder filling and day-time and/or night-time urinary frequency. There is no proven infection or other obvious local pathology.
2020 East Asian Guideline {Homma 2020} IC/BPS is the condition with chronic pelvic pain, pressure or discomfort perceived to be related to the urinary bladder accompanied by other urinary symptoms, such as persistent urge to void or urinary frequency in the absence of confusable diseases. HIC is IC/BPS with Hunner lesions. BPS is IC/BPS without Hunner lesions.

The International Continence Society (8) (ICS) used the term Painful Bladder Syndrome (PBS) defined as "the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology". ICS reserved the diagnosis Interstitial Cystitis (IC) to patients with "typical cystoscopic and histological features", without further specifying these. It has however been shown that only a fraction of patients believed by experts to have IC/BPS fulfil this definition (9).

In the remainder of this chapter the condition will be referred to as interstitial cystitis/bladder pain syndrome (IC/BPS). Some of the older literature may be discussed using the original terminology in the interests of clarity. Logically "interstitial cystitis" should include some form of demonstrable inflammation in the bladder wall, while "bladder pain syndrome" should include pain in the region of the bladder (10). The diagnosis is based on exclusion of other diseases in the bladder, urethra, and other pelvic organs including the musculoskeletal system. As with other disorders without clear objective diagnostic criteria or pathophysiological explanation, countless theories have been put forward without adding much to the delineation or understanding of the disease.

In practice, patients with symptoms of IC/BPS are screened to exclude other relevant diagnoses or confusable diseases (6), and a focused evaluation is performed at the discretion of the physician or centre. This evaluation might include cystoscopy under local or general anaesthesia, bladder distension with registration of bladder capacity and/or the presence of glomerulations and Hunner lesion. Bladder wall biopsies might be obtained and evaluated for inflammation, ulcer, fibrosis, mast cells etc. The evaluation might also include urodynamics with registration of awake bladder capacity,

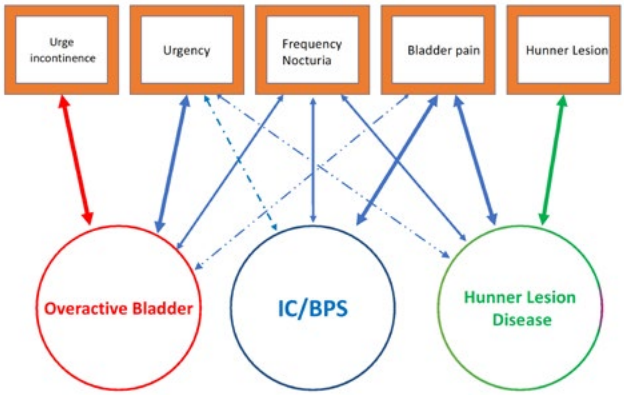

Figure 1. Overactive bladder and its relationship to IC/BPS and HLD. *Adapted from Abrams P, Hanno P, Wein A. Overactive bladder and painful bladder syndrome: There need not be confusion. Neurourol Urodyn 2005;24(2):149-50.*

compliance, and bladder stability (11). The potential symptom overlap of IC/BPS with overactive bladder (OAB) is graphically depicted in **figure 1** (12). The 14% incidence of urodynamic detrusor overactivity in the IC/BPS (13) patients is probably close to what one might expect in the general population if studied urodynamically (14). More recent publications suggest that the distinction with the confounding diagnosis of OAB is not quite as clear or easy to make as we had thought in the past. (15-18) Current thinking is illustrated in **Figure 2.** This is loosely adapted from the excellent work of Homma and the East Asian group studying the disorder. (19,20)

In the end, many of these investigations might prove to be normal and the patients are identified as having IC/BPS as a diagnosis of exclusion. The relevance of urodynamic, cystoscopic and histological findings is limited by a lack of consistency in technique, and it is therefore recommended to use the standardisations described by ESSIC (21) when comparing different cohorts of patients.

Coincident with this 2021 Consultation, there is much discussion in the world-wide literature with regard to the place of Hunner lesion patients in the IC/BPS spectrum (22-29) . This impacts directly on the issue of definition. The Consultation was one of the early leaders in calling for Hunner lesion patients to be classified as having a *disease* and no longer be considered as a part of the interstitial cystitis/bladder pain *syndrome.* (30) This puts Hunner lesion more in the spectrum of patients with an identifiable cause of their bladder pain and frequency such as radiation cystitis, urinary tract infection, ketamine cystitis, etc. This idea is not new and was originally proposed by Magnus Fall in 1987, but largely ignored (31). Fall, Nordling and the ESSIC group have reviewed this literature (32) and conclude that the Hunner lesion patient which first defined the patient group with “interstitial cystitis” should indeed be looked at as a disease unto itself in the absence of contrary data. A similar consensus has developed in Asia. (20) The large group of patients who meet the definition of IC/BPS as a diagnosis of exclusion are best served when viewed apart from those with specific disorders. As we learn more in the future, the IC/BPS group will by necessity diminish in size, but now makes up well over 60% of the combined Hunner lesion/IC/BPS population (33). The new classification of pain as either primary (a disease in its own right) or secondary (pain as a symptom of an underlying identifiable problem) that is proposed by the International Association for the Study of Pain would easily mesh with this concept. (34,35)

For now, FDA continues to look at IC/BPS as one disorder (36) and pharmaceutical companies are not obliged to study Hunner lesion and non Hunner lesion patients in individual trials. This may be subject to change in the future. In this chapter we will try to differentiate these groups as best as possible given previous publication and study parameters.

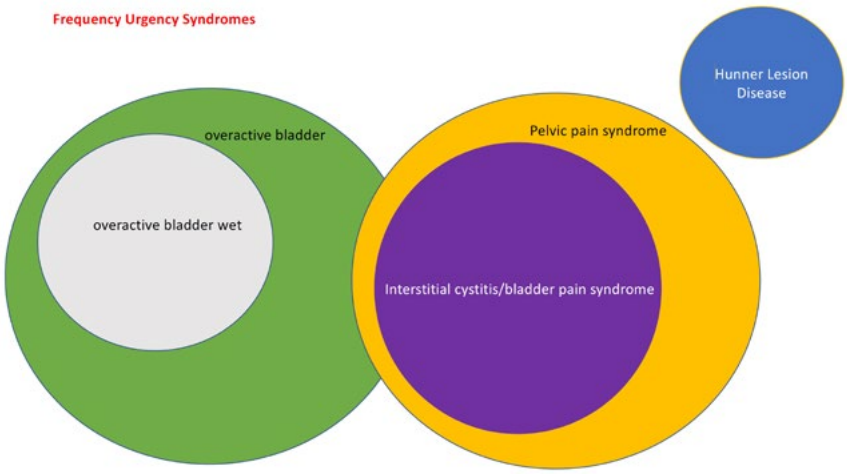

Figure 2. Relationship of Hunner Lesion Disease to frequency/urgency syndromes. *Adapted From Homma Y. Lower urinary tract symptomatology: Its definition and confusion. Int J Urol 2008, Jan;15(1):35-43. Homma Y, Akiyama Y, Tomoe H, Furuta A, Ueda T, Maeda D, et al. Clinical guidelines for interstitial cystitis/bladder pain syndrome. Int J Urol 2020, Apr 14;27(7):578-89.*
OAB: overactive bladder
IC/BPS: interstitial cystitis/bladder pain syndrome
HLD: Hunner lesion disease
Hunner lesion is considered a disease rather than a part of a syndrome and depends on characteristic findings on endoscopy and pathology. Hunner lesion in this diagram is separated from the purely symptomatic diagnoses though indistinguishable from BPS/IC based on symptoms alone.

II. HISTORICAL NOTES

Recent historical reviews confirm that interstitial cystitis was recognized as a pathologic entity during the 19th century. (37,38) In his textbook Practical Observations on Strangulated Hernia and Some Diseases of the Urinary Organs, Joseph Parrish, a Philadelphia surgeon, described 3 problematic cases of recurrent, severe lower urinary tract symptoms in which he made repeated attempts to locate a bladder stone, which was the most common source for these symptoms in early 19th century America. (39) As Teichman et al have convincingly argued, these patients displayed all the clinical hallmarks of IC including chronic frequency, urgency, dysuria and pelvic pain in the absence of demonstrable pathology. (40) Although he used the term repeatedly in his manuscript, Parrish did not elaborate upon the clinical definition of "tic douloureux," likely because contemporaneous physicians would have been familiar with the then popular neuralgia concept. Parrish attributed the term tic douloureux to his mentor, Dr. Phillip Syng Physick, who had applied it to patients with severe lower urinary tract symptoms with no discernible etiology. The most common etiology for these symptoms during the 19th century would be bladder calculi.

By 1808 Physick had developed a concept of bladder inflammation, a "bladder ulcer," that produced lower urinary tract symptoms in the absence of bladder stone. (38) Tic douloureux at the time represented a neurological irritation, most often associated with the trigeminal nerve but applicable to other sensory distributions as well, which produced pain and discomfort in the absence of injury or other specific physical findings. In applying the concept of tic douloureux to bladder sensation, Parrish was ascribing the paroxysmal lower urinary tract symptoms occurring in patients to an idiopathic process affecting the nerves of the bladder. Furthermore, tic douloureux allowed him to formulate a diagnosis for those patients who chronically manifested the symptoms caused by a stone (severe frequency, urgency, dysuria and pelvic pain) but had no stone that could be detected. That is, he considered a neuralgic aetiology in the absence of any other tangible causes of bladder pain.

By 1876, the 3rd edition of the book by Samuel D. Gross, revised and updated by his son Samuel W. Gross, reported that "When all the coats are implicated, it is termed interstitial or parenchymatous cystitis". (41)

Two years later, Skene used the term interstitial cystitis to describe an inflammation that has "destroyed the mucous membrane partly or wholly and extended to the muscular parietes". (42) Early in the 20th century, at a New England Section meeting of the American Urological Association, Guy Hunner reported on 8 women with a history of suprapubic pain, frequency, nocturia, and urgency lasting an average of 17 years. (43,44) He drew attention to the disease which he himself described as "elusive ulcer". However, the red, bleeding areas Hunner described on the bladder wall soon acquired the pseudonym "Hunner's ulcer". As Walsh observed, this has proven to be unfortunate. (45) In the early part of the 20th century, the very best cystoscopes available gave a poorly defined and ill-lit view of the fundus of the bladder. It is not surprising that when Hunner saw red and bleeding areas high on the bladder wall, he thought they were ulcers. For the next 60 years, urologists would look for actual ulcers and fail to make a diagnosis in their absence. The disease was thought to be a focal, rather than a pancystitis.

Hand authored the first comprehensive review about the disease, reporting 223 cases. "I have frequently observed that what appeared to be a normal mucosa before and during the first bladder distention showed typical interstitial cystitis on subsequent distension" he notes, further adding "small, discrete, submucosal haemorrhages, showing variations in form…dot-like bleeding points… little or no restriction to bladder capacity." (46) He describes three grades of disease, with grade 3 matching the small-capacity, scarred bladder described by Hunner. Sixty-nine percent of patients were grade 1 and only 13% were grade 3. Walsh later coined the term "glomerulations" to describe the petechial haemorrhages that Hand had described. (45) But it was not until Messing and Stamey discussed the "early diagnosis" of IC that attention turned from looking for ulcers to the concepts that 1) symptoms and glomerulations at the time of bladder distention under anaesthesia were the disease hallmarks, and 2) the diagnosis was primarily one of exclusion. (47) However, this description proved unsuitable for defining this disease in a manner that would help physicians make the diagnosis and set up research protocols.

The National Institute of Diabetes, Digestive, and Kidney Disorders (NIDDK) held a key meeting in 1987 with researchers and clinicians from around the world. (48) This ultimately resulted in the 1990 Revised NIDDK Criteria: Pain associated with the bladder or urinary urgency, and glomerulations or Hunner's ulcer on cystoscopy under anaesthesia in patients with 9 months or more of symptoms, at least 8 voids per day, 1 void per night, and cystometric bladder capacity less than 350cc. (49)

To validate the criteria, which were designed not for clinical diagnosis, but rather to ensure that patients enrolled in research trials could be agreed upon to have the disease, a database with broad entry criteria was created. The 1997 NIDDK Interstitial Cystitis Database Entry Criteria: Unexplained urgency or frequency (7 or more voids per day), OR pelvic pain of at least 6 months duration in the absence of other definable etiologies . (50) Urgency was not defined in the protocol. Participants were given a 10 point scale, and those who scored 2 or higher on self-report satisfied the urgency criteria.

A comparison of the NIDDK revised criteria with the database entry criteria revealed that up to 60% of patients clinically believed to have IC by experienced clinicians were being missed when the NIDDK research criteria were used as a definition of the disease. (51) With the demise of the NIDDK criteria as an appropriate clinical definition of the disorder, the controversial issues of nomenclature, taxonomy and diagnosis were actively debated internationally over the next 2 decades with no consensus reached. The numerous different names, definitions and criteria resulted in a great deal of confusion worldwide. (52) By 2002, the newly designated "overactive bladder syndrome" was dominating attention in urology to such an extent that IC/BPS was increasingly relegated to the field of pain and psychology, ultimately bringing any real progress in research and treatment to a virtual standstill. (53)

The history has been nicely summarized in a 2014 review by Meijlink. (54)

Over the last several decades, along with numerous attempts to improve therapies, nomenclature and taxonomy have taken center stage to improve methodology to enhance research in aetiology and treatment.

III. MODERN HISTORY

The literature over the past 200 years has seen numerous changes in the description and nomenclature of the bladder disease variously referred to as tic douloureux or neuralgia of the bladder, (chronic)

interstitial cystitis, parenchymatous cystitis, elusive ulcer, Hunner's ulcer, panmural ulcerative cystitis, urethral syndrome, painful bladder syndrome and bladder pain syndrome. (37,40,42,44,55-57)

From the nineteen seventies to the end of the 20th century, the name stabilized as interstitial cystitis, even though it was by now being used for patients with both lesion and non-lesion disease. However, publication of the formal definition of the term ''painful bladder syndrome'' by the ICS in 2000 (8) led to a move in the first decade of the new millennium to change the name from what some then felt to be a too restrictive term (interstitial cystitis) to a broader umbrella term (bladder pain syndrome) in line with an 'organ-pain-syndrome' classification system first conceived by the International Association for the Study of Pain (IASP). It first appeared in a European Association of Urology (EAU) guideline on chronic pelvic pain in 2004 (58) and was then adopted by ESSIC. (6) The place of IC/BPS in the complete taxonomy of chronic pelvic pain syndromes has been published by the International Association for the Study of Pain. (35)

The lack of consensus among stakeholders about nomenclature is not merely a theoretical problem. Table 4 It has hampered international harmonization in the field and may be impacting progress on identifying aetiologies, epidemiologic studies, and implementation of effective therapies. The failure to discover important phenotypes within the syndrome has affected treatment trials and produced conflicting data. As a result, health and regulatory authorities approve and reimburse treatments vastly differently throughout the world.

1. LANDMARKS IN THE NEW MILLENNIUM

2002: In its Standardization of Terminology of Lower Urinary Tract Function document, the International Continence Society (ICS) introduced the term "painful bladder syndrome", defining it as: "the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology", reserving "interstitial cystitis" for a specific diagnosis requiring confirmation by typical cystoscopic and histological features. The fact that it did not exactly describe these features caused some confusion and the disorder subsequently came to be known as PBS/IC or IC/PBS. (53)

2003: At the 1st meeting of the International Consultation on Interstitial Cystitis, Japan (ICICJ) in Kyoto, it was agreed that the term ''interstitial cystitis'' should be expanded to ''interstitial cystitis/chronic pelvic pain syndrome'' when pelvic pain is at least of 3 months duration and associated with no obvious treatable condition/pathology. (59)

2003: At a meeting of the NIDDK entitled ''Research Insights into Interstitial Cystitis'', it was concluded that ''interstitial cystitis'' will inexorably be replaced as a sole name for this syndrome. It will be a gradual process over several years. At the meeting it was referred to as ''interstitial cystitis/painful bladder syndrome'' in keeping with ICS nomenclature. (60)

2004: The International Consultation on Incontinence (ICI) included the syndrome as a part of its consultation. The chapter in the report was titled, ''painful bladder syndrome (including interstitial cystitis),'' suggesting that IC formed an identifiable subset within the broader syndrome. Because such a distinction is difficult to define, within the body of the chapter it was referred to as PBS/ IC (one inclusive entity). (60)

2004: The European Association of Urology (EAU) published a guideline on chronic pelvic pain, based on the 1994 IASP taxonomy of chronic pain, and opted for bladder pain syndrome. "Since symptoms invariably define the clinical condition the term ''Painful bladder syndrome'' or ''Bladder pain syndrome'' is more apposite." (58)

2006: Abrams et al published an editorial focusing on the nomenclature problem. (61). They noted that: "It is an advantage if the medical term has clear diagnostic features that translate to a known pathophysiologic process so that effective treatment may be given. …These organ-based diagnoses are mysterious, misleading and unhelpful, and can lead to therapies that are misguided or even dangerous." The editorial went on to say that a single pathologic descriptive term (interstitial cystitis) for a spectrum of symptom combinations ill serves patients. The umbrella term ''painful bladder syndrome'' was proposed, with a goal to define and investigate subsets of patients who could be clearly identified within the spectrum of PBS.

2006: At the IC research conference, held by the National Institute of Diabetes, Digestive, and Kidney Disorders (NIDDK), the ESSIC group suggested that Painful Bladder Syndrome be redesignated as Bladder Pain Syndrome (BPS), followed by a type designation. This was because PBS did not fit into the taxonomy of other pelvic pain syndromes such as urethral or vulvar pain syndromes, and because IC is open to different interpretations. (6)

2008 (-2021) The NIDDK decided a completely new approach needed to be taken and set up the Multidisciplinary Approach to the Study of Chronic Pelvic Pain (MAPP) project with a broader, multidisciplinary input and included researchers with clinical, epidemiological, and basic research expertise, all working collaboratively. Urologic Chronic Pelvic Pain Syndrome (UCPPS) is the term adopted by the network to encompass any urologic chronic pelvic pain syndrome, including IC/BPS and chronic prostatitis/chronic pelvic

pain syndrome in men. These syndromes were hypothesized to be similar until proven otherwise by MAPP research, thus receiving the similar designation of UCPPS. In creating yet a new diagnosis, the data generated became difficult to assess with regard to any previously defined syndromes. It has made the mountains of data generated by the MAPP difficult to interpret.

2009: The Japanese Interstitial Cystitis guideline committee re-introduced an earlier concept of hypersensitive bladder, originally defined in an ICS Standardization Document in 1988 as increased bladder sensation on filling. (62) This Japanese guideline suggested the term "hypersensitive bladder syndrome" for the symptom syndrome associated with IC or IC-like conditions. (63)

2012: The IASP Classification of Chronic Pain was updated in 2012. Bladder pain syndrome was defined as "the occurrence of persistent or recurrent pain perceived in the urinary bladder region, accompanied by at least one other symptom, such as pain worsening with bladder filling and daytime and/or night-time urinary frequency. There is no proven infection or other obvious local pathology." It further notes that "other terms that have been used include "interstitial cystitis", "painful bladder syndrome", and "PBS/IC" or "BPS/IC"; these terms are no longer recommended." (64)

2013: At the joint meeting of the 3rd International Consultation on Interstitial Cystitis, Japan and ESSIC in Kyoto, it was agreed to limit the use of the term "interstitial cystitis" to patients with bladder pain syndrome with a Hunner lesion. (65) This was supported by findings that suggest that Hunner lesions or what was classically referred to as "interstitial cystitis" denote a truly different disorder than "bladder pain syndrome" and can either be considered a distinct phenotype lying within the IC/BPS framework or a separate disease entirely. (25)

2013: In an editorial, Homma pointed out that IC is a disease name long used in medical and patient societies, but that it lacks clear definition. Furthermore, PBS and BPS both include the word "pain", creating the impression that patients must have pain, although a substantial number *do not interpret discomfort or pressure as being pain*. Homma noted that the urgency and frequency experienced by these patients are suggestive of increased sensation of the bladder or urothelium and therefore proposed the term "hypersensitive bladder (HSB)". (66)

2014: In a review article, Homma described taxonomy or nomenclature concerning interstitial cystitis and its related symptom syndromes as being in a state of confusion. In Japan, "interstitial cystitis is defined by three requirements: (i) hypersensitive bladder symptoms; (ii) bladder pathology; and (iii) no other diseases, where bladder pathology should be clearly stated either as Hunner's lesion or glomerulations after hydrodistention. Hypersensitive bladder can be used for the condition with hypersensitive bladder symptoms, but no obvious disease explaining hypersensitive bladder symptoms identified." (67)

2018: 4th ICICJ Conference, Kyoto, with an International Discussion Meeting. The theme was Hunner lesion and non-Hunner lesion. The meeting underlined the global confusion and lack of consensus and the damage that this was doing to the patients. While most of the delegates had been recommending splitting off Hunner lesion from non-lesion disease as a matter of urgency for clinical trials, it was reported that the FDA (USA Food & Drug Administration) Advisory Committee had inexplicably voted unanimously in favour of combining patients with and without Hunner lesions in clinical trials! (68)

2019: At the ESSIC Annual Scientific Meeting in Amsterdam, JJ Wyndaele noted that it is very concerning that there are multiple national and international guidelines in use, with differences in nomenclature, definitions, and recommended diagnostic investigations. Philip Hanno emphasized that we need a new international guideline sensitive to different healthcare systems and sensibilities. This should be a guideline that embraces new ideas from the past 5 years, and which is easily updated in accordance with new developments and insights. Many speakers emphasized the absolute importance of cystoscopy to differentiate between lesion and non-lesion, stressing that it is now urgent to separate the two. It was also noted by meeting chair Dick Janssen that it is important to incorporate patients and their organizations in research and listen to them to improve our healthcare.

2020: Global Interstitial Cystitis/Bladder Pain Syndrome Society (GIBS), INDIA, Virtual Annual Meeting September 2020.

By now meetings had gone virtual due to the COVID-19 crisis. Here too it was stressed that Hunner lesion disease should not be evaluated with non-Hunner disease in clinical studies. The only proven phenotype in 2020 is the Hunner lesion. The Hunner lesion patient population seems to be different to non-Hunner lesion patients. Its histology is also quite different. Gynaecologist Dr Tanvir Singh noted that cystoscopy should be mandatory to exclude other conditions and to diagnose Hunner lesion. Speakers emphasized the need for mandatory cystoscopy to distinguish Hunner lesion and exclude other disorders and this has now been incorporated an an Indian guideline.

2020: Being unable to hold an annual meeting, ESSIC organized a virtual Masterclass series.

There was much discussion of phenotyping and Hunner Lesion, with Philip Hanno quoting Magnus Fall:

"We have to, bit by bit, identify various causes of the IC/BPS syndrome (like CNS diseases, peripheral nerve damage, pelvic floor dysfunctions, inflammatory conditions, etc.). Diseases so identified have to be given proper denominations and have to be included in the diagnostic algorithms. The ultimate goal is to be able to administer the proper and best treatment for each condition. In oncology, various phenotypes are identified all the time and more intelligent and target-oriented treatments can be offered. To ignore identification of diverse clinical subgroups of IC/BPS with essentially different aetiology and pathogenesis in upcoming drug studies would be an historical mistake."

2. THE URGENCY DEBATE

An urgent need to void has always been one of the hallmark symptoms of IC/BPS and was perhaps most vividly described in 1918 by Guy Hunner, writing that "the patient often had such extreme urgency that she had to leave a street-car in order to enter the nearest house and ask for permission to void." (44)

This "sensory" (or hypersensitive) type of urgency, due to increasingly overwhelming, intolerable pain or unpleasant sensation as typically experienced by IC/BPS patients has always been the cause of immense stress and anxiety for these patients who may be afraid to leave their home in case they cannot find a toilet when they need it. It was described in the 1988 summary of the 1987 meeting of the National Institute of Diabetes and Digestive and Kidney Dis-

eases (NIDDK) on Interstitial Cystitis which stated that an automatic exclusion was an “absence of sensory urgency”. (48)

The 1988 International Continence Society (ICS) Standardization of Terminology of Lower Urinary Tract Function document noted under point 3 Procedures Related to the Evaluation of Urine Storage: “Urgency (this is defined as a strong desire to void accompanied by fear of leakage or fear of pain)”. [It should be noted here that “fear of pain” was never really appropriate and it would have been more accurate to describe this as “due to pain”]. This document also subdivided urgency into “motor urgency” and “sensory urgency” stating in sub-section 6.1.3 that: “Urgency may be associated with two types of dysfunction: a. Overactive detrusor function (motor urgency), and b. Hypersensitivity (sensory urgency)”. (62)

However, this all changed following the launch of the term Overactive Bladder Syndrome (OAB), when the term urgency was redefined in 2002 in the Standardization of Lower Urinary Tract Function Report from the Standardization Sub-committee of the International Continence Society as: “a sudden compelling desire to void” with no mention of sensory urgency. Addition of the word “sudden” made it exclusively applicable to OAB and urge(ncy) incontinence and urgency from this moment on was consequently only applicable to OAB patients. On paper, IC/BPS patients no longer had urgency. (8)

In 2007, the US Association of Reproductive Health Professionals (ARHP) and the Interstitial Cystitis Association (ICA) attempted to replace the term urgency in the IC patient with “persistent urge”, the stated purpose being to distinguish the symptoms of IC/painful bladder syndrome from those of overactive bladder. This was an attempt to harmonize with ICS but keep the symptoms described by many IC patients. They defined IC/PBS as follows: Pelvic pain, pressure, or discomfort related to the bladder, typically associated with persistent urge to void or urinary frequency, in the absence of infection or other pathology. However, persistent urge is not the same as an urgent need to find a toilet and misrepresents IC/BPS symptoms. Sensory or painful urgency needs to be reconsidered in official definitions for the sake of meaningful research and treatment of the patients in the future. (69)

IV. RECOMMENDATIONS FOR TERMINOLOGY

The Consultation has opted to use the term interstitial/cystitis/bladder pain syndrome (IC/BPS). Hunner lesion disease (HLD) will be used for patients with discrete inflammatory areas in the bladder that meet the definition of Hunner lesion and are diagnosed by cystoscopy. Further ongoing efforts at phenotyping will no doubt require changes and be reflected in future iterations of the Consultation.

V. PATIENT PERSPECTIVE

IC/BPS is a distressing bladder condition with far-reaching psycho-social consequences for the patient and can change not just a patient’s whole life but even their whole character. The problems they may have experienced in getting a diagnosis – in simply being believed – may have completely taken away their self-confidence and their confidence in the medical profession.

Bladder pain is a particularly stressful type of pain, while the frequent need to urinate both day and night means that many patients never get a proper night’s sleep and this sleep deprivation can have many detrimental consequences, both physical and psychological. In the daytime, the constant, urgent need to find toilets is a source of immense stress and anxiety, resulting in many patients hardly ever leaving their home, and becoming socially isolated.

While every patient is different, and the severity of their IC/BPS can vary from very mild to totally debilitating, IC/BPS can have a hugely detrimental impact on a patient’s quality of life, ability to function in society, and on their family life as a whole. IC/BPS can have a negative impact on intimate relationships since sexual intercourse may be painful or even impossible for both male and female patients. Since patients may find it difficult to raise this intimate and embarrassing subject with their doctor, it is important for the healthcare provider to raise this aspect. Furthermore, bladder issues are still taboo today. Patients find it embarrassing to talk about their bladder condition, while family and friends certainly don’t want to hear about it. This makes IC/BPS a very lonely disease.

The psycho-social impact on patients means that they need a great deal of empathy, support, time and patience from their healthcare providers. This might also go some way towards helping to restore the self-confidence of the patients and helping them to cope. Treating these patients requires specialized training and, ideally, specialized IC/BPS clinics.

IC/BPS also has a negative financial impact on patients and their families since work in some jobs becomes impossible when you need to keep running to the toilet, are suffering from chronic fatigue or even dangerously drowsy from pain medication. This financial aspect is exacerbated by the fact that in many countries effective treatment is not reimbursed, making it unaffordable for many desperate patients who then must make do with less effective treatment or none at all.

Despite years of research, treatment is still an art rather than a science, and patients increasingly have the feeling that the medical world has failed them. The past two decades have been disappointing and frustrating for the IC/BPS patients and their support groups who feel that no real progress has been made either in finding the right treatment for the right patient or in identifying the cause(s) of their pain, urgency and frequency which have such a devastating impact on their lives.

New patients are astonished to discover that this condition has so many different names and definitions and have difficulty in comprehending how this has happened. There are now a number of new patient support groups around the world and their leaders are experiencing great difficulty in persuading a) physicians in their country to take this nebulous, multi-named condition seriously and b) health and insurance authorities to approve and reimburse treatment.

An additional reason behind this lack of official approval is the repeated failure of studies and trials to produce convincing evidence of efficacy. A significant factor in this regard is that patients with every kind of bladder/pelvic pain disorder, with and without lesions and with or without bladder-centric symptoms, have been bundled together instead of being separated into subtypes and phenotypes. How did this happen? Or rather, why is it still happening?

It is clear that a different approach is now urgently needed. Hunner lesion must now be separated from non-lesion disease at least for research and treatment, while both Hunner lesion and non-lesion

types urgently need meaningful phenotyping so as to enable the best possible treatment and improvement in the patient's quality of life. Research must be able to move forward for the sake of the patients. (70)

VI. EPIDEMIOLOGY

In this 2021 Consultation, the nomenclature has been updated and is now referred to IC/ BPS and/ or HLD. Since the clinical diagnosis of IC/BPS is controversial, epidemiology studies of IC/BPS have been problematic and have randomly used BPS/ IC/ HLD. (71) The previous lack of an accepted definition, the absence of a validated diagnostic marker, and questions regarding etiology and pathophysiology, as well as overlapping causes of bladder pain, lower urinary tract symptoms and pelvic pain present challenges for clinical practice and research. (72) The other major difficulty in evaluating various prevalence research is that some is based on unverified self- report, others by physician diagnoses (with or without some type of verification) or by identification of IC/BPS symptoms (with or without exclusion of other confusable conditions) , each of which gives a different figure. This confusion becomes apparent when one looks at the variation in prevalence reports in the United States and around the world. These range from 3.5 per 100,000 population in Japan (73), to a questionnaire based study that suggests a figure of 20,000 per 100,000 in US women. (74) Studies, however, have consistently shown that bladder pain symptoms are more common than suggested by coded physician diagnoses. (75) In the following section, the terms BPS/ IC/ HLD are used as previously described in the original publication. Prevalence studies are difficult given the overlapping nature and taxonomy of chronic pelvic pain syndromes. (**Figure 3**)

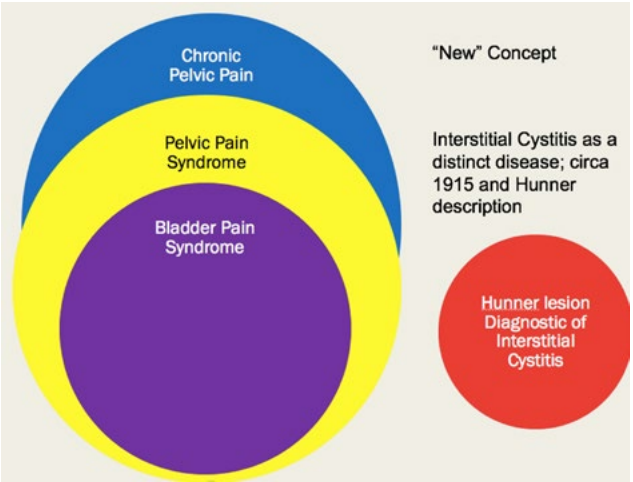

Figure 3. International Consultation Conception of bladder pain syndrome and interstitial cystitis.

2.1. Early epidemiological studies:

One of the first population-based studies (76) included "almost all the patients with interstitial cystitis in the city of Helsinki". This superb, brief report from Finland surveyed all diagnosed cases in a population approaching 1 million. The prevalence of the disease in women was 18.1 per 100,000. The joint prevalence in both sexes was 10.6 cases per 100,000. Ten per cent of cases were in men.

Another early population study, this in the United States, first demonstrated the potential extent of what had been previously considered a very rare disease. (4) The following population groups were surveyed: 1) random survey of 127 board-certified urologists 2) 64 IC patients selected by the surveyed urologists and divided among the last patient with IC seen, and the last patient with IC diagnosed 3) 904 female patients belonging to the Interstitial Cystitis Association and 4) random phone survey of 119 persons from the US population. This 1987 study reached the following conclusions (interestingly, most of these conclusions have stood the test of time and many further epidemiological studies described later in this section):

1. 43,500 to 90,000 diagnosed cases of IC in the USA (twice the Finnish prevalence)
2. Up to a five-fold increase in IC prevalence if all patients with painful bladder and sterile urine had been given the diagnosis, yielding up to half million possible cases in the USA
3. Median age of onset 40 years
4. Late deterioration in symptoms unusual
5. 50% temporary spontaneous remission rate, mean duration 8 months
6. 10 times higher incidence of childhood bladder problems in IC patients vs controls
7. 2 times the incidence of a history of urinary tract infection vs. controls
8. Lower quality of life than dialysis patients
9. Costs including lost economic production in 1987 of $427 million ($988 million in 2021 dollars)

2.2. Patient Self report surveys:

As mentioned earlier, the prevalence of IC/BPS can be estimated from patient self-reports, physician diagnoses and/or symptom based surveys. Jones and Nyberg (77) obtained their data from unverified self-report of a previous diagnosis of IC in the 1989 National Household Interview Survey. The survey estimated an overall prevalence of 500 per 100,00 populations (0.5% of the population), or >1,000,000 people in the United States with a self-reported diagnosis of IC. For women this prevalence figure was 865 per 100,000. As part of the third National Health and Nutrition Examination Survey (NHANES III), patients who answered yes to two questions (pain in the bladder/frequent urination and a diagnosis of IC or PBS) resulted in a remarkably similar estimated prevalence of 470 per 100,000 (850 per 100,000 women). (78) Ibrahim et al. analysed the prevalence of self-reported IC diagnosis and IC-like symptoms among 823 community-dwelling women. Depending on the questions used, the authors estimated a prevalence of 3.7% to 4.4%. If the survey was expanded by including women who reported pelvic pain only it increased to 17.3% giving an estimated number of 422,803 to 21,454,813 women with IC in the US. (79) These numbers must be viewed with caution because of inaccurate patient recall or confusion with other pain or bladder related conditions. However, these patient-reported diagnoses figures certainly suggest that IC/BPS is a common occurrence.

2.3. Physician Diagnoses Studies

Estimations of prevalence based on physicians' diagnoses may be thought to produce more accurate estimates, and while they do provide different figures, these are in part based on the local or geographic diagnostic criteria employed. Bade et al (80) used a physician questionnaire-based survey in the Netherlands yielding an overall prevalence of 8-16 per 100,000 females, with diagnosis heavily dependent on pathology and presence of mast cells. The Nurses Health Study I and II (81) showed a prevalence of IC between 52 and 67 per 100,000 in the USA. This report was based on self-reports with validation using data from medical records. The prevalence of a physician-based diagnosis of IC/BPS in men and

women in a managed care population in the US Northwest was 197 per 100,00 women and 41 per 100,000 men. (78) However, these rates decreased to 99 per 100,000 women and 19 per 100,000 men if the definition of the condition was limited to individuals who had undergone cystoscopy. Nickel, et al performed a prospective practice audit in outpatient urology practice populations of 65 urologists and noted that the prevalence of IC and IC diagnosis in urology outpatient practice, confirmed by both investigation and symptom scoring, was determined to be 2.8%. (82) Significantly lower was the estimated incidence in a study from Roberts et al. based on a population of around 150.000 in Olmsted county, USA, all patients who had received a physician-assigned diagnosis of IC/ BPS between 1976 and 1996 were identified through the resources of the Rochester Epidemiology Project. The age-adjusted incidence rates were 1.6 per 100000 in women and 0.6 per 100000 in me. (83) This of course does not represent in any way the burden of this condition in the general population, but rather reflects the national referral and practice traditions. There are other limitations using physician diagnoses to determine prevalence. Studies that utilize physician diagnoses to define the presence of IC/BPS will likely underestimate the true prevalence, primarily because they do not identify patients with undiagnosed disease, or they may not assign a diagnosis when the symptoms are present (reluctance to label a patient with the condition or alternatively are not familiar with diagnosing it).

2.4. Symptom based surveys

Another and possibly more sensitive method to examine prevalence and incidence of IC/BPS is to assess the presence of symptoms that suggest IC/BPS. A follow-up study utilizing the Nurses' Health Study (NHS) cohort) (84) used a mailed questionnaire followed by a detailed supplementary questionnaire if the participant responded "yes" to a bladder or pelvic pain question. They observed that the prevalence of IC/BPS symptoms was 1.7% in women younger than 65 years and increased progressively to 4.0% in women aged 80 years or older. This study suggested that the prevalence of IC/BPS increases with age. Warren, et al (85) combined a mail-in survey with randomly selected telephone surveys to determine the prevalence of IC/BPS amongst first degree relatives in comparison to that of the general population. They concluded that adult female first degree relatives of patients with IC/BPS may have a prevalence 17 times that found in the general population. This suggests but does not prove a genetic susceptibility to IC/BPS. The Boston Area Community Health (BACH) Survey (75), a population based cross-sectional survey of individuals in the Boston area which included an in person interview, determined the prevalence of painful bladder symptoms to be 0.83% to 2.71% in women and 0.25% to 1.22% in men depending of the definition used.

The O'Leary Sant (OLS) and the Pelvic Pain and Urgency/Frequency (PUF) questionnaires were compared by Rosenberg and Hazard (86) in the same general practice population of 1218 patients. The prevalence of IC/BPS with the OLS was determined to be 0.57%, with the PUF the prevalence was determined to be 12.6%. Leppilahti and colleagues estimated the prevalence in the general Population of Finland using a rather robust definition based on the OLS to be 0.68%. (87,88) However, when a sample of those women was examined by one of the urologists, the more accurate prevalence was 0.3%.

Clements et al employed 3 different definitions of IC/BPS related symptoms. The first included only self- reported pelvic pain with voiding symptoms. (78) The second included increasing pain with bladder filling and relief with urination. The third included a score of 12 or more on the OLS, including 2 episodes of nocturia and a pain score of 2 or greater. The prevalence estimates based on these definitions were 11,200 per 100,00 women and 6,200 per 100,000 men for definition 1; 3,300 per 100,00 women and 1,400 per 100,00 men for definition 2; and 6,200 per 100,000 women and 2,300 per 100,00 men for definition 3. Using a similar methodology, (89) it was concluded that the prevalence of IC/BPS-like symptoms in South Korean women appear to be lower than in Europe (90) and the United States, similar to Japan and higher than in China. (91) It is conceivable that the acknowledgement by individual patients of these specific IC/BPS symptoms may be influenced by cultural differences.

The most comprehensive and perhaps most accurate estimation of the prevalence of IC/BPS symptoms involved population-based symptom prevalence estimate using 2 validated case definitions to identify bladder pain syndrome/interstitial cystitis in 131,691 adult females. (92) Based on a high sensitivity definition, 6.5% (6,500 per 100,000) of women met the symptoms criteria, while 2.7% (2,700 per 100,000) of women met the criteria for a high specificity definition. These percentages translated into 3.3 to 7.9 million US women over 18 years of age with symptoms of bladder pain and/or interstitial cystitis. But only 9.7% of these identified women reported being assigned a bladder pain syndrome or interstitial cystitis diagnosis. A further study compared 3,397 women identified in this RAND Interstitial Cystitis Epidemiology (RICE) survey (71) with urinary symptoms consistent with a diagnosis of IC/BPS to 277 women with an actual IC/BPS diagnosis recruited from specialist practices in the USA. (93) The two cohorts showed remarkably similar demographics, symptoms and quality of life measures, confirming that IC/BPS is a very prevalent condition that is very likely under diagnosed and under-treated in the USA.

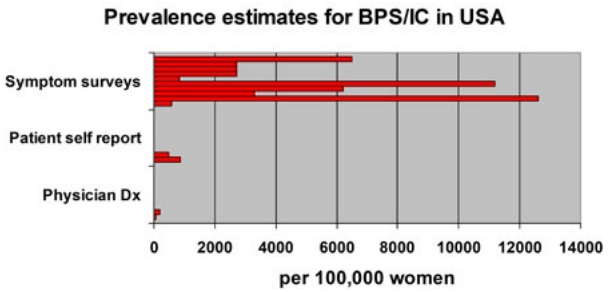

Figure 4. BPS Prevalence Varies by Methodology.

Conclusion: Based on these studies, it is impossible to determine an accurate estimation of the prevalence of IC/BPS or HLD, but a review of studies suggests that this is a very prevalent medical condition (Figure 4). The lowest prevalence figures are derived from physician diagnosis, while the prevalence of IC/BPS symptom complexes are more common than those based on patient self-report diagnoses. It is apparent that there has been no standardized method of determining the prevalence of IC/BPS, with wide variation of estimates in the same study employing different definitions or criteria for identifying the condition. Many factors including bias, cultural differences, methodology, geographic variations in diagnostic criteria and/or possibly real differences in different populations lead to further variations between countries.

Recommendation: A reasonable prevalence estimation for world-wide patients diagnosed with IC/ BPS would be about 300 per 100,000 women. This is based on O'leary Sant symptom surveys which yield comparable data in the United States, Finland, Austria, and Korea. (86,88-90) The male prevalence is 10% to 20% of the female estimate but potentially up to 60% of

the female number based on Rand data. (94) The prevalence of women and men *with symptoms suggestive of BPS* could be as much as 10 times more. (95)

Level of Evidence: 1 Grade of Recommendation: A

1. INCIDENCE

Only a few estimates of incidence have been reported. The annual incidence of new female cases in Oravisto et al, 1975 study was 1.2 per 100,000. (76) The overall age- and sex-adjusted incidence rate of physician assigned diagnoses of IC/BPS in Olmstead county (75) was 1.1 per 100,00 per year (1.6 per 100,00 per year for women and 0.6 per 100,000 for men. (96) Another review of physicians' diagnoses identified a much higher yearly incidence of 21 per 100,000 women and 4 per 100,000 men. (78) A physician-coded diagnosis supplemented with chart review of the Kaiser Permanente database suggested an IC/BPS incidence rate of 15 per 100,000 women per year. (97) The mean average age of patients was 51 years. Lower numbers were observed in a comparative study using a US claims database. 0.06% of 3,973,000 subjects from the general population developed IC within 2 years. Of the 249,200 individuals with depression, 320 (0.13%) developed IC suggesting that depression increases the risk of developing IC. (98) Similarly in a nationwide population-based cohort study where data were gathered from the National Health Insurance Research Database of Taiwan women with systemic lupus erythematosus showed an increased incidence of IC rate ratio of 2.26 (95% confidence interval 1.57-3.27, P < 0.0001). (99) With such a wide variation between two similar studies in the same country, it is evident that we really do not have an accurate estimation of IC/BPS incidence.

Recommendation:
The available data suggests that the incidence of IC/BPS diagnoses is somewhere between 1 and 15 per 100,000 per year. This does not include the women who have developed symptoms but have not been diagnosed with the condition.

Level of Evidence: 2 Grade of Recommendation: B

2. OTHER CONSIDERATIONS

2.1. Children

Geist and Antolak (100) reviewed and added to reports of disease occurring in childhood. A childhood presentation of IC/BPS is extremely rare and must be differentiated from the much more common and benign-behaving condition variously called the *urinary frequency syndrome of childhood or dysfunctional elimination syndrome*, a self-limited condition of unknown etiology. Nevertheless, there is a small cohort of children with chronic symptoms of bladder pain, urinary frequency, and sensory urgency in the absence of infection who have been evaluated with urodynamics, cystoscopy, and bladder distention and have findings consistent with the diagnosis of IC/BPS. In Close and colleagues' review of 20 such children (101), the median age of onset was younger than 5 years, and the vast majority of patients had long-term remissions with bladder distention. Rackow et al assessed 28 women aged 13 to 25 with chronic pelvic pain syndrome and confirmed that 39% had a diagnosis of IC while a further 25% had both IC and endometriosis. (102) The relationship between dysfunctional voiding and bowel symptoms in early life was suggested in a mail based questionnaire study in 215 IC/BPS patients and 823 controls. (101) Doiron et al. analyzed 190 women with IC/ BPS stratified by irritable bowel syndrome (IBS) (103). Women with IBS were more likely to recall painful urination in childhood assessed by a modified form of a clinical bladder and bowel dysfunction (BBD) questionnaire (BBDQ), as well as Interstitial Cystitis Symptoms Index (ICSI), Interstitial Cystitis Problem Index (ICPI), Pelvic Pain and Urgency/Frequency (PUF) questionnaires and UPOINT categorization. Another study examining early childhood events (102) showed that early childhood trauma, in particular sexual trauma was more common in IC/BPS patients than asymptomatic control subjects. While not proven in these studies, it may be possible to link early childhood events to the eventual development of IC/BPS symptoms in some patients.

Recommendation:
The diagnosis of IC/BPS, while extremely rare, should be considered in children and adolescents with typical symptoms with no other explanation.

Level of Evidence: 3 Grade of Recommendation: A

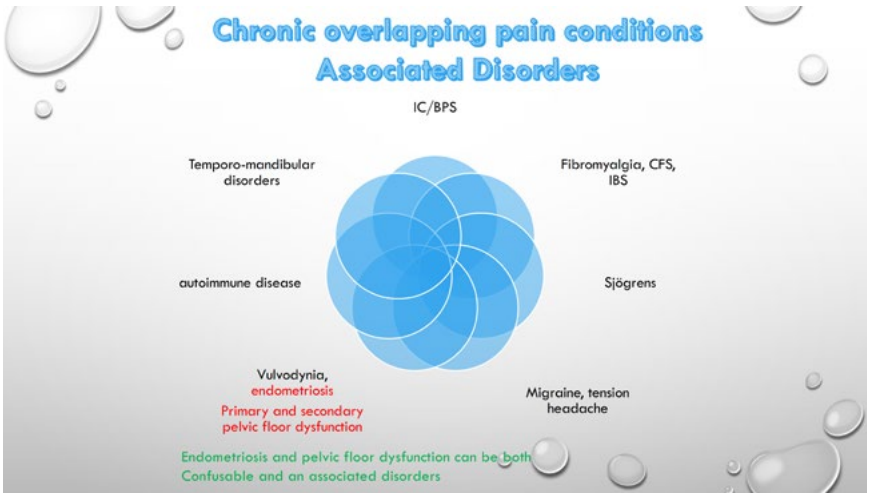

Figure 5. Associated and confusable disorders commonly diagnosed in patients with IC/BPS.

2.2. Men

Most studies show a female to male preponderance of 5:1 or greater. (60,78,104) In the absence of a validated marker, it is often difficult to distinguish IC/BPS from the chronic pelvic pain syndrome (nonbacterial prostatitis, prostatodynia) that affects males (105,106), and the percentage of men with IC/BPS may actually be higher. (107,108) Men tend to be diagnosed at an older age and have a higher percentage of Hunner lesion in the case series reported. In the Rand NIH epidemiology prevalence study the male to female ratio approached one to one. (94)

Recommendation:
The Male to Female ratio of IC/BPS cases is approximately 1:5. IC/BPS in men may be underdiagnosed and overlooked due to confusable disorders including chronic pelvic pain syndrome/ nonbacterial prostatitis, overactive bladder, and outlet obstruction.

Level of Evidence: 2 Grade of Recommendation: B

2.3. Overlapping Comorbidities

While the obvious clinical pain site associated with the diagnosis of IC/BPS is the bladder (pelvic pain only), it has become quite evident that many women with IC/BPS have multiple pain sites outside the bladder and pelvis area, with over 75% of women with a clinical diagnosis of IC/BPS reporting pain outside the pelvis (pelvic pain and beyond). (109)

Multiple observations have shown that IC/BPS patients are more likely than controls to have pain related syndromes manifesting symptoms beyond the bladder and even the pelvis. In 1997, Clauw, et al (110) reported on the symptom overlap between two cohorts of patients, one with fibromyalgia and one with IC/BPS. In the same year an analysis of a survey by Alagiri, et al (111) of over 6,700 persons who had a physician diagnosis of Interstitial Cystitis reported that individuals with IC/BPS were 100 times more likely to have inflammatory bowel disease, and that allergies, irritable bowel syndrome, sensitive skin, and fibromyalgia also have an increased association with IC/BPS. The presence of non-bladder syndromes (NBSs) and IC/BPS has further complicated the interpretation of epidemiological studies. Investigators have subsequently compared IC/BPS patients to controls on multiple NBSs. Wu et al. (112) compared 749 cases with IC/BPS to 1498 randomly selected and matched controls. Significantly more cases had FM, IBS, chronic pelvic pain (CPP), endometriosis, depression, anxiety, and vulvodynia. Overholt et al. analyzed 431 women with IC/BPS; out of those 82 (19%) had co-occurring endometriosis. These women were more likely to carry several comorbid, systemic pain diagnoses ($p<=.05$). (113) Clemens et al. (114) compared 239 women with ICD-coded IC/BPS to 717 matched controls and showed that cases significantly exceeded controls in myalgias, gastrointestinal symptoms, gynecologic pain, headache, back disorders, depression, and anxiety. Similarly, Chung et al. also found a higher incidence of anxiety disorder in women with IC/BPS compared to randomly selected female controls. Chung 2013c} This finding was still significant after adjusting for chronic pelvic pain, irritable bowel syndrome, fibromyalgia, migraines, sicca syndrome, allergies, asthma, and an overactive bladder (OR 4.37 (95% CI = 2.16-8.85, $P < 0.001$). Warren et al. (115) demonstrated that significantly more IC/BPS cases than matched controls had 11 antecedent syndromes: FM, CFS, IBS, sicca syndrome, Chronic pelvic pain, migraine, allergies, asthma, depression, panic disorder, and vulvodynia. Nickel et al. found significantly higher prevalence of self-reported FM, CFS, IBS, migraine and tension headaches, vulvodynia, temporomandibular disorder and low back pain in 207 female IC/BPS cases than in 117 controls as well as significantly more with depression and anxiety in a study in several urology practices in 3 continents. (116) A review confirmed that fibromyalgia (FM), chronic fatigue syndrome (CFS), and irritable bowel syndrome (IBS) were associated with IC/BPS. (117) In a study from Cheng et al., in 150 women with chronic pelvic pain undergoing laparoscopy glomerulations were identified in 48/150 (32%) individuals, and 80/150 (53%) had symptoms of IC/BPS. (118) The etiological and epidemiological questions that remain unanswered is how are these NBSs associated with IC/BPS; do these NBSs precede or follow IC/BPS and do multiple NBSs increase the risk of IC/BPS. Irritable bowel syndrome was shown to increase the subsequent risk of IC/BPS in a 12 year cohort study conducted in Taiwan (119). Warren and colleagues (120) have introduced a number of hypotheses, however the studies to validate these await data analysis from the NIDDK MAPP research effort. Relatives of IC/BPS patients appear to have an increased risk of associated conditions including myalgia and fibromyalgia as well as constipation, suggesting shared underlying genetic factors. (121) Women with IC/ BPS might have a higher rate of previous primary dysmenorrhea as has been assessed by Chung et al through a population-based data study (OR 1.86 (95% CI 1.37-2.52, $p < 0.001$. (122) Similarly, women with pelvic inflammatory disease seem to have a higher risk for suffering from IC/BPS according to Chung et al. ($p<0.001$). (123) There might also be an association with rheumatoid arthritis according to Keller et al. (124) based on an analysis of the Taiwan National Health Insurance Database, with significantly higher rate of previous rheumatoid arthritis in women with IC/BPS compared to controls. A similar study design revealed a possible correlation with a higher incidence of succeeding coronary heart disease during a 3-year follow-up period. (125)

One other comorbidity that is sometime neglected or forgotten in these epidemiological associations is the association of IC/BPS with sexual dysfunction. Multiple studies have shown that women with IC/BPS diagnoses or symptoms experience very high levels of sexual dysfunction. (126-129) This is likely related to deep dyspareunia (pain with deep vaginal penetration) associated with anterior vaginal wall pain from a hypersensitive bladder but can also be related to vulvodynia, a common NBS seen in female IC/BPS patients. (130)

Recommendation:
Overlapping comorbidities are common in patients with a diagnosis of IC/BPS.

Level of Evidence: 1 Grade of Recommendation: A

2.4. Progression:

The disease onset is generally described as subacute rather than insidious, and full development of the classic symptom complex occurs over a relatively short time. It appears that IC/BPS does progress initially, but usually reaches its final stage rapidly (within 5 years) and then continues without significant change in symptomatology. (131) Subsequent major deterioration is unusual. (76) The duration of symptoms before diagnosis was 3-5 years in the Finnish study (76) while a very early American study quoted 7-12 years. (46) Time to diagnosis has likely diminished in the internet era. The Interstitial Cystitis Database Cohort (ICDB) of patients has been carefully studied, and the findings seem to bear out those of other epidemiologic surveys. (132) Patterns of change in symptoms with time suggest regression to the mean and an intervention effect associated with the increased follow-up and care of cohort participants. Although all symptoms fluctuated, there was no evidence of significant long-term change in overall disease severity. In an interesting Canadian study, chronic pelvic pain severity was

shown to decrease in the year after entry into the cohort, but higher pain catastrophizing scores at baseline were associated with greater chronic pelvic pain severity at 1 year. (133) MAPP study indicates that longer symptom duration is generally not associated with more severe symptoms in the majority of patients, nor is disease duration associated with risk for chronic overlapping pain conditions or mental health comorbidities. (134) The data suggest that IC/BPS is a chronic disease, and no current treatments have a significant impact on symptoms over time in the majority of patients. In a large series in Taiwan on patients with 5 or more years of consecutive medical records since diagnosis, about half of the patients with IC/BPS exhibited symptom improvement with time, with or without regular follow-up and receiving a new treatment. (5) Whether some patients undergo a phenotypic progression over time from a purely organ specific (eg. bladder) condition to a regional pain syndrome (eg. IBS, vulvodynia) to a more generalized pain syndrome (eg. FM, CFS) (135) is controversial. Long term longitudinal studies examining progression issues in IC/BPS are lacking.

Recommendation:
Epidemiological data required to describe progression patterns of IC/BPS is lacking.

Level of Evidence: 1 Grade of Recommendation: A

VII. ETIOLOGY

The etiology of IC/BPS remains a wide-open field for investigation. Etiology is still an enigma and often the proposed causes for IC/BPS cannot be mirrored to the suggested treatment. Hence, a possible pathophysiological pathway leading to clinical manifestation of IC/BPS cannot absolutely lead to the analogue treatment. Symptoms like urinary frequency and bladder pain may be indicative of bladder injury, but they are rather heterogenous, causing more diffusion when investigation tries to locate the origin of this situation. Moreover, research findings in animal and human models do not always match, challenging more studies even in novel pathophysiological pathways including adverse childhood experiences as a potential etiologic factor. (136)

1. IMMUNE CELL ACTIVATION

Immune response in IC/BPS could be provoked by the activation of specific series of immune cells, the mast cells. Mast cells are multifunctional immune cells that can secrete highly potent inflammatory mediators such as histamine, leukotrienes, serotonins and mainly cytokines (137). Actually, the pathway involving the inflammatory process could provide an adequate explanation for the clinical manifestation of IC/BPS and its microscopic findings, such as frequency, oedema, angiogenesis in lamina propria and fibrosis. Pathogenesis involving mast cells suggest their interference with other inflammatory cells and the nervous system, keeping their role in pathogen-

Figure 6. The complex potential etiologies of IC/BPS. See text for compete description.

esis of high importance (138). Moreover, mast cell concentration seems to be higher in those patients with Hunner lesion, comparing to those with non-Hunner lesion IC/BPS or those with overactive bladder (139,140). Researching the pathway of bladder insult, a study on a murine model demonstrated an inflammatory and pain axis implicating IL-33 and mast cell activation, suggesting a potent way of propagation for pain and inflammation (141). Activated mast cells release proinflammatory cytokines, such as TNF and the overexpression of TNF by urothelial cells in vivo caused significant pelvic pain behavior, voiding dysfunction, and urothelial lesions, which supports the potential role of TNF in the pathogenesis of IC (142). Recently, a potent role of microRNA in mast cells activation has been investigated, demonstrating that over-expression of microRNA-132 increased inflammatory cell infiltration, collagens I and III expressions and mast cell growth (143).

However, in contrast to all above, a digital quantitative analysis of mast cell infiltration in interstitial cystitis has shown that mast cell density is not significantly different between IC/BPS specimens and non-IC/BPS control specimens with a similar degree of background inflammation (144).

Apart from mast cells, an implication of another type of immune cell, the plasma cell, has been proposed, proving that CXCR3-positive plasma cells may play a role in Hunner lesion disease, but not in IC/BPS, activating the CXCR3 inflammation pathway (145).

The role of immune cell activation on the pathogenesis of IC/BPS seems to be crucial and future research may provide more information and evidence.

Level of Evidence: 1

2. INCREASED PERMEABILITY OF THE UROTHELIUM

The key barrier that inhibits the transit of low and high molecular weight solutes from urine to bladder interstitium, is bladder urothelium. This barrier consists of a dense layer of glycosaminoglycans and variable intercellular junctions. Hence, any damage at this level of inhibition could be the beginning of bladder insult, contributing to the development of IC/BPS. Decreased expression of the tight junction proteins ZO-1 and occludin, as well as increased expression of the adhesion protein E-cadherin, in patients with IC/BPS, could be associated with higher permeability of the urothelium, due to loosen intercellular junctions (146). Additionally, lower expression of E-cadherin could contribute to higher apoptosis in IC/BPS patients' urothelium (147).

MicroRNA is presented, also, as an important regulator of intercellular junctions in patients with IC/BPS. More specifically, microRNA miR-199a-5p has been identified as overexpressed in IC/BPS patients' urothelium, combined with incorrect tight junctions and increased urothelial permeability (148,149). However, currently, there are a variety of microRNA expressions under investigation demonstrating possible involvement in IC/BPS development. Upregulated microRNAs such as miR-21, miR-4435-2HG, and miR-155HG and downregulated miR-205HG were identified as key microRNAs in Hunner lesion disease (150). In another study of postmenopausal women with IC/BPS, the suppression of miR-214 expression has been found to promote the epithelial transition and contribute to bladder wall fibrosis (151).

The damage of the glycosaminoglycan (GAG) layer contributes, also, to a higher permeability of the urothelium with the sub-mucosal nerve filaments becoming more accessible to noxious substances of the urine. (152,153). However, Grundy et.al. demonstrated in an experimental model that while induced changes in bladder permeability are able to induce transient bladder afferent hypersensitivity in the absence of inflammation, highly regulated homeostatic mechanisms exist to rapidly repair the urothelial barrier and normalize bladder afferent mechanosensitivity, suggesting that additional pathophysiology is required to induce chronic bladder dysfunction. (154)

Level of Evidence: 2

3. INHIBITION OF BLADDER UROTHELIAL CELL PROLIFERATION

Explanted urothelial cells from patients with IC/BPS seem to differ from the controls in the rate of proliferation and the production of an antiproliferative factor (APF). This has been shown in a study over gene expression patterns in normal bladder urothelial cells treated with APF and with mock APF as compared to patterns expressed by IC/BPS urothelial cells (155). More specifically, this theory may involve both down-regulation of genes that stimulate cell proliferation along with up-regulation of genes that inhibit cell growth. Interestingly, APF seems to be specifically elevated in the urine of patients with IC/BPS but not in healthy or patients with confusable diseases (156,157). APF testing is done through a bioassay and initial studies have not been confirmed by subsequent investigators.

Recently, a novel function of p53 and p21 proteins, in regulating ZO-1 and E-cadherin gene expression in bladder epithelial cell explanted from IC/BPS patients, has been investigated and suggested a possible suppression in cell proliferation (158).

Level of Evidence:2

4. AUTOIMMUNE MECHANISMS

The role of autoantibodies and their association with the presence of IC/BPS has long been a research objective, but their precise identity has yet to be determined (159-162). Actually, the autoimmune disturbances of the most common autoimmune diseases do not differ significantly from those of IC/BPS, with the presence of antinuclear antibodies and histopathological characteristics quite similar to the autoantibody profiles of some systemic diseases, like Sjögren syndrome (163-165). However, only a portion of IC/BPS patients have autoantibodies and those seem to be related to more severe symptoms (166).

The involvement of the immune system in the development and expression of IC/BPS has been recently investigated at the level of toll-like receptors (TLR), showing TLR7-gene expression and TLR7 immuno-reactive cells in the bladder biopsy specimens of patients with Hunner lesion disease compared with the controls. It is already known that TLR7 contributes to the development of several autoimmune diseases, such as Systemic Lupus Erythematosus and Sjögren (167).

Vascular immunopathology with immune deposits in the bladder wall, as well as activation of complement are additional findings of several studies, enhancing the association of IC/BPS with autoimmune responses (168,169). It is, also, an interesting observation that T-cell infiltrates and B-cell nodules were seen in Hunner lesion disease patients and not in non-lesion IC/BPS (170). Additionally, in a mouse autoimmune model, the antigenic T2 peptide activated T cells and interacted with TRPM8 receptor in the bladder tissue resulting in an autoimmune reaction leading to IC/BPS (171).

Autoimmune mechanisms may have a key role in the etiology of IC/BPS (172) , but even recent studies are quite heterogenous and difficult to compare, in order to allow for any conclusions.

Level of Evidence: 2

5. INFECTION

The role of micro-organisms as a key factor causing IC/BPS has been widely investigated. No Gram-positive or Gram-negative bacteria have been implicated in IC/BPS, nor has an increase of IgG or IgM been detected in the urine of IC/BPS patients (164,173) . In another study including women with IC/BPS, there was no significant correlation of the onset of symptoms with the appearance of UTI (174). With the absence of acute bacterial infection as a direct etiology for IC/BPS, attention has now turned to possible involvement of nano-bacteria and microbiota as potentially important. Hence, in the study of Zhang et al, nano-bacteria has been found in women's urine with IC/BPS and interestingly the anti-nano-bacteria treatment was also effective in improving symptoms (175). Nickel's study on microbiota role in women with IC/BPS revealed that those women with a flare of symptoms had a higher prevalence of fungi compared to those without flare. All patients had a persistent negative urine culture for common micro-organisms (176).
Additionally, another type of bacteria known as L-form bacteria could be cultured with specific materials and methodology and a role in pathogenesis has not been ruled out (177). Urinary microbiome and cytokine levels in women with IC/BPS have been investigated in another study, trying to find measurable differences in the urinary microbiota and cytokine levels. Authors suggested a role of Lactobacillus species, specifically L acidophilus. Their presence was associated with improved symptom scores when compared with IC/BPC women with deficiency of Lactobacillus species. Jacobs et.al. found the presence of Lactobacillus did not differ between cohorts of IC/BPS patients and controls and did not impact symptom severity. Bacteria were not isolated by expanded quantitative culture techniques. (178) In another study, the urinary microbiome of patients with IC/BPS was less diverse, less likely to contain Lactobacillus species, and associated with higher levels of proinflammatory cytokines than a control group. (179).
At this time there is no reason to believe that IC/BPS is a manifestation of an infectious disease.

Level of Evidence: 1

6. NEUROBIOLOGY

The effect of changes in the nervous system as related to IC/BPS symptoms is a field of wide research with a variety of etiologic hypothesis. Some studies on the S-100 family of proteins presence in Schwann cells, have shown lower levels of those proteins in patients with non-Hunner lesion IC/BPS, consistent with a decreased nerve content in these patients (180). On the other hand, the use of PGP9.5 antibody revealed increased nerve content in patients with IC/BPS compared to patients with overactive bladder and controls (181,182) . Also, the hypothesis of neurogenic inflammation as the origin of the pathophysiological sequence of IC/BPS has been proposed in the study of Elbadawi and Light (183).
A more complicated, but also challenging pathway implicating in the etiology of IC/BPS could involve the connection of neurobiology with the immune cell system, through the activity of intravesical substance P. In animal models, intravesical substance P has been found to induce remarkable referred hyperalgesia accompanying slight bladder mucosal swelling, without the presence of ulcerous surfaces (184). The fact of the co-interference of immune and neurogenic pathways in the etiology of IC/BPS could also be supported by the significant increase of tyrosine hydroxylase immunoreactivity in bladder tissue of IC/BPS patients, as compared to controls (185).
In a mouse model, a correlation of Toll-like receptor 4 (TLR4) with the development of IC/BPS has been studied. TLR4 is expressed in numerous cell types including neuronal and non-neuronal glial cells in the central nervous system, as well as immune and non-immune somatic cells including bladder epithelial cells. The activation of TLR4 leads to a consecutive inflammatory process through the production of cytokines. The investigators found an independent role of TLR4 especially in the expression of IC/BPS pain and inflammation, possibly through the production of IL-1β and IL-6 (186).
The implication of dysfunctional C-fibers might be another explanation of lower pain resistance in patients with chronic pelvic pain syndrome and specifically bladder hyperalgesia. Actually, the water avoidance test (WAS) assessed by cystometrogram has shown that stress-induced bladder dysfunction may derive from the increased sensitivity of C-fibers and mechanoreceptors. However, the role of C-fiber activation in WAS-induced bladder hyperalgesia has to be further investigated in IC/BPS patients (187).
Clinical observations over brain MRIs in IC/BPS women have shown increase in gray matter volume in several regions of the brain probably associated with lower pain tolerance and higher anxiety. This may imply cortical tissue in the neurobiological component of IC/BPS (188).

Level of Evidence: 2

7. PELVIC ORGAN CROSS-TALK

A bidirectional neural cross-sensitization of the colon and lower urinary tract has been demonstrated by few studies, showing that colon disease may be associated with bladder hypersensitivity and hyperalgesia in animal models (189-193). A central induced cross-organ sensitization of visceral nociception between the colon and urinary bladder has been demonstrated in cases of acute colitis and this may support a substantial overlap of IC/BPS with inflammatory bowel diseases, apart from the neurogenic etiology (106). Certainly, another reason of a crosstalk between bladder and colon in the era of IC/BPS is the observation in rat models that intravesical protamine sulfate increased permeability of bladder urothelium and the permeability of colon, as well (194).

Level of Evidence: 3

8. URINARY TOXIC AGENTS

Some investigators have suggested that some toxic substances may be a potent causative factor for the development of IC/BPS. Interestingly, the more cationic urine content seems to be harmful to the GAG layer of the bladder resulting to a cytotoxic effect on urothelial cells (195). Also, abnormal glycosylation of Tamm-Horsfall protein, produced in kidneys, has been found in patients with IC/BPS, while defective constituent cytokine production may decrease mucosal defense to toxic agents promoting bladder insult in IC/BPS patients (196,197) .

Level of Evidence: 3

9. HYPOXIA

The question as to whether an IC/BPS bladder may be hypoxic is still without a well evidenced answer. Lee et al have found that hypoxia-inducible factor-1alpha (HIF-1a) is over-expressed in the bladder tissue of IC/BPS patients (198). Other investigators have proposed disturbances in bladder microvascular density and deficiency in bladder perfusion (199-201). In another study, internal iliac artery blood flow has been found significantly lower in patients with IC/BPS compared with the control group and this is in accordance with atherosclerosis-induced chronic bladder ischemia and lower urinary tract dysfunction, already known by the research in animal models (202).

Level of Evidence: 4

10. THE ROLE OF GENETICS

The potent role of heredity in IC/BPC patients has also been researched and the first demonstration was a greater concordance among monozygotic than among dizygotic twins and certainly female first-degree relatives of patients with IC/BPS may have a prevalence of IC/BPS 17 time higher than found in the general population (85,203). In another study on more than 25,000 female twins, genetic factors have been found to contribute in less than one-third of the total variation in susceptibility to IC/BPS, suggesting the environment is an add-on factor for the development of the disease (204).

Patients and their first-degree relatives with panic and anxiety disorders have been suggested as susceptible to IC/BPS through chromosome 13 (205,206) . A recent investigation has provided significant evidence for genetic linkage on 3p13-p12.3 for IC/BPS. More specifically, genetic variants on chromosome 3 and possibly chromosomes 1, 4, 9, and 14 may contribute to IC/BPS predisposition (207).

Alternations on the regulation of several families of micro-RNA and mRNA have also been suggested as a genetic factor for the etiology of Hunner lesion disease through the disturbances on the expression of specific genes. (207,208)

Level of Evidence: 1

11. OTHER SUGGESTED FACTORS

A variety of independent etiological mechanisms has been proposed adding some evidence in the labyrinth of IC/BPS. Hence, endometriosis increased the risk of the disease, but this is provided only as epidemiological evidence (209). Infection with Epstein-Barr virus might be a causative factor of persistent inflammation in a subset of patients with IC/BPS (210).

12. CONCLUSION

The etiology of IC/BPS includes a lot of factors with a variation in their influence on the development and the physical history of the disease. Certainly, some of them seem to interact with others making the etiological labyrinth even more complex. Classifying IC/BPS among generalized somatic disorders could open new horizons for research, as it may open new pathophysiological pathways for investigation. Current evidence seems to guide novel research to neuroscience, immunology, infection, and genetics as potent major etiological factors for IC/BPS. Figure 6 summarizes the etiology for IC/BPS with respect to separate factors for each category. Study of Hunner lesion disease etiology awaits its recognition as a specific entity apart from IC/BPS.

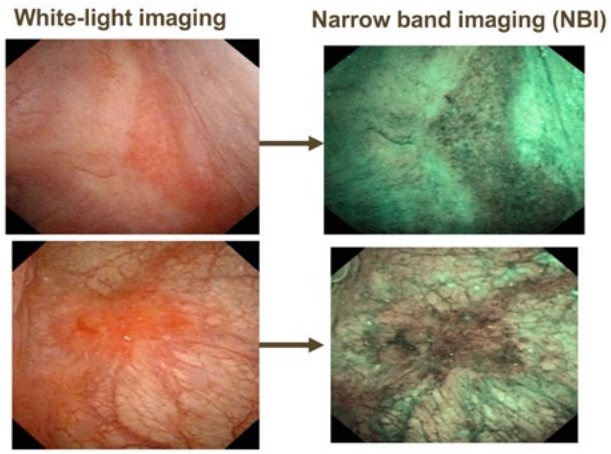

Figure 7. Hunner lesions: white-light imaging (left) and narrow-band imaging (NBI) (right) in 2 patients with IC/BPS. The entire erythematous area should be included in local treatment.

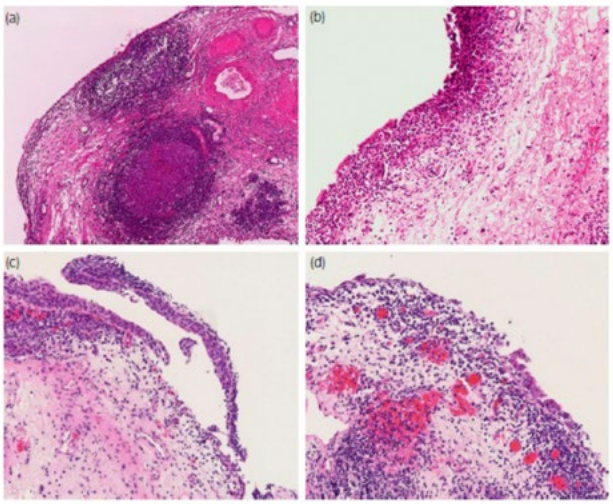

Figure 8. Histopathology of Hunner lesion disease. Dense inflammatory cell infiltration is observed in the subepithelial region. (a) Lymphoid follicles are frequently present. (b) Linear inflammatory cell infiltration is present in the subepithelial region. (c) Epithelial denudation is often observed. Numerous plasma cells are present along with lymphocytes in HIC bladder. Microvessels are increased. The superficial layer of the epithelium is lost. (d) The epithelial cells in the basal layers show degenerative changes. VIII. PATHOLOGY

(special thanks to Naoki Yoshimura)

The previous ICI chapter in 2017 summarized that bladder histopathology plays a supportive diagnostic role at best (30), and that the exclusion of other pathologically identifiable diseases is the primary utility of bladder biopsy (211,212) . However, recent studies have shown that Hunner-lesion disease (HLD) (**FIGURE 7)** not only is different clinically from IC/BPS (213,214), but also exhibits histological differences such as significant inflammation and denudation in the bladder, which are clinically and pathologically distinct from non-Hunner IC/BPS and may be categorized as a separate disease entity termed "Hunner lesion disease (HLD)". (24,28,32) .

1. HUNNER LESION DISEASE

Inflammation: Chronic inflammation in the lamina propria is a major characteristic of HLD **(FiGURE 8),** which is not only confined to the Hunner lesion areas, but also found in the region outside Hunner lesions. Infiltration of the inflammatory cells in the lamina propria, mostly consisting of lymphocytes and plasma cells, is a predominant histological feature of HLD bladders. Also, lymphoid germinal center formation is observed in approximately 40% of patients. While a small number of macrophages and neutrophils. can be present, eosinophils are generally absent.

Epithelial denudation: Another important histological finding of HLD is bladder epithelial denudation, partially or entirely of the epithelial layer in the Hunner lesion as well as in the surrounded area of Hunner lesions (**FIGURE 8)** (24).

Mast cells: The role of the mast cell in HLD has been described (137,215,216) . Proteinase immune staining with mast cell tryptase (**FIGURE 9**) yields higher numbers of mast cells in HLD mucosal stroma and detrusor muscle layers compared to counts in non-HLD and normal bladders. However, it has been suggested that mast cells may not play a pivotal role in HLD pathogenesis because mast cell infiltration is less dense compared to other infiltrating inflammatory cells in the lamina propria (20). Furthermore, mast cells, which are seen at a lesser degree, have been implicated in afferent hypersensitivity and neurogenic inflammation in non-Hunner IC/BPS (217).

Fibrosis: Fibrosis is also found in the deeper layer of bladder mucosa showing detrusor bundles separated by fibrotic tissues (32).

Proteomic analysis: Significant differences in protein expression have been found between HLD bladder tissue biopsies and IC/BPS tissue. HLD tissue had increases in inflammatory and endoplasmic

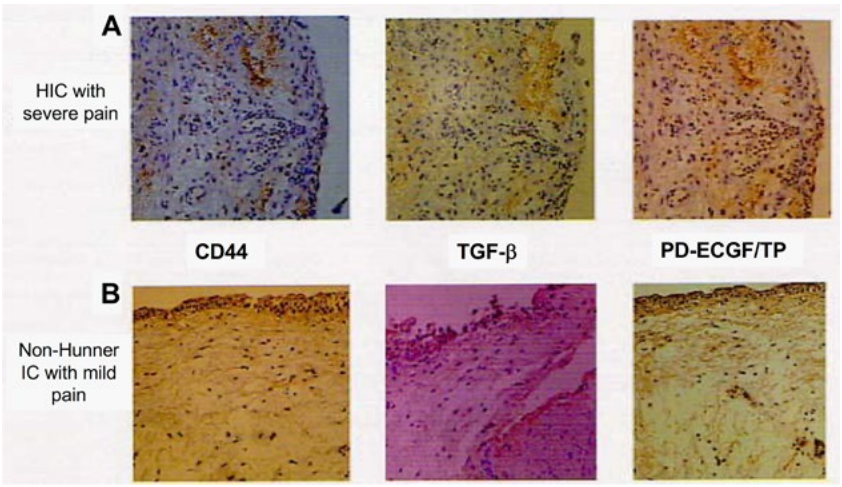

Figure 10. Overexpression of angiogenic factors in the bladder of IC/BPS patients.
The images show the results of immunohistochemical staining for epithelial and submucosal CD 44, transforming growth factor (TGF)-β, and PD-ECGF/TP in bladder tissue sections from patients with IC/BPS. A; Positive staining in the severe IC type (Hunner-type IC [HIC] patients with severe pain) is seen in the deeper part of the submucosal layer. B: Positive staining in the mild IC type (non-Hunner-type patients with relatively mild pain) is present along the basement membrane of the bladder epithelium; 200x magnification.

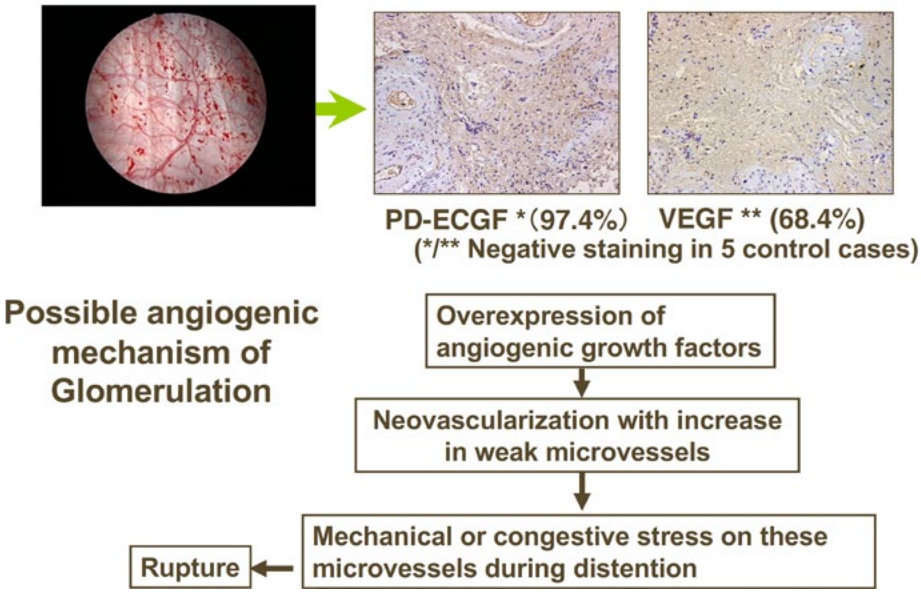

Figure 11. The angiogenic mechanisms inducing glomerulations.
In IC/BPS bladders, overexpression of angiogenic factors such as VEGF and PD-ECGF includes neovascularization with increases in weak microvessels, leading to rupture of microvessels during bladder distention, seen as glomerulations during cystoscopy.

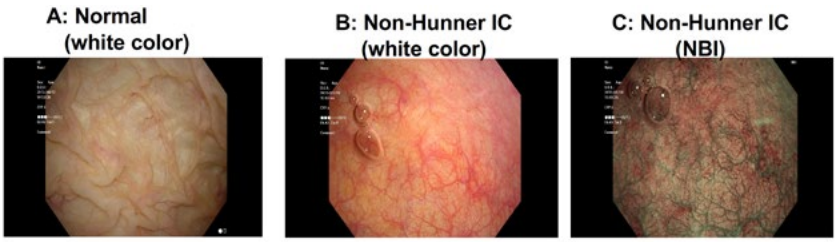

Figure 12. Representative cystoscopic images of the normal bladder (A) and the non-Hunner IC bladder under white light (B) or narrow-band imaging (NBI) (C).
A: The bladder epithelial mucosa was largely whitish in color with multiple folds on the mucosal surface in the normal bladder. Furthermore, the normal mucosal epithelium is stretchable in all directions during bladder distention because it is loosely connected to the underlying muscle layer
B & C: The abnormal bladder epithelium characterized by the stretched, hypervascular mucosa without mucosal folds in the non-Hunner IC bladder.

reticulum stress proteins, and a decrease in cellular adhesive proteins compared to IC/BPS. Other differences included a decrease in proteins associated with the Rap1 signaling pathway which regulates cell proliferation and would healing. (218)

2. NON-HUNNER IC/BPS

IC/BPS patients show limited inflammatory changes in the bladder wall. The bladder epithelium is usually well-preserved, and inflammatory cell infiltration in the lamina propria of non-Hunner IC/BPS bladders is much less remarkable compared to the HIC bladder (219). For the detection of bladder lesions of non-Hunner IC/BPS, cystoscopic identification of glomerulations, which is shown as mucosal bleeding after hydrodistension, has been viewed as a diagnostic method although the recent meta-analysis study concluded that glomerulations in non-Hunner IC/BPS patients do not correlate with symptoms and are also found in patients without IC/BPS (220).

However, previous studies reported that that there was overexpression of angiogenic factors such as vascular endothelial growth factor (VEGF) and platelet-derived endothelial cell growth factor (PD-ECGF) in the bladder of both non-Hunner IC/BPS and HLD patients with higher expression in the latter vs. the former, in association with overexpression of the adhesion factors such as CD44 and TGF-β, which are known to bind with angiogenic factors via heparin-binding and become solidified (**FIGURE 10**) (221,222) . Also, it has been shown that overstretching the bladder wall during bladder filling could be responsible for the rupture of newly developed blood microvessels (e.g., glomerulation) in non-Hunner bladders of IC/BPS patients (**FIGURE 11**) (223). Therefore, the underlying angiogenic mechanisms for neovascularization with overexpression of angiogenic factors such as PD-ECGF or VEGF, could be considered to be bladder-specific lesions in non-Hunner IC/BPS (**FIGURE 10**). Also, for the cystoscopic diagnosis of bladder lesions of non-Hunner IC/BPS, the detection of mucosal hypervascular lesions caused by angiogenesis, which differ from the normal bladder

mucosa **(FIGURE 12),** needs to be standardized instead of using hydrodistension-induced glomerulations as a diagnostic criterion.

IX. DIAGNOSIS

A thorough diagnostic evaluation is essential to exclude other diseases that may mimic the symptoms of IC/BPS, and which therefore may benefit from alternative treatment, and to aid phenotyping of patients with IC/BPS so that targeted treatment can be offered to those who are likely to benefit most. Attempts to define objective diagnostic criteria for IC/BPS have focused on cystoscopy under local or general anaesthesia, bladder distention with registration of bladder capacity and presence of Hunner lesions, bladder wall biopsies evaluated for inflammation, ulcer, fibrosis, mast cells, etc. and urodynamics with registration of bladder capacity, compliance, and bladder stability. Recent studies are starting to suggest that stratification of patients based on certain clinical, cystoscopic, histopathological and urodynamic variables may now or in the future enable targeted therapy based on the specific patient's phenotype. It is hoped that future research efforts will strengthen the evidence base in this area, thereby allowing firmer recommendations to be made.

Unless otherwise stated, what follows is based solely on expert opinion. Level of Evidence:4 Grade of Recommendation: C

1. HISTORY

A general thorough medical history should be taken. Special emphasis should be given to:

- Previous pelvic operations
- Previous UTI
- Bladder history/urological diseases
- Location of pelvic pain (referred pain) and relation to bladder filling/emptying.
- Characteristics of pain: onset, correlation with other events, description of pain
- Previous pelvic radiation treatment
- Autoimmune diseases
- Co-existing somatic conditions (fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome, temporomandibular disorder, migraine, vulvodynia)
- Psychological comorbidity (anxiety and depression)

A number of studies have assessed whether any specific symptoms are able to distinguish between Hunner lesion disease and non-Hunner lesion disease. Pain at vaginal penetration, greater pain severity, and increased urinary frequency and nocturia have been suggested in a recent meta-analysis to be more common in those with Hunner lesion disease, but reports are contradictory and there have not been any consistent findings in this regard (224,225,226,227,228,214) .

Regarding psychological comorbidity, a recent systematic review of 34 studies of patients with IC/BPS has revealed the high prevalence of clinical depression and generalised anxiety disorder in this population (3). Furthermore, patients with IC/BPS show higher levels of stress, poor illness coping, and more widespread pain symptoms than healthy controls, with a higher risk of suicidal ideation (229,230) . Although evidence for treatment is lacking, self-management techniques (guided imagery/self-hypnosis, mindfulness, and online health education) may improve symptoms and wellbeing, and so psychological comorbidity should be assessed as part of the initial history with appropriate psychiatric referral as appropriate.

Level of Evidence:3 Grade of Recommendation: C

2. PHYSICAL EXAMINATION

A common physical examination should be performed including palpation of the lower abdomen for

bladder fullness and tenderness:

- Standing: kyphosis, scars, hernia
- Supine: abduction/adduction of the hips, hyperaesthetic areas

In females, physical examination should include a vaginal examination with pain mapping of the vulvar region and vaginal palpation for tenderness of the bladder, urethra, levator and adductor muscles of the pelvic floor. Tenderness might be graded as mild, moderate or severe. (231)

Inspection:

- Vulva
  - exclusion of vulvar/vestibular diseases (vulvitis, dermatosis etc.)
  - evaluation of introital area (endometriosis)
  - tenderness of vestibular glands or vulvar skin (Touch Test: use wet cotton stick or finger tip)

- Vagina
  - tenderness during insertion and opening of
  - speculum
  - cervical pathology
  - vaginal fornices (endometriosis)

- Bimanual physical examination
  - tenderness of urethra, trigone and bladder
  - superficial/deep vaginal tenderness
  - tenderness of pelvic floor muscles (levator, adductor)
  - tenderness in adnexal areas

In males digital rectal examination (DRE) should be performed with pain mapping of the scrotal–anal region and palpation of tenderness of the bladder, prostate, levator and adductor muscles of the pelvic floor and the scrotal content.

3. LABORATORY TESTING

- Urine dipstick (blood, pH, leucocytes, nitrate), urine culture in all. If sterile pyuria culture for tuberculosis.
- Urine cytology in risk groups.
- Investigations for vaginal Ureaplasma and Chlamydia in females and prostatitis in men are optional.

Although the absence of infection is a pre-requisite for the diagnosis of IC/BPS, it is becoming clear that standard quantitative bacterial culture of a mid-stream urine specimen is less reliable than widely thought and many patients with symptoms suggestive of IC/BPS may have an infectious cause that can be successfully treated with antimicrobial agents (232,233) . A study that used specific culture media with longer incubation periods led to the identification of a uropathogen in 50% of patients with IC/BPS, and symptomatic improvement was reported after appropriate antimicrobial treatment

(177). Others have reported a greater incidence of fungal species in the urinary microbiome of patients with more severe symptoms, whereas higher levels of viral isolates (Epstein-Barr virus and Polyomavirus BK) have also been reported in patients with Hunner lesion disease (210,234,235) . However, studies are contradictory and so the relevance of changes in the urinary microbiome is unclear. Future urinary microbiome research should prospectively compare those with Hunner lesion disease to those with interstitial cystitis/bladder pain syndrome and assess outcomes from treatment in a randomized fashion.

While patients with IC/BPS symptoms who are found to have an infectious aetiology, by definition, do not have IC/BPS, it is not unreasonable to empirically treat this syndrome upon initial presentation with a trial of antibiotics given the possibility of infection despite negative culture. The vast majority of these patients will have undergone at least one course of antibiotics after symptom presentation before presenting to the provider who will ultimately make the IC/BPS diagnosis. Repeated courses of antibiotics should be discouraged in the absence of culture documented urinary infection.

4. SYMPTOM EVALUATION

- Voiding diary with volume intake and output for 3 days at initial evaluation. Patient sensation at voiding might be recorded (*see "outcome assessment").*
- At follow-up only number of voiding episodes during day and night is necessary. Morning volume might be recorded as a guide to the patient's largest functional capacity.
- The O'Leary–Sant Symptom Score should be used as the basic symptom score, supplemented with the Quality of Life Score from the International Prostate Symptom Score (*see "symptom scales").*
- Pain should be recorded using a Visual Analogue Scale (VAS) for pain during the last 24 hours (to fit with the voiding diary). Separate scores for the average, mildest and worst pain should be obtained ("*see symptom scales"*)

5. URODYNAMICS

The NIDDK criteria excluded patients with detrusor overactivity at filling cystometry in order not to confuse the picture in clinical trials (48). This does not however mean that detrusor overactivity (DO) cannot coexist with IC/BPS. In the interstitial cystitis database approximately 14% of IC/BPS patients had overactive bladders (13). Whether these patients respond better to antimuscarinics than IC/BPS patients with stable bladders has never been systematically investigated. If so, a rationale for routinely employing urodynamics as a part of the evaluation would follow. A Vanderbilt study with overactive bladder patients concluded that a majority of the 218 patients studied reported either painful urgency and/or pain on bladder filling (16). In another analysis, Ackerman et. al. reports that 35% of OAB patients have some degree of bladder pain and 25% of IC/BPS patients will report urge incontinence (17).

Studies comparing urodynamic findings in IC/BPS to OAB have shown that volumes at first sensation, normal desire, strong desire, and maximal capacity during filling cystometry were significantly lower in the IC/BPS group, and similar findings have been reported in patients with Hunner lesion disease compared to those without (236,237) . However, these findings are not consistently reported and so there is currently no evidence for routine use of urodynamics to phenotype patients in the absence of clinical suspicion as to diagnosis.

Urodynamics, however, is a useful tool to exclude confusable conditions in patients with IC/BPS. Patients with IC/BPS often describe voiding symptoms such as slow stream, straining or dribbling, and bladder outlet obstruction has been reported in up to 60% of women with IC/BPS (238,239) . In females, bladder outlet obstruction may be secondary to dysfunctional voiding, poor relaxation of the external sphincter or bladder neck obstruction. Urodynamics do not reliably differentiate primary myofascial pelvic pain from IC/BPS (240) .In males, infravesical obstruction may also be a differential diagnosis (241). Therefore, uroflowmetry is recommended in all patients with IC/BPS who describe voiding LUTS, and pressure-flow studies are recommended for men with peak flow rate <15ml/second and women with a peak flow rate <11ml/s, or in those where voiding dysfunction is suspected.

Level of Evidence:3 Grade of Recommendation: B

6. POTASSIUM TESTING

Parsons has championed an intravesical potassium chloride challenge, comparing the sensory nerve provocative ability of sodium versus potassium using a 0.4 M potassium chloride solution. The test has proved controversial (242). Pain and provocation of symptoms constitutes a positive test. Whether the results indicate abnormal epithelial permeability in the subgroup of positive patients, or hypersensitivity of the sensory nerves is unclear. Normal bladder epithelium can never be absolutely tight, and there is always some leak, however small (243). It was thought that this test would help stratify patients into those who would respond to certain treatments (perhaps those designed to fortify the glycosaminoglycan layer) (244). Used as a diagnostic test, the potassium chloride test is not valid (245). The gold standard in defining IC/BPS for research purposes until the last decade has been the NIDDK criteria. These criteria are recognized to constitute a set of patients that virtually all researchers can agree have IC/BPS, though they are far too restrictive to be used in clinical practice (51). Thus, this group of patients should virtually all be positive if the KCl test is to have the sensitivity needed to aid in diagnosis. Up to 25% of patients meeting the NIDDK criteria will have a negative KCl test (246). In the group it should perform the best in, it is lacking in sensitivity. When we look at the specificity side of the equation, in the universe of asymptomatic persons, it performs relatively well and is rarely positive, although one study reported a 36% false positive rate in asymptomatic men (247). It is in the patient population with confounding conditions for which we would want help in sorting out IC/BPS from other disorders. Sixty percent of patients with overactive bladder test positive (248) and virtually all patients with irritative symptoms from radiation cystitis and urinary tract infection test positive (246,249) . The results with chronic prostatitis / chronic pelvic pain syndrome in men are variable, but 50-84% of men have been reported to test positive (247,250,251) . In women with pelvic pain results are similar (252). Therefore, the KCl test is very nonspecific, missing a significant number of IC/BPS patients and over-diagnosing much of the population. Prospective and retrospective studies looking at the KCl test for diagnosis in patients presenting with symptoms of IC/BPS have found no benefit of the test in comparison with standard techniques of diagnosis (245,253,254) .

A later modification of the test using 0.3 molar potassium chloride for potential differentiation between patients with IC/BPS and DO showed that the 0.3 M KCl reduces maximum cystometric capac-

ity in IC/BPS and DO, the effect being more pronounced in DO. Urothelial hyperpermeability was not specific to IC. Comparative cystometry using NS and 0.3 M KCl does not help to differentiate IC/BPS from DO (255,256) . The development of a painless modification of the potassium chloride test (257) using cystometric capacity and a 0.2M solution may improve acceptability among patients. The so-called revised or Comparative Potassium Test has shown prognostic value in bladder irrigation studies (258) but is considered optional by ESSIC.

If performed it should be performed according to Daha et al. (257): A Foley balloon catheter (14F) is inserted, and the bladder drained. Instill into the bladder 500 ml saline (0.9%) at a rate of 50ml/min via an infusion set until the maximum capacity is reached. Drain the bladder and measure the saline filling volume. Repeat the instillation and measurement with 500 ml 0.2 M potassium chloride at a rate of 50 ml/min (taking care that filling lines are emptied of all saline before KCl instillation), and calculate the filling volume difference. A difference in bladder capacity > 30% is considered positive. Besides reduction of bladder capacity with 0.2 M KCl there is a stronger feeling of urgency in IC patients compared to the saline filling, which is also clinically relevant.

Level of Evidence:1 Grade of Recommendation: Not recommended

7. CYSTOSCOPY

Cystoscopy under local or general/regional anaesthesia is an essential investigation to identify Hunner lesion disease for which specific targeted treatment is recommended. Therefore, cystoscopy should be performed early in the diagnostic evaluation of patients with suspected IC/BPS.

Level of Evidence:2 Grade of Recommendation: A

8. LIDOCAINE INSTILLATION

The intravesical instillation of lidocaine as a diagnostic test has only been reported in one small case series of 22 women with pelvic pain (259). Instillation of 20 ml of 2% lignocaine solution led to significant pain relief in 68% (15 out of 22), and 13 of these 15 were found to subsequently have features of IC/BPS at cystoscopy. None of the non-responders to lidocaine instillation had cystoscopic features of IC/BPS, suggesting that lidocaine instillations can help to identify a bladder-centric phenotype. However, this is a small series in which positive cystoscopic features of IC/BPS included glomerulations, which are a non-specific finding. The use of this investigation is a promising tool to aid classification of IC/BPS, but further studies are required to confirm these initial findings, and so its use is not routinely recommended at present.

Level of Evidence:4 Grade of Recommendation: D

9. HUNNER LESION DISEASE

The classic Hunner lesion phenotype of IC/BPS as an “elusive” bladder localized area of bladder mucosal inflammation with a corresponding cystoscopic appearance of patches of red mucosa exhibiting small vessels radiating to a central pale scar, and was described by Hunner in 1915 (43,260). **(FIGURES 13, 14, 15).** The finding of a Hunner lesion varies. Some researchers find a Hunner lesion in 50% of their IC/BPS patients (261), while others rarely see one (262). Nevertheless, overall, in series where Hunner le-

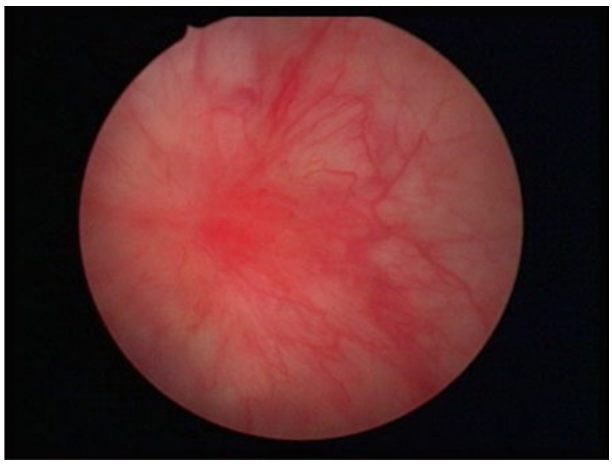

Figure 13. Hunner lesion prior to bladder distention. Courtesy of Jörgen Nordling

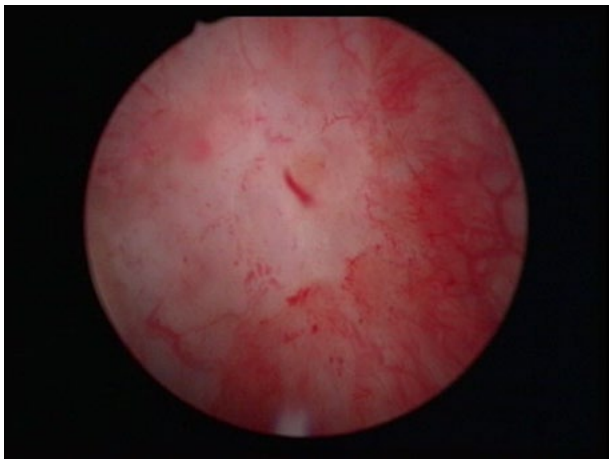

Figure 14. Hunner lesion at 80cm water pressure. Courtesy of Jörgen Nordling

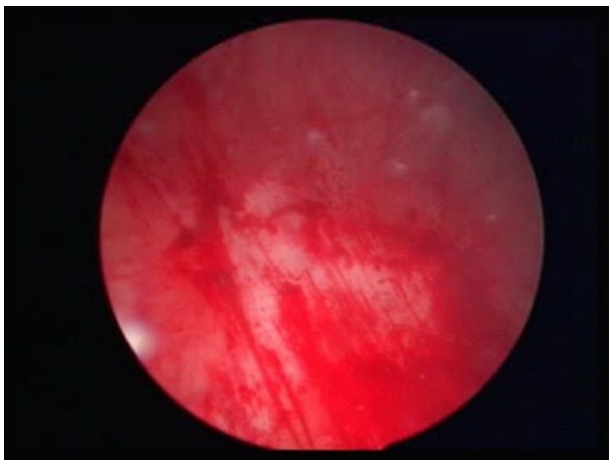

Figure 15. Hunner lesion post distention. Courtesy of Jörgen Nordling

sion has been looked for, the lesions are found in about one-third of patients (33). Identification of this lesion is important, as targeted therapy with fulguration or triamcinolone injection has been shown to be effective in this group (263). Recently, it has also been shown that the extent of the Hunner lesion corresponds to symptom severity, with more extensive lesions associated with more severe symptoms and a smaller bladder capacity (264).

10. GLOMERULATIONS

After 1978, glomerulations, described as punctuate petechial haemorrhages observed after hydrodistention, became the primary cystoscopic feature of IC/BPS (47,241) . (Figures 10 and 11, courtesy of Tomohiro Ueda). However, not all patients with symptoms of IC/BPS have glomerulations (50,51,265,266) and not all patients with glomerulations have symptoms of IC/BPS (248,267) . Neither presence nor severity of glomerulations correlate with any of the primary symptoms of IC/BPS (268), unlike the presence of a Hunner lesion which is significantly associated with bodily pain and urinary urgency (267). A recent review on glomerulations after bladder distension found no diagnostic or prognostic value of this finding (220). Despite ongoing research studies looking at what cystoscopic hydrodistention features might provide prognostic information (269), clinically at this time, the presence or absence of glomerulations on cystoscopy should not be used as a diagnostic or prognostic criteria for IC/BPS.

Level of Evidence:2 Grade of Recommendation: B

11. BLADDER CAPACITY UNDER ANAESTHESIA

Bladder capacity during hydrodistension has not drawn much attention, although it is strongly associated with increased urgency (262). Recent studies have found low bladder capacity under anaesthesia to be associated with more severe symptoms and to be indicative of a bladder-centric phenotype rather that a more systemic phenotype of IC/BPS (270,271) . Furthermore, patients with an anaesthetic bladder capacity of <400ml are more likely to have Hunner lesions and have histological evidence of significantly more acute and chronic inflammation compared with patients with a bladder capacity >400ml (272). Therefore, low anaesthetic bladder capacity may represent a specific, bladder-centric phenotype of IC/BPS. It is recommended that bladder capacity be routinely reported if hydrodistention is performed. Further studies of the prognostic significance and predictive value of this finding are required.

Level of Evidence:3 Grade of Recommendation: B

12. HYDRODISTENSION OF THE BLADDER

Because considerable variation in the duration of distension, repetition of distension, the pressure used for distension, and the measurement of bladder capacity have been described (273), the ESSIC has suggested a standardized procedure for cystoscopy and hydrodistension (274).

A rigid cystoscope is preferred to facilitate taking of adequate biopsies. Glycine or corresponding filling fluid should be used to allow for coagulation after biopsies. Infusion height should be approximately 60-80cm above the Symphysis Pubis. A dripping chamber is used, and the bladder is filled until fluid dribbling stops. If necessary, a digital block is applied around the urethra to prevent leakage. Pre-distension inspection includes observation for radiating vessels, coagulum or fibrin deposits, white spots, hyperaemia, oedema, cracks, scars or any other mucosal changes. Continuous inspection while filling the bladder is advised. When maximum capacity is reached, the distension is maintained for 2-5 minutes. The bladder is emptied, and the colour of the fluid checked for the degree of bleeding. The total volume drained is the measured maximum bladder capacity. During a second filling, the bladder is filled to approximately 1/3rd to 2/3rd of the bladder capacity to achieve optimal vision for inspection and biopsies. The bladder should not be filled to maximum capacity or distended again to avoid further provocation of changes with doubtful reproducibility.

13. INSPECTION

Describe lesions in anterior wall, posterior wall, lateral quadrants and fundus. At the fundus one should be alert for possible artefacts if there is blind introduction of the scope. Bladder mapping by drawing is mandatory. Photographs are recommended but optional.

14. CLASSIFICATION

Grade 0 ..... = normal mucosa
Grade I ..... = petechiae in at least two quadrants
Grade II ..... = large submucosal bleeding (ecchymosis)
Grade III ..... = diffuse global mucosal bleeding
Grade IV ..... = mucosal disruption, with or without bleeding/ oedema

As previously mentioned, the importance of the finding of glomerulations after hydrodistension is, however, questionable as 45% of asymptomatic females, 20% of males with LUTS suggestive of BOO and 85% of females with OAB and no bladder pain demonstrates typical glomerulations after hydrodistension (248,275,276) and 10-34% of patients with IC/BPS do not (50,266) .

15. HOW USEFUL IS HYDRODISTENTION?

It is necessary to distinguish between short term hydrodistension for classification of IC/BPS and long term hydrodistension for treatment. As a diagnostic tool, cystoscopy following hydrodistension is a recommended part of the diagnostic algorithm in order to phenotype patients based on the presence or absence of Hunner lesions, so that targeted treatment can be offered to those with Hunner lesion disease. As a therapeutic measure, hydrodistension results fail to identify any statistically significant differences in post-distention therapeutic benefits when patients are categorized according to presenting symptoms (277). A recent systematic review of 17 studies reported subjective improvement in 57% but the duration is short-lived (mean 2 months) and the quality of the evidence base is weak (278,279) . With 90% of Hunner lesions diagnosable on local cystoscopy (280), hydrodistention can now be reserved for when endoscopic treatment of Hunner lesion under sedation is indicated for therapy or in cases wherein distention is used as a therapy itself.

It is important to keep in mind that the cystoscopic appearance of the bladder wall after hydrodistention may not be constant over time, and the absence of initial findings of glomerulations or terminal hematuria does not preclude further development of these findings of the disease on subsequent evaluation (281). Rare cases of hydrodistension induced bladder necrosis have been described (282).

Level of Evidence:3 Grade of Recommendation: C

16. MORPHOLOGY

Pathological changes in light microscopic and electron microscopic features in patients with IC/BPS have been described including infiltration with inflammatory cells in all or specific parts of the bladder wall. Although these findings are important in our attempt to understand the disease and perhaps as an aid to stratification of patients, there are at this time no pathognomonic findings on biopsy in terms of diagnosis (268). Expert opinion as per the ESSIC suggests the following procedures when biopsy is planned for IC/BPS evaluation (274):

16.1. Biopsies

Bladder biopsy is important primarily to exclude confusable diseases and malignancy, and otherwise should not be routinely done. Certain pathology features may be characteristic for Hunner lesion disease and biopsy can possibly help to phenotype patients in the research setting. Biopsies from patients with Hunner lesion disease typically display marked inflammatory infiltrate with neutrophils, lymphocytes, macrophages, plasma cells and mast cells, with fibrosis and epithelial denudation (24,32) . Bladder biopsy procedures should be performed by using large forceps and include detrusor muscle; alternatively, double punch biopsies or resections of lesions can be used. Flexible cystoscopic biopsy may lead to inadequate sampling and assessment of mast cell count (283). To limit the possibility of perforation, biopsy should be carried out after distention and with the bladder largely decompressed.

16.2. Number of Biopsies

At least 3 biopsies from the two lateral walls and bladder dome should be taken in addition to biopsies from visually abnormal areas. The biopsies are to be immediately fixed in neutral buffered 4% formalin.

16.3. Biopsy Handling

Biopsies are treated conventionally. Six adjacent 3mm sections are cut and placed with 3 specimens on each of two specimen slides. The first slide is stained with H&E, the next with a connective tissue stain suitable for the individual institute. Twenty-four 10 mm sections are then cut, and every third section is mounted on a specimen slide for mast cell counting. The specimens are stained by Lederstain (naphtolesterase) according to routine procedures. Finally, a 3mm section is obtained to ensure the presence of detrusor muscle in the specimens.

16.4. Mast Cell Counting

The use of a measuring grid (e.g. Leitz periplan 6F10_N ocular containing a standardized grid) is necessary. Only mast cells containing nucleus are included. When counting the cells those covering or touching the bottom should be excluded whereas those covering the upper and left line are included. At least 3 biopsies must be the subject of mast cell counting and if possible, one including a lesional area. Biopsies for mast cell counting should contain detrusor muscle.

16.5. The pathology report

Epithelium:

- Not present
- Present
- Dysplasia with grading
- Abnormal but no dysplasia: description is mandatory.

Propria:

- Normal
- Inflammation: description with a grading
- Other findings are described

Detrusor muscle:

- Abnormal muscle cells: describe intrafascicular fibrosis
- Not present
- Present

Mast cell count:

At least three biopsies should be included in the counting. Only the biopsy with the highest number of mast cells per mm2 should be reported. The enzymatic (naphtolesterase) staining is, for the time being, recommended since standardized values are available:

- less than20mast cells/mm2:no detrusor mastocytosis;
- between 20 and 28 grey zone
- more than 28 mast cells/mm2: detrusor mastocytosis.

Larsen recommends examining the detrusor biopsies with tryptase-stained 3 micron thick sections, with every seventh section used for quantification; 27 mast cells/mm2 is considered indicative of mastocytosis (216). These guidelines have been reported to be easy to follow. A statistically significant correlation was found between the cystoscopic aspect and inflammatory infiltration, mast cell count in the detrusor muscle and stromal edema. Maximum bladder capacity was negatively correlated with inflammation, detrusor mast cell count, haemorrhages and the overall cystoscopic aspect (284). Correlations have also been demonstrated between urothelial damage and inflammatory infiltrates and between normal epithelium and detrusor mastocytosis suggesting either 2 different types of IC/BPS or different stages in the pathophysiological process of IC/BPS {Geurts 2011. However, data regarding mast cells is mixed with a recent study showing higher levels of mast cells in non-Hunner lesion patients (285). The question of whether an elevated mast cell count represents a distinct phenotype of BPS independent of the presence of Hunner lesions remains to be determined.

17. BIOMARKERS

The lack of universally accepted clinical diagnostic criteria for different IC/BPS phenotypes affects all aspects of making progress in understanding this disease. Insights into risk factors, pathogenesis, trials for effective therapy, prognosis, and outcome criteria for treatment are all affected by this lack of objective diagnostic criteria. A major factor affecting the controversy over accepted clinical diagnostic criteria is that the current criteria are predominantly symptom specific. An objective biomarker would advance the establishment of reproducible diagnostic criteria for IC/BPS and also aid in monitoring effects of treatment. A biomarker for any disease needs to demonstrate high sensitivity and high specificity. In addition, the marker assay needs to be reproducible in many laboratories and should be suitable for use in a clinical diagnostic laboratory. Several biomarkers (from urine, blood, stool and bladder tissue) have been studied in recent years,

and different phenotypes of IC/BPS may be distinguishable based on these markers.

Many of the published studies have been on biomarkers isolated from urine. Erickson et.al has published excellent reviews of urine markers for IC/BPS (286,287) . The most thoroughly investigated marker is antiproliferative factor (APF) (288,289) . A study of 64 patients with IC/BPS (38 with Hunner's lesions and 26 without), found that 92% of IC/BPS patients had APF activity compared to only 3% of controls (290). Treatment of symptomatic IC/BPS by either hydrodistention or neurostimulation normalized the APF levels concurrent with symptom relief (291). It is not known if other forms of treatment will affect APF levels. Preliminary studies in 58 women with documented IC/BPS demonstrated a sensitivity value of 91.4% and a specificity of 90.6% (292). A later study with 219 symptomatic IC/BPS patients and 325 controls with and without other urological disorders documented the sensitivity as 94% and the specificity at 95% (293). Keay et al. have suggested that APF might inhibit cell proliferation by the downregulation of genes that stimulate cell proliferation along with the upregulation of genes that inhibit cell growth (155). Cell growth inhibition of human urothelial cells appears to be mediated by p53 (294). APF treatment caused significant increases in the paracellular permeability of normal bladder epithelial cell monolayers and the attenuation of tight junctions compared to mock APF, similar to changes seen in IC cells. APF treatment also decreased expression of the tight junction proteins zonula occludens-1 and occludin (295).

APF seems an ideal candidate for a biomarker for symptomatic IC/BPS. There need to be additional studies to determine if it can serve as an IC/BPS marker for patients in remission or for those who have not yet become symptomatic. Furthermore, it is unclear whether AFP can distinguish Hunner lesion disease from non-Hunner lesion disease, and this requires further study. Currently, the findings on symptomatic patients have yet to be replicated by laboratories around the world, and the biologic assay has not proven suitable for commercial development as it currently exists. For whatever reason, this previously promising research tract seems to have reached a dead-end.

There have also been many published studies on heparin-binding epidermal growth factor-like growth factor (HB-EGF) (155,296-299) . HB-EGF is a growth factor found in normal urine. It has been shown that APF inhibits the production of HB-EGF. There have been no large population studies focusing solely on HB-EGF as a biomarker for IC/BPS.

The urinary markers, macrophage migration inhibitory factor (MIF) and the chemokine CXCL10, have been shown to be able to discriminate between Hunner lesion disease and non-Hunner lesion disease, but their ability to predict response to treatment has not been studied and validation of these markers are required before their use can be recommended (300,301) .

Recent results from the MAPP studies indicate some urinary metabolites capable of discriminating female IC/BPS patients from controls. Ethiocholan-3α-ol-17one sulfate (Etio-S) did so with a specificity and sensitivity >90%. Among IC/BPS patients Etio-S levels are correlated with elevated symptom scores and could resolve high- from low- symptom IC/BPS (302). However, patients were not subdivided into those with or without Hunner's lesions and response to treatment has not been assessed. Recent studies show that urine cytokine profiles may differentiate IC/BPS patients from a control group (303). In the future an objective measurement of progression and resolution of symptoms may come from evaluation of urinary biomarkers (304).

A recent study using next-generation sequencing of RNA from bladder biopsies of patients with IC/BPS has demonstrated distinct genetic features compared to controls, with overexpression of VEGF and BAFF correlating with more severe symptoms and a distinct phenotype of IC/BPS (305). In the future, genomic markers may prove clinically useful in diagnosis, phenotyping, prognosis and predicting response to treatment.

Level of Evidence:3 Grade of Recommendation: D

X. CONFUSABLE DISORDERS

1. NON-GYNECOLOGIC

Confusable disorders are those that can be easily misdiagnosed as IC/BPS. Associated disorders are disorders that can occur with some frequency in the IC/BPS population. One does not want to mistake IC/BPS for a confusable disorder, as the ensuing treatment will not be appropriate. However, it may be difficult to ascertain whether the symptoms bothering an IC/BPS patient are primarily due to the IC/BPS diagnosis or an associated disorder like endometriosis or irritable bowel syndrome. The distinction between confusable and associated disorder is an important one in clinical practice and when researching potential therapeutics. Once a clinician has confirmed a clinical diagnosis of IC/BPS, an accompanying disorder is no longer a confusable disorder.

The diagnosis of IC/BPS can made on the basis of exclusion of confusable diseases and confirmation by the recognition of the presence of the specific combination of symptoms and signs of IC/BPS. For the diagnosis, two methods (by recognition of the specific combination of features of the target disease or by exclusion of confusable diseases) might be used in a pool of confusable diseases because:

- Confusable diseases are often more common than IC/BPS, so recognition is mandatory because many can be treated.
- Failure to diagnose a confusable disease would automatically incorrectly yield a diagnosis of IC/BPS.
- Patients may have a confusable disease plus IC/BPS.

IC/BPS may occur together with confusable diseases such as chronic or remitting urinary infections or endometriosis. If the main urinary symptoms are not explained by a single diagnosis (confusable disease or IC/BPS), the presence of a second diagnosis is possible.

For therapeutic reasons it makes sense to identify patients who also have a confusable disease because symptoms and signs may be caused by BPS, the confusable disease, or by both. For prevalence studies of IC/BPS, on the other hand, all cases with IC/BPS should be included, also those with a confusable disease. This approach eliminates the need for separate diagnostic criteria for clinical practice and scientific studies. (**TABLE 5)** summarizes confusable diseases related to BPS and their mode of exclusion. (6).

Following this logic, Hunner lesion disease is a confusable disease that can be diagnosed with cystoscopy. It is not an associated disease but easily mistaken for IC/BPS in those who have not undergone endoscopic examination.

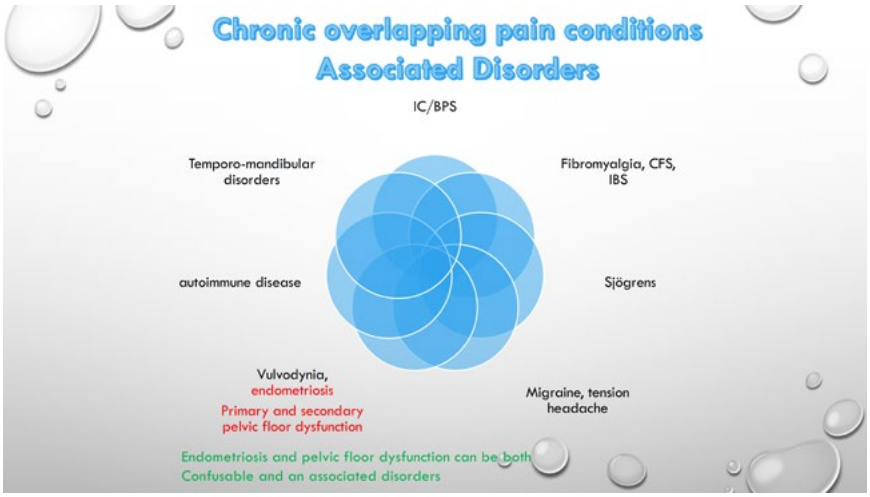

Figure 5. Associated and confusable disorders commonly diagnosed in patients with IC/BPS.

In female populations affected by IC/BPS gynecological diseases may be present in about 20% of patients. There is also an overlapping of musculoskeletal pathologies in 12% of cases (306).

The confusable disorders could be gynecological or non-gynecological; the distinction may be not clearly defined. The treatment should be according to each individual disease diagnosis.

Some of the most frequent non-gynecological disorders in IC/BPS population include:

1.1. Pudendal Neuropathy vs IC/BPS

Pudendal neuropathy is a common feature of syndromes such as dysfunctional voiding, non-obstructive urinary retention, chronic pelvic pain syndromes, and urinary and fecal incontinence. It should be ruled out as a confusable disease in IC/BPS patients. Pudendal neuralgia is a functional entrapment of the pudendal nerve, and pain occurs during compression or stretch maneuvers, such as repetitive microtrauma, orthopedic fracture, straining with constipation and childbirth, falls onto the buttocks, and suture entrapment during pelvic surgery. The main symptom is pain aggravated by sitting/driving/exercise, reduced

by recumbence or standing and relieved by sitting on a toilet. The quality of neuropathic pain varies and can be described as burning, stabbing, ache, or pressure, and can be induced by voiding, defecating, vaginal penetration, or orgasm. It can occur anywhere in the pudendal territory, but primarily includes the perineum and urethra, and extends to suprapubic, inguinal regions and to the upper medial thighs.

Urinary symptoms and rectal dysfunction might occur. Foreign body sensation in the rectum, vagina, urethra or perineum is frequent. Sexual dysfunction can be present. Females may suffer reduced clitoral sensation, pain at vaginal penetration, reduced lubrication and anorgasmia.

Pinprick sensation is tested bilaterally at the level of the clitoris posterior labia and posterior perianal skin. Hyperalgesia is more common than hypoalgesia. Pressure can be placed at the level of the Alcock canal attempting to reproduce pain, bladder or rectal symptoms (the Valleix phenomenon). The para-sacral area is also examined for a back mouse (epi-sacroiliac lipoma). Several tests can measure pudendal neuropathy including: biothesiometry, sacral latency test, sensory-evoked potentials, motor-evoked potentials and motor latency tests. Ultimately an MR neurogram and pudendal nerve block may be important in confirming the diagnosis and determining treatment options. (307,308)

Management

1.Pharmacotherapy

Tricyclic antidepressants were the first medication category

effective in placebo-controlled trials. Other drugs, such as gabapentin, pregabalin, oxcarbazepine, tramadol and duloxetine, significantly reduce

pain and improve sleep, mood, and quality of life.

2.Transgluteal Pudendal Nerve Blocks

Two injections are given at the ischial spine at 1-month intervals. A third is given into the Alcock canal using computed tomography guidance.

3.Surgical Therapy

Transperineal and Transgluteal Approach : Pudendal nerve decompression by the perineal route is a blind procedure carried out under local or regional anesthesia. To suppress the blind character of the procedure, a transgluteal approach has been proposed and the reported surgical success rates range from 60% to 70%. Pain-free status might take some years. Bladder, bowel and sexual dysfunctions show variable improvement (309).

More recently, a transvaginal approach has also been proposed (310).

Until now, the results on pain are the same as those obtained by the Shafik's approach (311), but with the concurrent sections of one or two ligaments of the pelvis (sacro-spinal and/or sacro-tuberous ligaments).

However, the long-term effects of these sections on the stability of the pelvic region are as yet unknown. Up to now, no data are available about a potential effect of the transgluteal or transvaginal procedures on urinary or anal incontinence.

1.2. Urinary tract infection vs IC/BPS

The symptoms of interstitial cystitis/painful bladder syndrome often mimic urinary tract infection, but cultures are negative (312). When interstitial cystitis/painful bladder syndrome is clinically suspected, patients should be asked about suprapubic pain; urinary frequency; urgency; nocturia; and pain of the pelvis, perineum, labia, vagina, or urethra. Physicians should also ask female patients about exacerbations related to the menstrual cycle and sexual intercourse (312-314) . It is best to treat any documented urinary infection and determine if IC/BPS symptoms persist in the presence of negative cultures, in which case the IC/BPS diagnosis is warranted and should be treated.

1.3. Overactive bladder V.S Interstitial cystitis/Bladder Pain Syndrome

There is a gray area where the distinction between OAB and

IC/BPS becomes a relevant and clinically important problem affecting a substantial number of patients (17). This can lead to delays in diagnosis and administration of appropriate treatments, due to the fact that patients can endorse symptoms predominantly suggestive of either OAB or IC/BPS yet have the other condition.

Further complicating matters is that no “gold standard test” exists to differentiate between OAB and IC/BPS. Cystoscopic findings following HD, urodynamic testing, and even clinical history often can coincide. We believe that increased emphasis on the history and physical exam can help to differentiate types of urgency and pain, leading to improved diagnostic rates (315).

Mechanism between OAB and IC/BPS

The bladder microbiome, bacterial infection, inflammation, and urothelial permeability contribute to the development of peripheral afferent hyperexcitability that is fundamental to the development of frequency and urgency in OAB, and pain in IC/PBS. In addition, the higher psychological stress levels, increased prevalence of anxiety and depression, as well as clinical co-morbidities with other visceral pain disorders suggests pathological plasticity within the CNS is an important component in the mechanisms underlying both OAB and IC/PBS (15). Despite our difficulties in differentiating one disease from the other, it is notable that treatment at times overlap, with behavioral therapies, SNS, BTX-A injections, and enterocystoplasty/urinary diversion available in certain instances to effectively treat either condition.

2. GYNECOLOGICAL ASSOCIATED/CONFUSABLE DISORDERS

In female population affected by IC/BPS the gynecological associated disorders may be present in about 20% of patients. There is also an overlapping of musculoskeletal pathologies in 12% of cases. (306) The following comprise the most frequent gynecological disorders in the IC/BPS population:

2.1. PELVIC FLOOR DYSFUNCTION (PFD)

Pelvic floor dysfunction affects the anterior, apical or posterior vaginal compartment. Pelvic floor dysfunction can be hypotonic (LPFD) or hypertonic (HPFD) **[Table 6].** Many patients with IC/BPS have concomitant HPFD, with muscle tenderness, spasms, and voiding dysfunction. (316)

Table 6: Classification of Pelvic Floor Dysfunction

HYPOTONIC DISORDER	HYPERTONIC DISORDERS
Stress Urinary Incontinence	Chronic Pelvic Pain
Pelvic Organ Prolapse	BPS/IC
Fecal Incontinence	Overactive Bladder
	Overactive Bowel
	Overactive Pelvic Floor
	Vulvodynia
	Sexual dysfunction

Several studies have reported that myofascial pain and HPFD are present in 50% to 87% of IC/BPS and/or chronic pelvic pain syndrome. (317) The mechanism is likely very similar to Category IIIB Chronic Prostatitis/Chronic Pelvic Pain Syndrome (CP/CCPS) in the male population. PFD exacerbates IC/BPS symptoms and has been reported to appear in response to events such as bladder inflammation, gait disturbance, and trauma. (318,319)

Patients with IC/BPS have pelvic floor hypertonicity on MRI, which manifests as shortened levator, increased posterior puborectalis angles, and decreased puborectal distances. This pelvic floor hypertonicity in patients with IC/BPS, may contribute to or amplify pelvic pain . (320)

Pelvic floor dysfunction exacerbates IC/BPS symptoms, and has been reported to appear in response to events such as bladder inflammation, gait disturbance, and trauma. (318)

Yong et al. reported a prevalence of 40% of pelvic floor muscle tenderness in a group of 189 women with chronic pelvic pain compared to 32 (13%) in healthy controls. (321)

Other pain disorders, such as irritable bowel syndrome, inflammatory bowel disease, fibromyalgia, and vulvodynia are all found to have a high prevalence in HPFD and myofascial pain and frequently associated with IC/BPS. (111)

2.1.1. PATHOPHYSIOLOGY

In a normal bladder, the peripheral nerve transmission is mediated by A∂-fibers that transfer tension, pain and cold and C-fibers that transfer burning, heat, pain and itching. C-fibers are normally silent, only becoming active in response to bladder inflammation or irritation. An inflammatory disorder of the pelvic viscera, a trauma or exceptional behavior might elicit noxious stimuli to the sacral cord that sets up a pelvic floor muscle dysfunction with sacral nerve hypersensitivity and a sacral cord “wind-up “whereby the viscero-muscular guarding reflex is activated and increases (winds-up) the tone of the pelvic floor during stress or routine daytime activity. (322)

The current model of IC/BPS pathophysiology suggests that central nervous system dysfunction results in aberrant responses to stimulation of pelvic visceral and somatic neurons manifest as chronic pelvic pain out of proportion to demonstrable pathology. As a result of limbic efferent stimulation, the pelvic musculature undergoes tonic contraction. (323)

Pain afferents from the pelvic floor and bladder transmit this noxious stimulus back to the sensitized limbic system, reinforcing efferent contraction of pelvic muscles and perpetuating chronic pain.

(324) Given cross-talk between the pelvic floor and bladder and bowel neurons in the spinal cord (189,193,325,326)

pelvic floor dysfunction may perpetuate voiding dysfunction, defecatory dysfunction, urinary urgency and frequency, and pelvic pain.

In IC/BPS patients, there is an afferent autonomic bombardment that can enhance and maintain a guarding reflex that manifests itself as a hypertonicity of the pelvic floor.

2.1.2. PHYSICAL EXAMINATION

A commonly overlooked finding in patients with CPP is levator muscle spasm and its associated myofascial pain. (327) Patients with HPFD are unable to produce more contractile strength and therefore cannot produce an effective squeeze. A single finger can be introduced in the vagina to assess pelvic floor awareness, and the ability to squeeze and relax the levator ani. Often patients with HPFD will have a "V" configuration of the introitus and, as a finger is advanced, it will drop off the shelf caused by the contracted levator muscles. Active "trigger points" are often identified by an exquisitely tender area palpable at the level of the pelvic side wall within a taut band that reproduces the patient's pain, as well as the referral pattern of her pain

2.1.3. DIAGNOSTIC STUDIES

Muscle activity can be measured using a perineometer or an electromyography probe. (328) Urodynamics include fluctuating or interrupted flow, abnormal voiding studies, elevated urethral pressure and urethral instability. Schmidt and Vapnek observed pain episodes in such patients coinciding with behavioral increase in the sphincter tone, more than in the bladder. (329) When symptoms involve obstructed defecation and rectal pain, defecography should be used to identify the presence of a non-relaxing pelvic floor or even parodoxic activity of the pelvic floor during defecation.

2.1.4. TREATMENT

The pelvic floor physiotherapy should be considered as a first-line treatment in the case of HPFD. The goal of these stretching exercises is to lengthen the contracted muscles by decreasing tension, releasing trigger points in the levator muscles, reeducating the muscles to a normal range of motion and improving patient awareness. (330) The therapy also includes: behavior modification, muscle relaxants, Thiele's massage, sacral and tibial neuromodulation, trigger point injections, and botulinum toxin.

2.2. ENDOMETRIOSIS

Endometriosis and IC/BPS are common causes of chronic pelvic pain (CPP) in women. (331-336)

Endometriosis is determined by the presence of endometrial glands or stroma outside of the endometrial cavity and affects 1–7% of the general population. (337). Retrograde menstruation is the generally accepted mechanism underlying the pathogenesis of endometriosis (338). This mechanism was originally proposed whereby endometrial fragments migrate from the fallopian tubes into the peritoneal cavity during menstruation. More recent data show the prevalence of retrograde menstruation is no different in women with or without endometriosis, suggesting a more complex etiology (339,340).

It is considered that immune dysfunction and the subsequent inability to effectively clear these fragments enables endometrial lesions to form in the peritoneal cavity (341).

Ectopic endometrial debris is cleared from the peritoneum by an innate immune response. Dysregulation in this innate immune reaction in response to ectopic endometrial tissue has been implicated in endometriosis pathophysiology. (342). Common sites of implantation include the ovaries, uterosacral ligaments, cul-de-sac, and the uterovesical peritoneum. (343,344)

As with the normal uterine endometrium, these extrauterine implants remain under the cyclic influence of ovarian hormones and are stimulated to grow and then break down with each menstrual cycle. Endometrial pain is usually a visceral pain and it is caused by inflammation that results from cyclic sloughing of these endometrial glands, by the release of neurokinins and prostaglandins F^2a and E^2. (345)

Endometriosis is considered as not only a chronic inflammatory disorder but also an estrogen dependent disease. (346,347) As a matter of fact E2 concentrations in endometriotic lesions are known to be elevated. (348) MCs may mediate the role of E2 in the pathogenesis of endometriosis that promotes the growth of endometriotic lesions and triggers pain by activating MCs, which subsequently release a variety of mediators. (349)

The painful symptoms (dysmenorrhea, cyclic pelvic pain or deep dyspareunia) are present in up to 70% of such women. (350) It is important to ask about the onset of symptoms like dyspareunia and urinary urgency/frequency and the extent and location of the pain. In IC/BPS, pain usually worsens as the bladder fills and improves after voiding.

During the physical examination, the physician may detect tender nodules and masses in the pelvic region, a tender retroverted uterus, or implants in uterosacral ligaments and to determine whether the tenderness elicited reproduces the pain that the patient typically experiences. (351) Given the similarities between endometriosis and IC/BPS nonspecific symptomatology, as well as pain in the absence of other symptoms it is critical that gynecologists consider IC/BPS as a diagnostic possibility when a patient initially presents with symptoms of CPP.

Laparoscopic-guided biopsy is considered the *"gold standard"* for diagnosis. (352). In women who undergo a laparoscopy to evaluate CPP, the prevalence of endometriosis is 30–90%. (353)

No known causal relationship exists between endometriosis and IC, in part because the origin of both conditions is poorly understood. It is speculated that both diseases are caused by autoimmune disorders, with an unknown factor acting as a trigger for one or both . (354)

Another possible explanation is that neuropathic upregulation leads to neurogenic inflammation and viscerovisceral hyperalgesia, in which chronic noxious stimuli at one site can contribute to referred pain and inflammation at other visceral organs. (316)

There is a high prevalence and association of IC and endometriosis. A study by Chung et al. of 178 women with CPP found that 65% of CPP patients suffered from both active endometriosis and IC, the so called "the Evil Twin Syndrome". (355) In a prospective study carried out of 162 patients with CPP, Paulson and Delgado found that 66% of the sample was diagnosed with both endometriosis and IC. (356) A recent systematic review estimated the prevalence of IC/BPS, and the coexistence of IC/BPS and endometriosis in women with CPP. Nine studies including 1016 patients with CPP showed the mean prevalence of IC/BPS was 61%, of endometri-

osis 70%, and coexisting IC/BPS and endometriosis 48% (range 84 16–78%, CI 44–51%). These data suggest the importance of considering the bladder as the source of pain even where endometriosis is confirmed, and in the case of unresolved endometriosis and persistent pelvic pain, patients must be evaluated to rule out the presence of IC/BPS. (357)

2.3. FEMALE SEXUAL DYSFUNCTION & VULVODYNIA

Female sexual dysfunction (FSD) is a prevalent condition affecting women's health and is present approximately in 40% of women. Common symptoms associated with FSD include diminished vaginal lubrication, pain and discomfort upon intercourse, decreased sense of arousal and difficulty in achieving orgasm.

FSD and IC/BPS are two conditions affecting women's health. Both FSD and IC/BPS significantly impairs a woman's abilities to pursue and enjoy sexual relations. In the group of women affected by FSD, 0.5–12% have the presence of IC/BPS. (358,87,359,84,75) . Up to 54 % of women with IC/BPS were found to often avoid sexual intercourse with their partners and IC/BPS was found correlated with sexual dysfunction. (360,361)

2.3.1. Sexual pain and IC/BPS

IC/BPS is not a disease confined to just the bladder and pelvic area; it is a complex disease that includes the outside of the genitourinary tract. A study investigating the pain characteristics of IC/BPS using whole-body diagram pain locators, found that women with IC/BPS reported significantly more pain all over their body, compared to healthy women without. Only 27% of the IC/BPS pats. presented pain restricted to the bladder and pelvic area. (362). In regards to the pain associated with FSD, vulvodynia may be contributing to flare-ups of IC/BPS symptoms and could be the reason why IC/BPS patients avoid sexual activity. (363)

As expected, women with provocative Vulvodynia (PVD) had more severe superficial and deep dyspareunia. The relationship between PVD and deep dyspareunia is mediated by the associations between bladder/pelvic foor (levator) tenderness and IC/BPS. (364,365)

It may be that contact with a tender bladder or tender levator ani during deep penetration leads to deep dyspareunia. A possible explanation may be cross-sensitization, convergence and subsequent cross-talk of afferent signals within the spinal cord. (191)

2.3.2. Vulvodynia

The International Society for the Study of Vulvovaginal Disease (ISSVD) has redefined the previous concept of *chronic vulvar pain, vulvar vestibulitis or vulvar dysesthesia syndrome* with the new term of Vulvodynia. The definition includes *" an unpleasant altered sensation in the vulva defined as vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable,with the neurologic disorder".* This "burning pain" is suggestive of a neuropathic pain response. Pain can be unprovoked, varying from constant to intermittent, or occurring only on provocation, such in sexual intercourse. Sometimes an area of redness might be visible, but more often the vagina and the vulva show no abnormalities on gynecological or dermatological evaluation.

Classification of Vulvodynia might include localized or generalized , or both, provoked or non-provoked and primary or secondary. (366) The prevalence of vulvodynia has been estimated to range between 4-25%. (367,368)

2.3.3. Pathophysiology

Because both the vestibule of the vulva and the bladder are derived from the urogenital sinus, it could be hypothesized that the coexistence of vulvodynia and IC/BPS in some patients represents a generalized disorder of urogenital sinus-derived epithelium. (369) The etiology of vulvodynia is presumed to involve many factors: infections, altered vaginal acid-base balance, and the upregulation of pro-inflammatory immune responses. (370) Various noxious stimuli could cause changes in the vulvar epithelium: contraction in the pelvic floor, and mast cell activation with subsequent degranulation and release of histamine. This causes chronic pain and inflammation through the stimulation of peripheral neurons of the autonomic nervous system, an upregulation of the pain system, and a possible shift from nociceptive to neuropathic pain. (371) An increased peripheral tactile, pressure, and pain sensitivity in the pats with vulvodynia has been reported histologically. (372,373) . Mast cell hyperactivation has been identified in patients with vulvodynia and degranulation is consider to stimulate peripheral pain transmitting neurons (C and A-δ fibers). (374,375) . Borenstein *et al.* compared vestibular tissue from women with vulvodynia for mast cell count and nerve spreading. They found a significant increase in the total mast cell count and degranulated mast cells in pats with vulvodynia compared to controls. The total nerve fiber area was found to be 10 times higher in the group of vulvodynia compared to the control group. (376)

Neurogenic inflammation plays a role in local pain and inflammation, but also at referred sites. Much of the pain experienced by IC/BPS and vulvodynia patients appears to be neuropathic. (377,378). This may explain why patients with IC/BPS may experience referred pain in the vulva and patients with vulvodynia may experience referred pain in the bladder and urethra. Local vasodilation, edema, hyperalgesia and allodynia are typical in a subset of IC/BPS and vulvodynia. Symptom flares in these patients may in fact be modulated by the estrogens before menses that induces the release of histamine from mast cells resulting in increased amounts of substance P. (379,380) A neuromodulatory role of estrogen on pain transmission at various sites has been clearly documented. (381). A further observation documents in a large community-based study that vulvodynia was strongly associated with childhood physical or sexual abuse. (382)

2.3.4. Peripheral sensitization of Vulvodynia and IC/BPS

The potential underlying mechanism of peripheral pain hypersensitivity noted in both vulvodynia and IC/BPS could be due to sensory nerve upregulation. Previous studies have shown that sensory nerve density is significantly increased in the vulva vestibule and bladder. Compared to the normal controls, patients with vulvodynia were found to have increased nociceptors in their vulvar vestibule (383-385) . Consequentially, this increased density of peripheral nociceptors results in increased sensitivity. It was also found that transient receptor potential V1 (TRPV1) exists in these nociceptive nerve endings and enhances pain signaling. (386,387) Similarly with vulvodynia, it has been highlighted that IC/BPS patient bladders have upregulated sensory innervation and TRPV1 expression. (388-390)

The mechanisms of the association between IC/BPS and vulvodynia are unclear, visceral nerve cross-talking and the anatomic relationship between genital organs and the bladder can be an explanation. Another possible mechanism behind the relationship is abnormal pain hypersensitivity induced by peripheral and central sensitization. The abnormal pain response frequently observed in vulvodynia patients is caused by central or peripheral maladaptive pain processing from local insult, injury, or trauma. Pain conditions

such as fibromyalgia, irritable bowel syndrome, interstitial cystitis, temporomandibular joint and muscle disorders, and chronic fatigue syndrome are common among women with vulvodynia. (117,391-393) . Women with vulvodynia, regardless of type, are likely to have at least two additional pain conditions as Fibromyalgia and IBS, indicating that more severe vulvar pain is significantly associated with multiple comorbidities. (394) In a recent paper a group of 212 women with vulvodynia and 230 without vulvodynia were analyzed. All women with vulvodynia, compared to those without, were substantially more likely to be bothered by night time voiding, and reported the experience of moderate to severe urgency after urination. The findings suggest that women with vulvodynia are substantially more likely to report voiding dysfunction and symptoms of urgency than women with no history of vulvar pain. (395)

The standard clinical test for vulvodynia is the cotton swab (Q-tip) test, measuring vulvar pain ratings on a visual analog scale. Q-tip palpation for tenderness of the vulvar vestibule

was performed on each patient at the 12, 2, 4, 6, 8, and 10 o' clock positions. (372)

2.3.5. THERAPY

Physical therapy plays an important role in the initial management of vulvodynia and IC/BPS.

Internal and external myofascial release and massage with soft tissue mobilization and pelvic floor stretching exercises and biofeedback comprise the initial approach. Strengthening exercises should be avoided because the pelvic floor of these patients must be re-educated for relaxation rather than contraction which in fact would worsen the condition.

The Goals of physical therapy treatment are:
- Normalize pelvic floor resting tone
- Normalize pelvic floor contractile abilities
- Restore sexual function
- Return to recreational exercise

A retrospective study on 24 patients with vulvodynia treated with physical therapy demonstrated in 71% an improvement greater than 50% (396). Myofascial techniques, Trigger-point therapies and Thiele massage for Pelvic Floor overactivity are well documented. (397). Manual therapy involves skilled hands-on techniques intended to increase range of motion, mobilize soft tissue and joints, induce relaxation, reduce pain, and improve function. This can include massage, stretching, trigger point therapy, myofascial release, and joint and scar tissue manipulation performed internally and/or externally. Thiele massage consists of digital pressure and subsequent elongation of the musculature to relax muscles, restoring normal pelvic tone and the ability to coordinate muscle behavior.

It should be noted that vulvar pain can be very distressing, and myofascial techniques should be applied in a manner that is well tolerated. The aim is to reduce overactivity and desensitize the CNS. (398). Adjunctive therapies may be employed including transcutaneous electrical nerve stimulation (TENS), electromyographic (EMG) biofeedback and dilators. Topical lidocaine may be a valuable adjunct to help override a vaginismus response.

A randomized clinical trial compared myofascial physical therapy to global therapeutic massage in IC/BPS patients (n=81). Participants were randomized to either group for ten 60-minute sessions over 12 weeks. A total of 59% of the physical therapy group reported moderate or marked improvement, compared to 26% in the massage group on the global response assessment (P=0.0012). (399)

Use of steroids is currently not recommended to treat vulvodynia. (400)

Lidocaine and Cognitive Behaviour Therapy significantly improved vestibular pain thresholds, quality of life scores, and sexual functioning at 12-month followup. (401)

Kim et al. reported an early experience with the use of topically applied combination of Meloxicam 0,3% (a selective COX-2 inhibitor) combination agent and topical lidocaine 5% with the aim of reducing nociceptive thresholds in patients diagnosed with vulvodynia.

Of the 8 participants, 6 had a subjective improvement in their symptoms with the use of the combination gel after a one-week trial. The most common side effects reported were burning and stinging. (402)

Seven patients who exhibited pain, taut bands and/or trigger points on the pelvic floor and intractable genital pain have been treated with Botox injection 20-40 U BTX A at vestibule, levator ani, or the perineal body. In all patients, pain disappeared VAS improved from 8.3 to 1.4 Mean follow-up 11.6 months, no side effects. (403). Nickel et al., in a non-placebo controlled trial, studied the improvement in sexual functioning in IC/BPS patients who received 300 mg pentosan polysulfate sodium for 32 weeks. They reported a significant improvement in sexual functioning scores at 8th to 32nd week of treatment. The improvement in sexual functioning at the end of the study was also found correlated with symptom resolution ($r = -35$, $p = 0.0002$). (404)

In another uncontrolled study conducted with 103 IC/BPS patients receiving intravesical hyaluronic acid , the short form of the Pelvic Organ Prolapse/Urinary Incontinence Sexual Function Questionnaire (PISQ-9) a significant improvements were noted after 1 to 6 months of dyspareunia and intensity of orgasms. (405)

Intravesical treatment for IC/BPS with lidocaine, heparin and sodium bicarbonate was also found efficacious in pain relief related to sexual intercourse in another uncontrolled study. Welk et al. reported the outcomes of 23 sexually active IC/BPS patients treated with an intravesical solution of lidocaine, heparin and sodium bicarbonate. FSFI pain domain scores before and after instillations were 1.9 ± 0.9 and 3.7 ± 1.6, respectively ($p<0.01$). And a resolution in dyspareunia was observed in 57% of the patients. (406)

Several studies have shown that gabapentin as tricyclic yields significant results reducing pain perception, with more than 80% of patients reporting improvement. More recently, botulinum toxin has been proposed for the treatment of vulvodynia. It was found that the visual analog scale score was reduced from 8.1 to 2.5 ($P < 0.001$), and eight (72.7%) out of 11 patients were satisfied. (407-409) There are treatment modalities with growing interest but limited evidence, including hypnotherapy and acupuncture. Small studies show positive but limited outcome improvements with acupuncture for PVD. (410,411)

There is early work looking at deep brain stimulation, spinal cord stimulators, transcranial magnetic stimulation, somatosensory psychotherapy, mind–body therapies (including yoga and tai chi) and Botulinum Toxin A, but with no long-term trials. Botulinum Toxin A has emerging evidence for use in refractory pelvic pain. (412,413)

XI. CLASSIFICATION AND PHENOTYPING

Accurate phenotyping of patients with IC/BPS is important in order to offer personalized therapy and optimize treatment outcomes. Potential phenotypes based on clinical, cystoscopic, radiological and urodynamic factors, have been suggested, but these require further study to determine their clinical utility in determining disease prognosis and/or treatment outcome (414).

1. HUNNER LESION DISEASE

The most well-described phenotype of IC/BPS is Hunner lesion disease, which has distinct clinical, cystoscopic and histopathological features, and for which specific lesion-directed therapies are available (see treatment section). The finding of a Hunner lesion was historically regarded as a diagnostic criterion for IC. Messing and Stamey introduced glomerulations as another typical finding for IC/BPS and this was included in the NIDDK criteria. Magnus Fall proposed, that patients with Hunner lesion (classic IC) and patients with glomerulations (non-ulcer type) represented two different subtypes (31) with different clinical pictures, different outcomes, and different responses to treatment (261) meaning that patients fulfilling the NIDDK criteria represent at least two different patient populations. Moreover, up to 60% of patients clinically believed to have IC/BPS by experienced clinicians do not fulfil the NIDDK criteria (51) and whether or not these patients are comparable to the patients fulfilling the NIDDK criteria is unknown. Finally, East Asian urologists have proposed that “interstitial cystitis” should be preserved as a disease name for patients with urinary symptoms and cystoscopic findings of Hunner lesion as outlined in the NIDDK criteria (20).

In an attempt to unite these different philosophies into a coherent schema, ESSIC proposed a classification of IC/BPS based on findings during cystoscopy with hydrodistension and morphological findings in bladder biopsies (6) (**Table 2**). The classification includes groups not having had cystoscopy with hydrodistension (groups 1,2,3) as well as groups not having had morphological investigation of bladder biopsies (groups A,B,C). By using this classification glomerulations after hydrodistension are today regarded more or less as a nonspecific finding, while IC/BPS patients with Hunner Lesion has been suggested to be a specific and distinct disease.

Table 2. ESSIC Classification of Bladder Pain Syndrome. *From van de Merwe JP, Nordling J, Bouchelouche P, Bouchelouche K, Cervigni M, Daha LK, et al. Diagnostic criteria, classification, and nomenclature for painful bladder syndrome/interstitial cystitis: An ESSIC proposal. Eur Urol 2008, Jan;53(1):60-7.*

		cystoscopy with hydrodistension			
		not done	normal	glomerulations[1]	Hunner's lesion[2]
biopsy	not done	XX	1X	2X	3X
	normal	XA	1A	2A	3A
	inconclusive	XB	1B	2B	3B
	positive[3]	XC	1C	2C	3C

[1] cystoscopy: glomerulations grade II-III
[2] with or without glomerulations
[3] histology showing inflammatory infiltrates and/or detrusor mastocytosis and/or granulation tissue and/or intrafascicular fibrosis

2. BPS WITH CO-EXISTING FUNCTIONAL SOMATIC SYNDROMES

A review of eleven studies has suggested that in a subgroup of patients, IC/BPS may be one manifestation of a more systemic functional somatic syndrome (FSS) (415). The prevalence of co-existing functional somatic syndromes (e.g. fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome, temporomandibular disorder, migraine) is higher in non-Hunner lesion patients compared to those with Hunner lesions or asymptomatic controls, and the presence of multiple FSS are a risk factor for the development of IC/BPS (416,417) . IC/BPS with co-existing FSS is therefore likely to represent another distinct phenotype, but whether these patients will benefit from therapies that are useful in FSS remains to be studied.

3. INPUT

Recently, a novel clinical phenotyping system – INPUT (infection, neurologic/systemic, psychosocial, ulcers and tenderness of muscles)- has been suggested as a tool to enable targeted treatment for all domains simultaneously, where required (418). This system was studied in 239 patients and over 50% of patients reported positive neurological, psychosocial and tenderness domains highlighting the potential diversity of phenotypes of IC/BPS, and the need for multimodality treatment for these patients.

XII. INITIAL CONSERVATIVE TREATMENT AND BIO-PSYCHO-SOCIAL MODEL APPROACH

Complementary therapies for bladder pain syndrome have been shown to be beneficial, though larger, more rigorous placebo-controlled trials are sorely needed. A recent systematic review highlights dietary manipulation and physical therapy as useful modalities and suggests that acupuncture and relaxation therapies might also have a role, but the data for the latter two is somewhat lacking (419). Many patients seem to respond to a variety of complementary and alternative medical options, and they form a basic pillar of treatment and serve to empower patients (420,421) . A bio-psycho-social approach may improve outcomes of conservative management.

1. EDUCATION

Patient education is in the first line management of virtually all treatment algorithms. All guidelines recommend patient education regarding normal bladder function, the chronic nature of IC/BPS, and promoting realistic expectations for management. Patient education about normal bladder function, what is known about IC/BPS, currently available treatment options, and the likely need for trial of multiple therapeutic options and multimodal therapy is important.

Internet education and short message service texting were found to be effective in improving quality of life and disease self- management (422). Health interventions have utilized mobile technology in a variety of ways to increase health knowledge, promote health education, and change health behaviors (423,424) .

3. BEHAVIORAL MODIFICATION

Behavior modification includes many aspects of modification of lifestyle and is important in the management of IC/BPS.

Behavioral therapy for IC/BPS can include education, timed voiding (scheduled voiding time and interval), and controlled fluid intake to avoid a very concentrated urine but not drink so much as to exacerbate urinary frequency. Participants in both arms of a large NIH funded randomized placebo-controlled trial evaluating amitriptyline in IC/BPS (425) received a standardized education and behavioral modification program (EBMP). Adherence to the EBMP at 6 weeks was assessed in 4 categories of (A) Symptom management ; (B) Fluid management; (C) Diet modification ; (D) bladder training. For each of these EBMP categories adherence was defined as the overall percentage of participants who reported adhering to each component of the EBMP at each telephone contact or clinic visit.

For the 241 subjects evaluable for EBMP adherence, the rate at 6 weeks was 75% for symptom management, 83% for fluid management, 82% for diet modification and 71% for bladder training. The overall Global Assessment Response rate was approximately 57% for adherers in any of the 4 EBMP categories, whereas it was lower for non-adherers. This rate neared statistical significance for diet modification, which demonstrated only a 41% response

rate among non-adherers (p = 0.051).

Recommendation
Behavioral therapy should be a cornerstone of treatment for patients with BPS.

Level of evidence: 2 Grade of recommendation: B.

4. PHYSICAL THERAPY

Pelvic floor physical therapy with myofascial trigger point release and Thiele massage can be successful in both men and women with chronic pelvic pain and can be self-administered after a period of training (426).

All the studies observed improvement in PFM contraction using various methods, but none were superior over the others. The studies revealed no adverse effects of the interventions used. Patient preferences should be taken into account in clinical decision-making. More studies of high methodological quality on this topic are needed (427).

The vast majority of patients with IC/BPS (non Hunner lesion) need management of their pelvic floor muscles as the primary therapy, complemented by bladder-directed therapies as needed as well as a multidisciplinary team to manage a variety of other regional/systemic symptoms (23).

Physical therapy methods are widely used among patients with chronic pelvic pain and are regarded as particularly helpful. Trigger point therapy shows some promising approaches. Physiotherapy should not be the only treatment in these patients, but rather a component of a multidisciplinary treatment regime with accompanying psychosocial therapy approaches. In accordance with the recommendations for multidisciplinary management of chronic pelvic pain , future studies should consider integration of physical and psychosocial therapy modalities in one treatment regime (3).

Biofeedback and soft tissue massage may stimulate the relaxation of the pelvic floor muscles Trans-vaginal Theile massage was also reported to be effective for 9 of 10 patients of the same group (428).

An NIH study (429) to determine the feasibility of conducting a randomized clinical trial was undertaken to compare 2 methods of manual therapy (myofascial physical therapy and global therapeutic massage) in patients with urological chronic pelvic pain syndromes. The global response assessment response rate was 57% in the myofascial physical therapy group compared to 21% in the global therapeutic massage treatment group. This statistically significant difference (P=0.03) was primarily driven by the response seen in women (24 women) compared to the men (24 men) enrolled in this small pilot study. A follow-up randomized trial comparing similar treatments but only in women with IC/BPS and demonstrable pelvic floor pathology showed a clear benefit of directed myofascial physical therapy. In the myofascial physical therapy group, 59% of IC/BPS women had a positive Global Response compared to 26% of IC/BPS women who were randomized to the global therapeutic massage group (p=0.0012) (430).

Recommendation
Physical therapy of selected and motivated patients with IC/BPS, particularly those with demonstrable pelvic floor dysfunction, is indicated.

Level of evidence: 1. Grade of recommendation: A

5. STRESS REDUCTION

It is long been observed that mental stress is one of the factors which aggravate the symptoms of IC/BPS. Rothrock et al (431) reported that when comparing patients with IC/BPS and healthy people, increased pain and urgency caused by stress were observed only in patients with IC/BPS.

Case-cohort studies have confirmed that patients diagnosed with IC/BPS experience considerably more stress than patients without the condition (432).

Stress was shown to correlate with both the severity of symptoms and quality of life. In another study of patients with IC/BPS identified in urology tertiary care clinic populations (433), mental health disorders were identified in 23 % of IC/BPS female cases compared to 3% of female control subjects. Medications for anxiety, depression or stress were taken by 37% of patients with IC/BPS compared to 13% of female controls.

Mindfulness based stress reduction has been shown to be effective in a small randomized controlled trial (434). World-wide patient support groups, including the Interstitial Cystitis Association (ICA) (435), the International Painful Bladder Foundation, and the Interstitial Cystitis Network, are important sources of information for patients with IC/BPS. Patients with IC/BPS frequently suffer depression, which may negatively impact upon the quality of life (432) and perhaps symptoms.

Recommendation
Stress and depression are related to poorer quality of life and increase in severity of symptoms.

Level of evidence: 1 Grade of recommendation: A
Reduction of stress and depression may contribute to an overall improvement in quality of life and perhaps even symptoms

Level of evidence: 4 Grade of recommendation: C

6. DIETARY MANIPULATION

The understanding of the mechanisms by which diet affects IC/BPS is limited; however, there are common bothersome foods and beverages (**Figure 16**), as well as individual variations that elicit flares (436,437) .

Acidic beverages, coffee, spicy food, and alcohol may aggravate the symptoms of most patients with IC/BPS (438,439) . However, this has proven difficult to prove and Nguan et al (440) reported that there was no statistically significant difference in pain and other symptoms, when they evaluated the influence of the changes in urinary pH on the symptoms of 26 patients with IC/BPS by instilling pH5.0 and pH7.5 saline solutions into the bladder. One of the best studies designed to determine the effect of particular foods, beverages and/or supplements (comestibles) on IC/BPS symptoms was undertaken by Shorter et al (441). One hundred and four patients with IC/BPS were asked to indicate on a validated questionnaire whether each of 175 individual items worsened, improved or had no effect on symptoms. Of the patients surveyed, 90% indicated that the consumption of certain foods or beverages caused symptom exacerbation. The comestible items that had the most effect were caffeinated, carbonated and alcoholic beverages, certain fruits, artificial sweeteners and spicy foods.

Foods/beverages identified as most bothersome to patients with IC/BPS	Foods/beverages identified as least bothersome to patients with IC/BPS
Coffee (caffeinated)	Water
Coffee (decaffeinated)	Milk, low-fat
Tea (caffeinated)	Milk, whole
Cola carbonated beverage	
Non-cola carbonated beverage	Bananas
Diet carbonated beverage	Blueberries
Caffeine-free carbonated beverage	Honeydew melon
Beer	Pears
Red Wine	Raisins
White Wine	Watermelon
Champagne	
	Broccoli
Grapefruit	Brussels Sprouts
Lemon	Cabbage
Orange	Carrots
Pineapple	Cauliflower
Cranberry juice	Celery
Grapefruit juice	Cucumber
Orange juice	Mushrooms
Pineapple juice	Peas
	Radishes
Tomato	Squash
Tomato products	Zucchini
Hot peppers	White potatoes
Spicy foods	Sweet potatoes/yams
Chili	
Horseradish	Chicken
Vinegar	Eggs
Monosodium glutamate	Turkey
	Beef
NutraSweet	Pork
Sweet'N Low	Lamb
Equal (sweetner)	Shrimp
Saccharin	Tuna fish
	Salmon
Mexican food	
Thai food	Oat
Indian food	Rice
	Pretzels
	Popcorn

Figure 16. Experience with specific foods and beverages reported by patients with IC/BPS. Gordon B, Shorter B, Sarcona A, Moldwin RM. Nutritional considerations for patients with interstitial cystitis/bladder pain syndrome. J Acad Nutr Diet 2015, Sep;115(9):1372-9.

Dietary manipulation was ranked in the top five frequently used treatments in a cohort study of the Interstitial Cystitis Data Base (ICDB) (442). As the influence of diet is variable with regard to food, beverage, and patient, there is no reason for patients to be uniformly on a strict diet. It is advised that each patient experiment to find out the foods that tend to aggravate their symptoms and avoid them. The ICA home page, (http://www.ichelp.org/) introduces the foods often avoided by patients with IC/BPS. The use of an elimination diet (eliminate all foods on the list) and then gradually reintroducing them one by one, will facilitate the development of a patient directed individualized diet strategy. In some cases when diet appears to play a major role in symptoms, a registered dietician nutritionist can become a critical part of the treatment team. Gordon et. al. comprehensive review of dietary issues is worth reading and provides a helpful handout for patients (436).

Recommendation
Personalized dietary manipulation should be part of the therapeutic strategy for patients with IC/BPS.

Level of evidence: 2 Grade of recommendation: B

7. BIO-PSYCHO-SOCIAL MODEL

The psychological impact of IC/BPS can be pervasive and severe (443,444) . The demographic findings suggest that the early stages of illness are a particularly vulnerable period (445,446) . Early access to psychological intervention may interrupt the development of these conditions. Untreated psychosocial factors worsen symptom presentation and prognosis.

The review by Grundy et al. highlights that higher psychological stress levels, increased prevalence of anxiety and depression, and clinical co-morbidities with other visceral pain disorders suggest that pathological plasticity within the CNS is an important component in the mechanisms underlying IC/BPS (15).

It is widely accepted that psychosocial factors play a substantial role in IC/BPS (447,448) . IC/BPS may be understood as a biopsychosocial disorder, whereby biological (physiological), psychological, and social factors interact to produce the symptoms experienced in IC/BPS (449-451) .

A recent systematic review indicated that psychosocial comorbidity is significantly elevated in those with IC/BPS (3). Individuals with increased symptom severity, psychosocial impact, and worse QoL are directed to receive additional psychological support such as cognitive behavioral therapy or counseling (452-454) .

There has been a shortage of psychosocial intervention studies. These have included a mindfulness-based stress reduction course (434), an online video-education system (424) , and a 90-min interview aimed at facilitating the link between stress, emotional conflict, and symptoms, and encouraging emotional expression (455). Kanter et al. identified three emergent patient experience concepts; debilitating effects; unpredictable and unrelenting disease course; significant isolation. Patients voiced strong preference for physicians who provided 1) education regarding the condition; 2) an array of treatment options; 3) organized treatment plans; 4) optimism and hope regarding treatment outcomes (456).

The role of healthcare practitioners is fundamental to informing patient perceptions of their illness and providing adequate support for their own self -management approaches (457). The ultimate goal of caring the patients is improving patients' quality of life. The goal is enhanced by a variety of approaches. These include focusing on the biological organ, proper phenotyping, focusing on comorbid conditions, and focusing on accompanying psychological problems. Education plays a major role as does group support and introduction of an electronic health system approach which facilitates self-management. The Taiwan Interstitial Cystitis Association and E-health system provides such an approach.

The MAPP Network study is the first to directly assess a large cohort of male and female patients with urologic chronic pelvic pain syndromes (UCPPS) using a broad range of psychosocial variables (458). Participants with UCPPS reported more psychosocial difficulties, including higher levels of current and lifetime stress, poorer coping and more self- reported cognitive deficits, than healthy control individuals matched for age and sex who did not have pain (229). However, the level of psychosocial problems was not solely attributed to the severity of UCPPS symptoms, suggesting that a reduction in the symptoms associated with UCPPS alone would be insufficient to produce clinically significant improvements in quality of life for some patients. It's not surprising that the presence of nonurological chronic overlapping pain conditions (fibromyalgia, IBS and/or CFS) in the UCPPS cohort was associated with higher rates of depression and anxiety, as well as greater UCPPS symptom severity (459). Several psychological variables —such as catastrophizing, a lowered sense of mental and, particularly, physical well- being, and the presence of life stressors — were associated with a low probability of symptom improvement over a 12-month period (460).

Many clinicians (and patients) assume that once symptoms improve, quality of life will similarly improve. MAPP Network findings have demonstrated that this assumption might not be the case if the patient has substantial coexisting psychosocial comorbidities or severe non-urological pain (459,460) . Furthermore, psychosocial dysfunction (that is, depression, anxiety or catastrophizing) was more commonly identified and was associated with more severe UCPPS symptoms and poorer outcomes in patients with comorbid nonurological symptoms than in those without such comorbidities. Thus, greater emphasis should be placed on the early identification and treatment of nonurological symptoms and psychosocial dysfunction as separate and exacerbating clinical factors in UCPPS.

The extent to which psychosocial factors play a role in IC/BPS is controversial and by no means universally accepted. Depression, anxiety, catastrophizing may be primarily consequences of the symptomatology rather that related to causation, and it may be more productive in the long run to see them in this perspective. Otherwise it can appear that the patient is responsible for their symptoms and response (or lack thereof) to therapy.

XIII. ORAL THERAPY

Oral medications have been a mainstay of the treatment of IC/BPS and a variety of drugs have been used for this purpose. Unfortunately, the evidence for the use of many of these drugs is rather poor. There is a lack of randomized placebo-controlled trials and most of the studies are heterogenous and not comparable. Management of pain remains a crucial focus and the recognition, translation and classification of pain symptoms is of high importance to enable proper selection among the plethora of analgesics.

1. PAIN MANAGEMENT AND ANALGESICS

1.1. Evaluation of pain

Management of patients with IC/BPS symptoms needs a multidisciplinary approach and any physician dealing with this difficult disease has to be familiar with the idea that collaboration with other specialties is highly advantageous. Additionally, patients with IC/BPS generally seek urologic care not only for the lower urinary tract symptoms, but also for the associated pain. In any case, they deserve pain relief. Pain severity can be assessed through the following steps:

- evaluation of pain severity
- medical history, also focused on pain characteristics
- physical/ neurological examination
- investigation of pain origin
- regular monitoring

An easy and widely used pain evaluating tool is **PQRST**:

P: Palliative or Provocative factors

Ask patients if there is something that makes pain less or more intense

Q: Quality
Ask patients what the pain looks like

R: Radiation
Ask patients if pain spreads in anywhere else

S: Severity
Ask patients to evaluate pain severity

T: Temporal
Ask patients is pain is permanent or it comes and goes

1.2. Pain measurement

The description of pain among patients is a difficult issue, as it is a subjective feeling and even measurement scales are heterogeneous and usually not comparable. The use of more than one of clinical scales in each for pain evaluation could be useful, but actually tailoring pain measurement seems to be more realistic. Some of the most commonly used pain evaluation tools include:

- verbal rating scales: patients categorize pain as mild, moderate or severe
- Visual analogue (VAS), Likert or Numerical Rating scale (NRS)
- Brief Pain Inventory (BPI), McGill Pain Questionnaire (461-463)

Urologists are usually not familiar with BPI and McGill's questionnaire, which are rather complicated, using several types of visual analogue scales grouped together and finally assessing pain. In these cases, a multidisciplinary approach may be useful.

1.3. Pharmacologic Management

Urologists using pharmacologic agents to control pain among patients with IC/BPS need to become familiar with a wide variety of analgesics. Some analgesics may not be commonly prescribed by urologists, and some require close monitoring. Adequate knowledge of pharmacokinetics as well as the assessment of beneficial versus harmful effects are necessary for management of pain in patients with IC/BPS.

The use of analgesics for the treatment of IC/BPS includes a great variety of drugs which can be used for varying durations, with several dosage schemes and different mechanisms of action. Some of them target local inflammation and others target the central nervous system. It is also critical to examine the limited role of opioids in a chronic disorder like IC/BPS in order to achieve therapeutic control and avoid toxic and addictive effects.

1.3.1. Acetaminophen

This is very little evidence for a possible use in chronic pain syndromes, like IC/BPS. It can be administered in patients with mild pain and with caution for hepatotoxicity (464-466) .

1.3.2. Nonsteroidal anti-inflammatory drugs (NSAIDs)

Nonsteroidal anti-inflammatory drugs are often given to patients with symptoms of IC/BPS. This is largely a symptomatic treatment and has the disadvantage of serious systemic adverse events after prolonged usage (467). NSAIDs are known to act on the cyclooxygenase (COX) enzyme, either as COX1 inhibitors or more selective COX2 ones. Blocking COX1 enzyme may be followed by the platelet, gastric and renal complications, while blocking the COX2 may lead to congestive cardiac failure, especially in patients with increased risk of cardiovascular disease. Both COX inhibitors seem to have equal effectiveness on pain, with the COX2 ones more useful in the acute phase. Evidence supporting the beneficial action of NSAIDs in IC/BPS is rather low, with superiority versus placebo and acetaminophen (468-470) .

Lower potency drugs, like ibuprofen, should be used as a first step and mainly in cases with mild pain. More potent agents, like diclofenac, can be a second step or for patients with more severe pain. COX2 selective NSAIDs should be regarded as of high potency and reserved for special cases, especially when the administration of non-selective drugs carries a high risk of serious adverse events.

Regardless which NSAID is selected, the possible benefit versus the respective harm must be evaluated before initiating treatment, keeping in mind the specific medical history of each patient.

1.3.3. Neuropathic analgesics

Gabapentin is a representative of the analgesic category of anticonvulsants with a mainly central action and a known effectiveness on neuropathic pain including diabetic neuropathy (471) and postherpetic neuralgia (472). There have been some small trials with patients with IC/BPS symptoms. As part of a combination treatment with amitriptyline and the NSAID etodolac, gabapentin has been suggested to be effective for patients with IC/BPS, but its individual efficacy wan not evaluated (473). Another study suggests a synergic action of gabapentin with morphine (474). In an animal model of IC/BPS gabapentin was able to reduce bladder hypersensitivity (475).

Pregabalin is another anticonvulsant representative with a similar action to gabapentin in neuropathic pain. It has also shown an ability to reduce bladder hypersensitity in IC animal models (476). Its effectiveness for treating pain associated with fibromyalgia has aroused a great interest, as it could be also effective in those patients with pain due to IC/BPS and concomitant fibromyalgia (477). Ketamine is an N-methyl-D-aspartate (NMDA) antagonist, acting also in opioid receptors. The effectiveness of ketamine in neuropathic pain has already been proven, including patients with chronic pelvic pain. Nevertheless, it is a potentially addictive agent with numerous possible serious adverse events including the possibility of inducing severe bladder inflammation that can mimic the most severe cases of interstitial cystitis (478-480) .

1.3.4. Opioids

Opioids can be a quite effective analgesic choice but are usually one of the last choices for pain treatment, not only for patients with IC/BPS, but also in any kind of chronic non-malignant pain syndrome (481). Patients may be guided to the opioids when other therapies and options seem to be inadequate. The potential for addiction in the long-term administration of opioids for nonmalignant pain is high, although the actual risk is controversial (482,483) . The marketing of oxycodone hydrochloride by Purdue Pharma left a legacy of misinformation among physicians and the public (484). With regard to narcotic use, the role of multidisciplinary medicine is important, as urologists need to collaborate with other specialties for a tailored therapy and a more effective monitoring. The most common side effects of the use of opioids are sedation, nausea, mild confusion, pruritis and constipation, while respiratory depression is rare. The long-acting formulations of opioids, as well as their co-administration with NSAIDS, cyclooxygenase inhibitors, acetaminophen, and tricyclic antidepressants, seems to be more effective (485). Since 2004, the European Association of Urologists has included opioids in the treatment of pelvic pains syndromes and IC/BPS specifically (58). The guidelines in this case are quite tailored and confirm that the use of opioids must be with a high level of consciousness regarding risks. Certainly, opioids should not be a first-line therapy for IC/BPS. Additionally, the multidisciplinary approach and dose titration are recommended, while the psychiatric profile of each patient must be evaluated. Patients must, also, be fully informed about the serious and non-serious adverse events of this therapy and need to sign an informed consent and treatment

contract before the initiation of this therapeutic scheme, knowing that there is not much evidence, supporting that one opiate is better than another. Only one provider should be authorized to treat any patient with opioids.

Morphine is a first-line opioid in the treatment of non-malignant neuropathic pain, including IC/BPS, used when other analgesic alternatives and direct disease treatment has failed. Starting with the lowest effective dose is important. An alternative use of fentanyl patches could be beneficial, especially for those patients who cannot receive an oral treatment, but dose titration is more difficult (486,487) .

Methadone is another opioid with a strong analgesic action, but its usefulness in IC/BPS could not be supported adequately (488). Similarly, meperidine has been found to be equal to morphine when administered intramuscularly, but with a poor recommendation in its oral formulation (489).

Some opioids are available in a slow or modified release preparations. Oxycodone, hydromorphone, and hydrocodone are representatives of this class of opioids, and they are useful in cases where tolerance remains a problem. Although they seem to be more safely administered, they need to be so closely monitored as morphine (490).

Codeine and tramadol are quite useful for mild and moderate pain, as they are regarded as opioids of less potency. However, the additional serotoninergic and adrenergic activity of tramadol, along with less addiction and fewer side effects compared to morphine, should be considered when looking for an effective alternative in patients with refractory pain. Optimal dose is not reliably established (491).

The committee believes that chronic opioids are best considered mainly in patients who do not respond to nonopioid analgesics and have not responded to standard therapies as outlined in the treatment algorithm at the end of this chapter. When their use is being considered, it is best to engage a pain management expert and move this portion of care to a pain clinic that will be responsible for all prescribed analgesics and can institute a pain contract with the patient so that one provider will have knowledge of all prescribed opioid and nonopioid analgesics. All patients and their families should be educated on the use of rescue medication in the event of accidental overdose and have such medications available (492,493) .

General recommendation for pain management

Patients with IC/BPS usually complain about their pain symptoms in addition to their voiding dysfunction, and thus, need to be treated for pain not only by urologists but in a multidisciplinary way. Evidence suggests a surfeit of analgesic agents as suitable for IC/BPS pain therapy, with a variety of potency and grades of recommendation. It has to be obvious that treating pain in IC/BPS patients may be complex and needs a detailed consultation. Also, initiating pain treatment with simple analgesics and low doses of the drugs could be more beneficial, while close monitoring is the gold standard to avoid serious adverse events in patients with long term analgesic treatment, especially with opioids. Figure 17 presents an algorithm for analgesic use.

Level of Evidence: 4 Grade of Recommendation: C

2. ANTIDEPRESSANTS

2.1. Amitriptyline

Amitriptyline is a tricyclic antidepressant which that blocks H1-histaminergic receptors, while stabilizing mast cells and inhibiting mediator stimulated vascular leakage. Its ability to reduce pain in

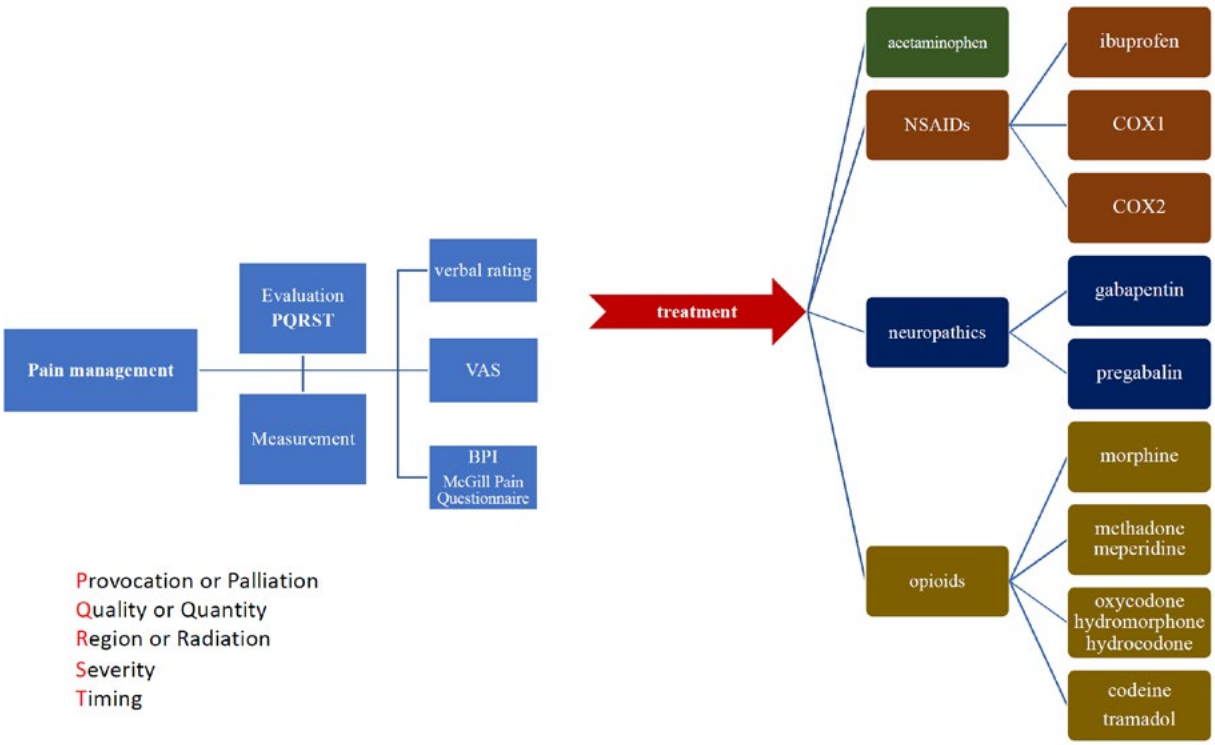

Figure 17. Analgesic options for treatment of IC/BPS and HLD

IC/BPS patients is based on the inhibition of the pain signal from the bladder to the respective level of the central nervous system. Amitriptyline may also have a beta-adrenergic stimulative action, enhancing bladder urine storage (494).
In the study of Hanno and Wein, the 75mg dose of amitriptyline proved to be quite effective in the most patients who could tolerate the drug. Almost one-third of the patients could not tolerate the drug at the 75mg dose because of sedation. Eighteen of 28 patients who could tolerate the drug had major relief of symptoms within 3 to 6 weeks of onset of therapy with a mean follow-up of 14.4 months (495).
In a prospective, double-blind, placebo-controlled study of amitriptyline, fifty patients were randomized to placebo or a titrated dose of amitriptyline up to 100mg daily. After a follow-up of 4 months, there had been a 30% improvement in symptoms of the amitriptyline group in comparison to 13% in the control group (496). Studies with longer monitoring have, also, shown an improvement in symptom scores in up to 64% of patients who could tolerate the side effects of the treatment (497).
In a large multicenter, randomized, double-blind, placebo controlled clinical trial of amitriptyline in IC/BPS treatment naïve patients, the benefit of amitriptyline plus behavioural modification was compared to that of behavioral treatment alone. Hence, both placebo and amitriptyline patients had been advised on an education and behavioral modification program. A dose of at least 50mg of amitriptyline was significantly more effective in this select group of patients compared to placebo. However, there was no significant difference when comparing the effectiveness of amitriptyline plus behavioral treatment with education and behavioral modification program alone looking at an intent to treat population (498) largely due to the sedation side effect of amitriptyline and the significant improvement with behavioural modification in the treatment naïve population. Despite the lack of comparable randomized control trials and meta-analyses, amitriptyline remains the drug whose exclusive efficacy for IC/BPS has been proven better than any other oral therapy.

Level of Evidence: 2 Grade of Recommendation: B

2.2. Other antidepressants

There are several studies investigating the efficacy of drugs like doxepin, desipramine and duloxetine in IC/BPS symptoms. Their overall therapeutic benefits are rather poor (499-501) .

2.3. ANTIHISTAMINES

The well-evidenced role of mast cells in the pathophysiology of IC/BPS could provide a possible targeted oral treatment with antihistamines. Actually, the sixty-year-old studies of Simmons using pyribenzamine showed some clinical improvement in IC/BPS patients, although in a short follow-up (502,503) .
Further uncontrolled studies on antihistamines included hydroxyzine, a H-1 receptor antagonist, which could be regarded as the most used antihistamine for IC/BPS patients. Some research has suggested hydroxyzine as an effective treatment, but the NIDDK randomized controlled trial demonstrated no significant statistical benefit when compared to placebo (504-506) .
The H-2 histamine receptor antagonist, cimetidine, has also been investigated as a possible oral treatment for IC/BPS. A wide variety of results and effectiveness has been described from a total relief of pain and symptoms in some studies to a significant reduction in some others. The rate of symptom remission varies as well. A prospective, placebo controlled RCT with 36 patients who received oral cimetidine or placebo showed clinical efficacy, but the statistical analysis inside and between groups was rather unclear (507). Despite being widely available and relatively inexpensive, it is not commonly used in this condition.

Level of Evidence: 3 Grade of Recommendation: C

3. IMMUNOSUPPRESSANTS

3.1. Cyclosporine

Cyclosporine is an immunosuppressant most used for patients with transplanted organs. The application of this drug for patients with IC/BPS was initially investigated in a Finnish clinical trial, in which the bladder capacity improved and pain reduced in most of the enrolled patients. The preferred dosage of cyclosporine in this study was 2.5-5 mg/kg daily for 3-6 months with a maintenance dose of 1.5 to 3mg/kg daily. Symptoms reoccurred when the drug was stopped (508).
The results of this clinical trial have been supported by a more recent one with a longer follow-up up to 60.8 months. The authors reported that the vast majority of IC/BPS patients treated with cyclosporine had a total relief of pain, while those who stopped therapy had a remission of the symptoms. Those who resumed treatment showed again a significant respond. Apart from pain, bladder capacity doubled throughout the monitoring (509).
In a more recent American study, cyclosporine was shown to be effective primarily in patients with Hunner lesion disease with a 75% response rate (510).
Compared to sodium pentosan polysulfate, cyclosporine has been shown superior in all clinical parameters after a follow-up of 6 months, while, in a basic research study, patients treated with cyclosporine had lower urinary levels of epidermal growth factor (511,512) . Separating those patients with IC/BPS with a Hunner-lesion from those without, cyclosporine seemed to be primarily effective in those with HLD (513).
The effectiveness of cyclosporine in HLD patients is undeniable, but this immunosuppressant needs to be closely monitored because of its common adverse events on renal function and blood pressure as well as a rare risk of malignancy. Drug level and toxicity monitoring with special attention to renal function and blood pressure should be done at least every 3 months, and more often on initiation of therapy. Drug level monitoring may allow dose reduction to minimize risk of side effects.

Level of Evidence: 2 Grade of Recommendation: C

3.2. Other immunosuppressants

Investigation on the effect of immunosuppression on IC/BPS has suggested other drugs apart from cyclosporine, without evidence of efficacy.
Suplatast Tosilate (IPD-1151T), an immune regulator interfering with the cytokine cascade affecting the production of IL-4 and 5, has been studied related to its its anti-allergic activity with regard to asthma, atopic dermatitis and rhinitis. Despite encouraging results in the study of Ueda et al (514), subsequent trials in USA and Japan, did not show the expected benefits and further clinical trials have not been planned (515).

Level of evidence 1: Not recommended

Corticosteroids, like prednisone, have been used mainly in refractory IC/BPS patients with mixed responses, either positive or discouraging. Actually, side effects following the long-term use of this treatment remain a significant handicap (516-519). Azathioprine and chloroquine derivatives have been, also, described in an old study with a moderate response among patients with refractory IC/BPS (520).

Level of Evidence: 4 Not recommended

3.3. Adalimumab

The role of cytokine in the development of IC/BPS has already been discussed and remains a challenge for novel treatment methods. Adalimumab is a Tumor Necrosis Factor-α (TNF-α) (a pro-inflammatory cytokine) inhibitor. It is used to treat rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, Crohn's disease, ulcerative colitis, psoriasis, hidradenitis suppurativa, uveitis, and juvenile idiopathic arthritis. Efficacy for IC/BPS proved to be no better than placebo in a study where this drug had been administered subcutaneously for 12 weeks. The significant changes in symptom scores were finally attributed to the placebo effect (521).

Level of Evidence: 1. Not recommended

4. SODIUM PENTOSAN POLYSULFATE

The role of the glycosaminoglycan (GAG) layer in the control of permeability of the urothelium is known to be important and has already been discussed in the section of IC/BPS etiology. The protection or the enhancement of the integrity of the GAG layer is theoretically important in order keep the urothelium impermeable to urinarycomponents. This is the main target of sodium pentosan polysulfate (PPS), a synthetic sulfated polysaccharide available in oral formulation which is excreted into the urine and may replenish the damaged GAG layer. PPS is the most investigated treatment for IC/BPS and the only oral drug approved by the American Food and Drug Administration (FDA) for the pain of IC/BPS.

In addition to the activity on the damaged GAG layer, PPS had an antihistaminic action through its feedback with mast cells and a possible anti-inflammatory mechanism of action through binding of molecules that can act as inflammatory stimulants in the urine (522,523) .

In the study of Parsons, 200mg or 300mg of PPS were daily given to patients with IC/BPS in equally separated doses 4 times or twice respectively. After 8 weeks of monitoring, over 90% of patients experienced a remarkable relief (524). In another randomized, placebo-controlled trial using a dose of100mg three times daily PPS was found to be effective in pain and urgency compared to placebo (525).

Further investigation on PPS includes RCTs with rather ambiguous and conflicting results. In an early, large multicenter, placebo controlled RCT 200mg of PPS twice daily for 4 months had no efficacy compared to placebo (526).

In the first pivotal study for FDA approval, 100mg of PPS three times per day for three months showed a slight improvement in the global response assessment in 28% versus 13% in the placebo group (527). FDA requested a second clinical trial. In this second RCT with the same dosage scheme and duration, controlled again by placebo, patient self-evaluation showed a global improvement of 32% of those on PPS, reporting 50% or more overall improvement. In the placebo group the respective rate was only 16%. The drug was approved by FDA for the pain of interstitial cystitis, as the parameters of frequency, nocturia and voided volume had not been significantly affected (528).

A National Institutes of Health study included comparison of six months of treatment with PPS with and without hydroxyzine versus placebo. No significant difference among groups was found (506). When PPS-only groups were explored and compared to placebo, results were similar to those with the above studies for FDA (529) . FDA mandated two phase four trials given questions about the drug's efficacy. The first was a 32 week dose-response trial with cohorts receiving 300mg daily, 600mg daily, and 900mg daily. While side effects increased with dose, efficacy did not (530). The second trial had cohorts receiving 300mg vs. 100mg vs placebo for 24 weeks. The study was halted because interim results did not demonstrate a treatement-effect vs placebo at any dose (529).

Until recently it was thought that despite questionable efficacy, PPS was a safe and well-tolerated medication (531). Long-term benefit was seen in 6-17% of patients (532). However recent reports have noted that pigmentary maculopathy, a vision threatening condition, can result from long-term exposure to the drug (533-537). FDA has placed a black box warning on the label. Patients on this drug need regular ophthalmology follow up.

Level of Evidence: 1 Grade of Recommendation: D

5. OTHER ORAL MEDICATIONS

5.1. Quercetin

Quercetin is an over-the-counter bioflavenoid with anti-inflammatory effects and has been investigated as a possible therapy for patients with IC/BPS. The administration of 500mg twice daily for two weeks had favorable affect in the symptoms of almost all patients, but there has been no further evidence to support those results (538).

Level of Evidence: 4 Grade of Recommendation: D

5.2. Antibiotics

While one empiric trial of an antibiotic can be justified in patients presenting initially with IC/BPS symptoms (539), there is no evidence that even intensive antibiotic therapy should play a role in the treatment of this disease. Infection, if discovered, should be regarded as a confusable disease and treated appropriately. In the absence of culture documented infection, antibiotics have no place in therapy (540). This issue is different from the consideration of infection as a possible initiating event in the etiology of the development of persistent symptoms.

Level of Evidence: 2 Grade of Recommendation: not recommended

5.3. Sildenafil

An interesting way of coping with IC/BPS symptoms could be the relaxation of bladder detrusor. The role of the phosphodiesterase type 5 inhibitors (PDE5Is) has been explored. In a small placebo controlled RCT, 25mg sildenafil daily was compared to placebo for 3 months in women with IC/BPS. Patients were closely monitored and evaluated with O'Leary-Sant IC symptom and problem indices, visual analog scale scores and a bladder diary. Urodynamic parameters were also monitored. Treatment effectiveness was regarded as significant when the documented improvement exceeded 50%. Sildenafil was found to be significantly more effective compared to placebo. Sildenafil was also well tolerated among patients in this study (541).

The high PDE5 expression in human bladder detrusor muscle could stimulate more investigation for PDE5Is and a possible proof of efficacy would not be a surprise.

Level of Evidence: 2 Grade of Recommendation: D

6. ORAL THERAPY IN CLINICAL TRIALS

6.1. Tanezumab

The inhibition of nerve growth factor as a treatment against pain in IC/BPS patients could be a promising means of therapy. Hence, the use of tanezumab, a humanized monoclinic antibody with a specific activity in inhibition of nerve growth factor has been investigated in a placebo controlled RCT, showing encouraging improvement on pain symptoms compared to placebo, after 6 weeks of administration. Moreover, tanezumab was found to be significantly effective even in frequency and urgency against placebo treatment (542).

Pooled analyses deriving data from three small clinical trials, included patients with CP/CPPS and IC/BPS exploring the population with the best response to the treatment with tanezumab. Statistical analysis has shown a statistical difference only in the reduction of pain in the group of women with IC/BPS, compared to placebo. Confirmation of this activity could establish tanezumab as a potent medication against pain in patients with IC/BPS (109).

The occurrence of osteonecrosis and central nervous system side effects resulted in the temporary cessation of the research for tanezumab for pain. However, further data evaluated by FDA have prompted a restart of some studies.

6.2. Certolizumab pegol

Agents inhibiting the action of TNFa on the immune system might also be beneficial for IC/BPS. Certolizumab pegol has been used to treat Crohn's disease, rheumatoid arthritis, psoriatic arthritis and ankylosing spondylitis. It is a fragment of a monoclonal antibody specific to tumor necrosis factor alpha. In an 18-week randomized, double-blind, placebo-controlled trial, certolizumab pegol was found to be effective in pain endpoints compared to placebo (543).

7. THE ROLE OF CANABBINOIDS

7.1. Beta-caryophyllene

The endogenous cannabinoid system (ECS) is involved in a variety of physiological processes including metabolism, pain-sensation, neurotransmission and inflammation. The effects of the ECS are mediated by two cannabinoid receptors; cannabinoid receptor 1 (CB1R) and 2 (CB2R) and the most common endocannabinoids, are N-arachidonylethanolamine or anandamide (AEA) and 2-arachidonoylglycerol (2-AG). Both of them have higher affinity to CB1R, while 2-AG to show a high affinity to CB2R, as well. Beta-caryophyllene (BCP) is a constituent of clove oil and has been found in cannabis. It has been reported to act as a CB2R agonist and it could be worthy of investigation as a treatment for IC/BPS. In a mice model, orally administered BCP significantly reduced the number of adherent leukocytes in submucosal venules and additionally, oral BCP was shown to provide analgesia for IC/BPS-induced pain. Intravesical route of treatment has, also, shown encouraging results (544).

7.2. Palmitoylethanolamide

A congener of the endocannabinoid AEA, palmitoylethanolamide (PEA) has been studied in several models for treating symptoms in patients with pelvic inflammation, including IC/BPS. PEA has been used in micronized (m-) and ultra-micronized (um) formulations and the m-PEA products have been found to be effective in patients with IC/BPS after six months of follow-up in open label studies (545,546) .

	Sildenafil	2	D
	L-Arginine	2	Not recommended
	Adalimumab	2	Not recommended
Cannabinoids	Palmitoylethanolamide	2	D

The ECS represents a pharmacological target for the treatment of IC/BPS. However, current evidence a suggest a high caution of the systemic administration of cannabinoids and a close monitoring of the possible side effects, including cardiovascular dysfunction, digestion failure and psycho-activity.

Level of Evidence: 2 Grade of Recommendation: D

8. CONCLUSION

One can sympathize with the conclusions of the Cochrane Database when reviewing this oral treatment section of the current chapter. “We are uncertain whether some treatments may be effective in treating patients with BPS because the certainty of evidence was generally low or very low. Data were available for a relatively large number of trials, but most had small sample sizes and effects of treatments often could not be estimated with precision. … Larger, more focused trials are needed to improve the current evidence base.” (547) Nevertheless, patients need help now, and the educated provider can come up with a plan based on the current knowledge base to intelligently treat these patients.

TABLE 8 summarizes the primary oral treatment choices for IC/BPS.

XIV. INTRAVESICAL THERAPY

The urothelium is not just a physical barrier between blood and urine but can express a host of receptors having a functional significance in micturition reflex. The identification of a cannabinoid, nicotinic, neurokinin receptors and potassium ion channels in urothelium have revealed the role of urothelium as an excitable cell layer that responds to stretch and conveys messages to underlying afferents in the bladder. (548) There is also mounting evidence to demonstrate expression of adrenergic, bradykinin, and transient receptor potential (TRP) receptors in urothelium in proximity to afferent nerves. (549,550) Urothelium is the primary nonneuronal source for the release of molecules such as adenosine triphosphate(ATP), acetylcholine, and nitric oxide, which are known to affect micturition. (551)

The data on use of intravesical therapy has been generally poor due to the limited number of controlled accessible studies on intravesical therapies for IC/BPS and non-standardized response criteria. (552,553) This situation is thankfully improving. What follows are treatments that have been reported in the recent literature, some of which are commonly used. Older therapies that are rarely used now include **silver nitrate** (104,554-557) and **chlorpactin WCS90**. (47,558-563) These have not been included in this current edition of the Consultation, but have level 3 evidence to support a grade C recommendation based on original reports. **(Table 9)**

1. DMSO (DIMETHYL SULFOXIDE)

Level of evidence 1, Grade of Recommendation: B

Dimethyl sulfoxide (DMSO) has been used for medical treatment and as a pharmacological agent in humans since the 1960s. It is the only intravesical agent approved for the treatment of intersti-

tial cystitis by the Food and Drug Administration. {GafniKane 2013. DMSO is believed to reduce inflammation, relax muscles, eliminate pain, dissolve collagen, and degranulate mast cells. It has long been used as a therapeutic agent for IC/BPS. Its mechanism of action, however, has not been clarified. Peeker et al reported that in a randomized study, frequency and pain were improved in Hunner lesion patients, although no improvement was observed in maximum bladder capacity. (564) Perez- Marrero et al reported that in a non-randomized controlled study, 53% of the patients showed remarkable improvement in subjective evaluation (placebo 18%), and 93% in objective evaluation (placebo 35%). (565) Around an 80% improvement rate has been reported in case series and retrospective studies. (566-572)

With regard to side effects after instillation of DMSO, most patients recognize a garlic-like odor, which disappears within a day, and about 10% of patients report an irritative symptom flare on initiation of treatment which resolves with or without intervention. (573) It is hypothesized that these transient exacerbations occur as the result of mast cell degranulation.

The number of significant side effects is considered to be small. Cataracts have been reported in animal studies, though not in humans. (574,575) Negative effects on bladder compliance have been noted in rat detrusor. (576) DMSO may accelerate the absorption of other drugs instilled simultaneously, which could be a source of side effects.

The instillation method has not been standardized. Generally, 50cc of a solution of medical grade 50% DMSO is instilled into the bladder. If pain occurs immediately following instillation, local anesthesia (e.g. 20ml of 2% lidocaine solution) may be instilled. Average retention time is considered to be 20 minutes. (573) The instillation is performed weekly for 6-8 weeks. After an initial course, treatment is suspended until symptoms recur. If a good result was obtained, another 6 week course (often followed by monthly maintenance) can be initiated. The long-term effect is unknown, although there is no upper limit for the duration of the treatment.

It is often administered as a cocktail combined with other medications sometimes including a steroid, heparin, sodium bicarbonate, and/or lidocaine. (577,578) The combination of triamcinolone and DMSO has been shown to increase bladder capacity and increase voiding intervals in a large, uncontrolled series of newly diagnosed patients. (579) Tutolo et al, in a prospective RCT reported that while Intravesical chondroïtin sulphate 2% is a viable treatment with minimal side effects, DMSO should be used with caution and with active monitoring of side effects. (580) In 2015, Tomoe reported DMSO was useful after hydrodistension in IC/BPS with Hunner lesions in both maintaining and improving the effectiveness. Further, in her study, DMSO did not have any particular efficacy in the treatment of IC/BPS in the absence of Hunner lesions. (581) A review of adverse reactions that have been reported in the literature has been reported since the last consultation report. (582).

A preparation of DMSO was recently approved for use in Japan as the result of a phase 3 placebo-controlled trial. It was administered intravesically biweekly for 12 weeks in patients with bladder-centric phenotype (primarily Hunner lesion disease). This preparation has little garlic odor side effects, and a placebo-controlled trial was thus possible. It was well-tolerated and improved symptoms, voiding parameters, and global response compared with placebo, adding to its history of safety and efficacy over the last 55 years. (219)

2. HEPARIN

Level of Evidence: 3, Grade of Recommendation: C

Side effects are rare and primarily related to effects of intravesical catheterization and slight chance of bladder hemorrhage. The glycosaminoglycan (GAG) layer on the bladder urothelium is a kind of muco-polysaccharide, working as a non-specific defense mechanism. It is believed that a deficiency or abnormality of GAG secondarily causes inflammation of the bladder by increasing the permeability of the bladder mucosa, leading to the pathologic cascade of IC/BPS. Heparin has similarities to the GAG layer of the bladder. When instilled into the bladder, theoretically it might replace the damaged GAG layer as originally shown by Hanno. (583,584) Kuo reported that the International Prostate Symptom Score, as well as bladder capacity at initial desire to void and maximum bladder capacity, improved significantly. (585) According to the report by Parsons et al in an uncontrolled study symptoms were reduced in 56% of patients treated 3 times weekly for 12 weeks. (586) These reports suggest the efficacy of heparin, however, there is no randomized comparative study to give conclusive evidence. One study indicated that intravesical heparin instillations may prolong the response to dimethyl sulfoxide treatment. (587) In another report, significant symptomatic benefits accrued from the addition of heparin to intravesical lidocaine solution treatments. (588)

No significant side effects have been reported, as it does not affect systemic coagulation parameters. In the case of patients with hematuria, however, it may exacerbate local hemorrhage. The instillation method has not been standardized. Generally, 10,000-40,000 units of heparin are instilled and diluted in 10 ml. It is unusual to have pain or irritation as a result of instillation, and retention times can be 30 minutes or more. Instillation frequency can be up to every other day and it is often administered at home by the patient. Parsons et al reported that when 40,000 units of heparin combined with 1 to 2% lidocaine was instilled 3 times a week for 2 weeks, about 80% efficacy was obtained with relief of symptoms in 12 hours. (589) There is no upper limit for the duration of the treatment, but

a long-term effect is unknown. Heparin for intravesical use is not approved by drug regulatory authorities.

3. HYALURONIC ACID

G Level of Evidence: 1, Grade of Recommendation: C

Hyaluronic acid, like heparin, is a muco-polysaccharide, that could theoretically improve or repair a damaged GAG layer of the bladder mucosa. Several reports have indicated efficacy in non-placebo controlled trials. (258,590,591) L (244,592-597) In the summer of 2003 Bioniche Life Science Inc and in the spring of 2004 Seikagaku Corporation reported double-blind, placebo-controlled, multicenter clinical studies of their hyaluronic acid preparations (40mg or 200mg per cc respectively) and neither showed significant efficacy of sodium hyaluronate compared to placebo in large phase 3 trials. These negative studies have not been published in peer reviewed literature. Neither preparation has been approved for use for IC/BPS in the United States. At the same time, no significant side effects were observed.

Forty-eight patients with typical symptoms and a positive potassium (0.4 M) sensitivity test were treated with weekly instillations of 40 mg hyaluronic acid for 10 weeks. Visual analogue scale scores showed symptom relief due to hyaluronic acid therapy, irrespective of bladder capacity. The improvement was particularly evident in patients with a reduction in Cmax < 30% compared to patients with a reduction of < 30% with 0.2 M KCl solution (P = 0.003). Long-term effects were investigated in a study of 70 patients previously treated with hyaluronan. (598) Of the initial 70, 48 improved. Of these, 50% reported complete remission with no further therapy. Another 41.7% of patients with symptom recurrence improved after retreatment. In a Korean study, intravesical instillation of 40mg of HA in 50ml of saline once a week, for 4 weeks, significantly improved VAS score, PUF, ICSI and ICPI in refractory IC/BPS. Previous treatment modalities did not affect the efficacy of the instillation and the presence of Hunner lesion was unrelated to outcomes. (599)

It has been suggested that HA and lidocaine be combined for instillation. In a non-randomized controlled open-label trial, 48 women with refractory IC/BPS were enrolled and divided in three groups: the trial group received HA, alkalinized lidocaine (AL) and sodium bicarbonate once a week for 8 weeks and then monthly for 4 months with a subsequent follow-up of 24 weeks, while the two control groups received HA, and AL plus sodium bicarbonate respectively following the same procedure. The HA+LA and the LA groups showed a rapid improvement of symptoms at week 2, while the HA treatment was ineffective until week 4. In the later stage of the treatment, symptoms in AL group recurred, probably because AL relieves symptoms through its anesthetic activity, but it cannot repair the defect of the bladder mucosa. Once the instillation was stopped or the frequency was reduced, the effect disappears gradually. (600) In a randomized prospective study, IC/BPS patients were randomized in two groups: group A received HA directly with a catheter and group B received HA with electromotive drug administration (EMDA). The VAS score and the micturition frequency were significantly lower in group B at 6 and 12 months. The difference between the two groups was not significant at 24 months, demonstrating a lack of long-term efficacy. (601) Shao et.al. showed a prolonged effect of bladder distension when combined with instillation of hyaluronic acid. (602) A study by Hung suggested that hyaluronic acid improves pain symptoms more than frequency and urgency. (603)

Ketamine abuse especially in the younger population, is an emerging issue in many countries, and ketamine cystitis (KC) is a growing disease which more and more urologists may encounter. The clinical presentation of ketamine cystitis varies and may mimic IC/BPS. KC patients present with severe irritative symptoms and an irregular, thickened, inflamed bladder wall on endoscopy. A case report by Ying-Lun Ou et al. showed a complete reversal change after intravesical HA instillation. (604)

4. CHONDROITIN SULFATE

Level of Evidence: 1, Grade of Recommendation: C

Chondroitin sulfate is the only sulfatated glycosaminoglycan located on the urothelial luminal surface and contributes to the urothelial barrier function. (605) Its efficacy was suggested for the first time 2002 when used alone (606) and in another trial when used in combination with hyaluronic acid. (607) Intravesical chondroitin sulphate demonstrated beneficial effects in patients with a positive potassium stimulation test in two non-randomised, uncontrolled, open-label pilot studies. Steinhoff (606) treated 18 patients with 40 mL instilled intravesically once weekly for 4 weeks and then once monthly for 12 months. Thirteen of 18 patients were followed for the entire 13-month study. Twelve of these patients responded to treatment within 3–12 weeks. A total of 6/13 (46.2%) showed a good response, 2/13 (15.4%) had a fair response, 4/13 (30.8%) had a partial response, and 1/13 (7.7%) showed no response. In a second trial 24 refractory patients with IC/BPS were treated with high-dose (2.0%) chondroitin sulphate instillations twice weekly for 2 weeks, then weekly with 0.2% solution for 4 weeks, and monthly thereafter for 1 year. (608) The average symptom improvement reported in 20 patients completing the trial was 73.1% (range: 50– 95%). The time to optimum response was 4–6 months. A more concentrated 2.0% solution was needed in eight patients to maintain results. Chondroitin sulphate instillation was effective and well tolerated in the therapy of various chronic forms of cystitis associated with a possible GAG layer deficit including IC/BPS in a large multicenter observational study. (609)

Two large, randomized placebo controlled trials of chondroitin sulfate as monotherapy for IC/BPS were carried out in North America by Watson. Sixty-five patients with IC/BPS were treated in a prospective, randomized, double-blind, inactive vehicle-controlled, 12-week study (6 weeks treatment, followed by 6 weeks follow-up). At the primary endpoint analysis (week 7), 22.6% of the vehicle control group were responders compared with 39.4% of the active therapy group, however, the difference was not significant. (116) A follow up randomized placebo-controlled trial with 98 female patients showed only minor improvements in IC/BPS symptoms and pain and failed to demonstrate a statistically significant drug effect vs. placebo. (610) The authors concluded that the study did not support the use of intravesical chondroitin sulfate as a monotherapy for this condition. In 2013 an individual participant data (IPD) metaanalysis was conducted to define the efficacy of intravesical 2% chondoitin sulfate in IC/BPS patients. {Thakkinstian 2013) Two hundred thirteen patients were included in this analysis. At the end of the treatment di overall global response assessment (GRA) rates were 43.2% in the chondroitin group and 27.4% in the control group and the chance of having become a responder with chondroitin sulfate was 55%, significantly higher than with placebo. The small decrease in total ICSI score and urine frequency between the two groups was less impressive and not statistically significant.

A prospective single centre study assessed CS effectiveness for treating IC/BPS in IC/BPS patients who had failed prior DMSO treatment. The global response to treatment was 80% at 10 weeks and 70% at 24 weeks. No significant side effects were reported. (611)

A recent small RCT compared effectiveness of intravesical chondroitin sulphate (CS) 2% versus dimethyl sulfoxide (DMSO) 50% in patients with IC/BPS. Seventy-three percent of patients receiving CS reported moderate or marked improvement and achieved a reduction in VAS scores, vs 14% on DMSO due to pain during and after instillation, intolerable garlic odor and lack of efficacy. CS group performed significantly better in pain reduction (-1.2 vs. -0.6) and nocturia (-2.4 vs. -0.7) and better in total O'Leary reduction (-9.8 vs. -7.2). The trial was stopped due to high number of dropouts with DMSO. (612)

5. CHONDROITIN SULFATE AND HYALURONIC ACID COMBINATION THERAPY

Level of Evidence: 2, Grade of Recommendation: C

The combination of hyaluronic acid and chondroitin sulfate forms a viscous agent, and was proposed several years ago for treatment of IC/BPS by Cervigni and colleagues. (607,613,614) It may also improve sexual function in female patients with IC/BPS. (615) The solution has been approved in parts of Europe for use as an intravesical therapy. It has been shown in a pilot study to relieve some symptoms of radiation cystitis. (616) In 2016 a randomized, open-label, multicenter study involving 110 women were randomized to receive 13 weekly instillations (3 months) of HA (1.6% - 800mg) and CS (2.0% - 1g) (Ialuril®; IBSA) or 50% DMSO solution (RIMSO®; Bioniche), with a 2:1 allocation ratio (HA/CS:DMSO). This study showed that treatment with HA/CS appears to be as effective as DMSO with a potentially more favorable safety profile. Both treatments increased health-related quality of life, while HA/CS showed a more acceptable cost-effectiveness profile. (617) In a recent paper Keane et al. confirmed these results. (618)

In 2019 Özkıdık compared the efficacy, safety and tolerability of intravesical hyaluronic acid (HA), chondroitin sulfate (CS) and combination therapies (HA+CS) in patients with IC/BPS over 24 months. All groups showed a significant improvement both in the parameters included in the 3-day micturition diary and self-reported questionnaires compared to the baseline values or scores recorded at the beginning of the study. The combination therapy was superior to both monotherapies in terms of improvement in HRQoL score and the difference was statistically significant ($p = 0.02$). Combination therapy provides better results than the monotherapies to obtain symptomatic relief in patients with IC/BPS. (619) Sherif et al. evaluated the safety and efficacy of intravesical instillation of hyaluronic acid/chondroitin sulfate in the treatment of refractory IC/BPS in 36 pts. An initial response to treatment in all parameters at variable degrees was noticed at 2 weeks after the last instillation when compared to the baseline, and these changes were statistically significant ($p<0.001$). Progressive improvement in all test parameters was noticed at 3 months after treatment, and this improvement was statistically significant compared with baseline and 2 weeks after treatment, respectively ($p<0.001$). Intravesical instillation with both hyaluronic acid/chondroitin sulfate in the treatment of refractory painful bladder syndrome is safe, effective, and well tolerated by all patients with no recorded side effects. (620)

6. PENTOSAN POLYSUFATE

Level of evidence: 4, Grade of Recommendation: D

Pentosan polysufate (PPS) is a mucopolysaccharide similar to heparin, with a similar postulated mode of action when used locally. Like other muco-polysaccharides, it has not been well-studied clinically. Bade et al in a randomized controlled trial found benefit in 4 patients out of 10 on PPS versus 2 of 10 on placebo. (621) A placebo-controlled study of 41 patients found the addition of a 6 week course of intravesical PPS to a regimen of oral PPS significantly improved results. (622)

Lander et al. determined the effect of intravesical instillation of PPS encapsulated in liposomes for refractory interstitial cystitis patients in an open label uncontrolled study. Patients received 400 mg of Pentosan Polysulfate (PPS) encapsulated into liposomes as an intravesical instillation performed every 2 weeks for 3 months. Clinically significant decreases in symptom scores greater than 50% were seen in virtually all outcome measures at 3 month follow up. All subjects reported remarkable subjective improvement in pain symptoms marked by decreased use of narcotics and increased enjoyment of daily activities. Intravesical Pentosan Polysulfate encapsulated into liposomes can significantly decrease frequency, urgency, pain and improve quality of life for two months after deployment. Additional studies are needed to determine cellular effects of glycosaminoglycan restoration, ideal doses, dosing intervals, safety and cost-effectiveness of this innovative therapy. Patients who received the PP/Liposome mixture experienced relatively rapid relief of symptoms. Some were able to stop narcotics use. Nearly all subjective outcome measures at 3 months showed a 50% or greater decrease in symptom and bother scores. Patients were followed for greater than 1 year and several of the patients noted durable and sustained relief of symptoms for greater than 15 months. (623)

7. VANILLOIDS (CAPSAICIN, RESINIFERATOXIN)

Level of Evidence: 1, Grade of Recommendation: -Not Recommended

It would seem reasonable that capsaicin, a C-fiber afferent neurotoxin, could alleviate the pain of IC/BPS by desensitizing bladder afferents. Resiniferatoxin is a potent analog of capsaicin, an alkaloid derived from chili-pepper that promotes the temporary depletion of substance P, a neuropeptide responsible for the transmission of pain impulses through peripheral sensory nerve fibers of type C. (624) Resiniferatoxin (RTX) is considered to have a stronger action than capsaicin, by desensitizing C-fibers more quickly, and causing less initial irritation. This action should inhibit the transmission of impulses to the central nervous system, and potentially alleviate the symptoms of IC/BPS.

Efficacy was indicated in five relatively small clinical trials. (625-629) No severe side effects were reported. A randomized multicenter placebo-controlled clinical trial of RTX failed to demonstrate benefit over placebo. (630)

Liu et al. compared the efficacy and safety of intravesical instillations. PubMed, the Cochrane Library, and Embase were searched. The primary outcome were interstitial cystitis problem (ICPI) and symptom (ICSI) scores. Eleven RCTs covering 8 agents with 902 patients were enrolled. According to the results of the ICPI and ICSI, Resiniferatoxin (0.1 μM) was more effective than other therapies. Combination therapy of hyaluronic acid and chondroitin sulphate ranked second in ICSI, third in ICPI, and first in the visual analog scale (VAS). Among regimens included for complication comparison, chondroitin sulphate was safer than other agents, with a probability of 78.5%. (631)

8. BACILLUS CALMETTE-GUERIN (BCG)

Level of Evidence: 1, Grade of Recommendation: Not recommended

BCG instilled in the bladder is thought to stimulate the immunological system. Seven articles reported on a BCG instillation therapy. Zeidman et al first reported that 5 patients who did not respond to other therapies showed symptomatic improvement. (632) Peters et al conducted a randomized double blind study showing a 60% improvement compared to 27% placebo response with good long-term results at 27 months. (633,634) Sixty-five percent of the patients experienced burning sensation, 41% irritation of the bladder, and 35% pelvic pain. One patient was reported to have dropped out due to joint pain. Peeker et al conducted a randomized double-blind study comparing intravesical BCG and DMSO and failed to find any efficacy with BCG. (564) A very large, multicenter randomized placebo controlled trial conducted by the National Institute of Diabetes, Digestive, and Kidney Disorders failed to identify benefit from BCG, although the side-effect profile was surprisingly similar to that of placebo. (635)

9. OXYBUTYNIN

Level of Evidence: 4, Grade of Recommendation D

Barbalias et al observed significant improvement when combining intravesical instillation of oxybutynin with bladder training (636) Oxybutynin on the bladder wall seems to be well tolerated with anticholinergic action and anaesthetic function too. Randomized trials are lacking.

10. LIDOCAINE

Level of Evidence: 1, Grade of Recommendation: C

Lidocaine is a local anesthetic that relieves pain by blocking sensory nerves in the bladder. It can be administered by electromotive drug administration (EDMA). (637-640) Using EMDA, ionized lidocaine is actively introduced into the bladder using an electrical current. Three articles reported that lidocaine and dexamethasone were instilled following hydrodistention. According to the report by Rosamilia et al, 85% of the patients had a good result, with the effect persisting for 6 months in 25%. (640) Other positive results are noted in case reports. (641,642) A report on a pharmacokinetic effect demonstrated pharmacologic levels of lidocaine absorption into the bladder tissue. (643) In a large, placebo controlled randomized trial, 102 adult patients (99 women) with a clinical diagnosis of IC/BPS were randomized from 19 centres in the USA and Canada to receive a daily intravesical instillation of alkalinized lidocaine or placebo (double-blind), for 5 consecutive days. (644) Treated patients had significant

sustained symptom relief for up to 1 month. The response rate in the active group was 30% vs 9.6% with placebo. However, further randomized, placebo-controlled trials are needed to ascertain efficacy, optimal treatment parameters, and length of response to intravesical lidocaine preparations. (406) Advantages seem to be immediate response, low-cost of generic medication, and ability of patients to self-administer at home. In a comprehensive review of lidocaine and bladder pain syndrome, Henry et.al. conclude that only weak evidence exists for supporting its clinical use currently. It appears to be a promising candidate drug to interrupt the self-perpetuating neuroinflammatory cycle found in IC/BPS. In the absence of more definitive clinical trials with various lidocaine preparations, it is reasonable to try daily instillations of 10-20ml of a 2% lidocaine solution with or without alkalinization for 7 days to see if a clinical response justifies ongoing treatment. (645)

11. OTHERS

Liposomes have been widely studied as drug carriers for a variety of chemotherapeutic. Agents improving the delivery by altering pharmacokinetics and reducing toxicity.

Empty or with entrapped drugs, liposomes can act as a topical healing agent. These studies encouraged investigation of empty liposomes as a therapeutic agent for bladder injury. (548) The use of liposomes as lipid-based biocompatible carriers for drugs administered by the intravesical bladder sparked a lot of interest. The lipidic bilayer structure of liposomes facilitates their adherence and penetration across to the apical membrane surface of luminal cells in the bladder epithelium. Recent clinical studies have tested multilamellar liposomes composed entirely of sphingomyelin as a novel intravesical therapy for interstitial cystitis. (646)

A two-center, double-blind, randomized, placebo controlled, study assessed lipotoxin to treat refractory IC/BPS as Intravesical instillation of liposomal formulated botulinum toxin A (lipotoxin). A total of 31 patients were assigned to intravesical instillation of lipotoxin (onabotulinumtoxinA 200 U with 80 mg sphingomyelin), 28 were assigned to onabotulinumtoxinA 200 U in normal saline and 31 were assigned to normal saline alone. Results shown Improvements in the pain scale and O'Leary-Sant symptom scores occurred in all 3 groups by 4 weeks after treatment. Lipotoxin instillation was associated with a statistically significant decrease in O'Leary-Sant symptom scores, ICSI, ICPI and the VAS pain scale, and an increase in GRA. However, there was no difference in improvement among the 3 groups. No significant adverse events

Lipotoxin failed to demonstrate a positive proof of concept compared to onabotulinumtoxinA or placebo. However, a single intravesical instillation of lipotoxin was associated with decreased IC/BPS symptoms compared to baseline in patients with moderate to severe IC/BPS. The effect was likely due to a significant placebo effect. (647)
Tacrolimus has the same mechanism of action of Cyclosporine A, effective in intractable cases of Hunner lesion disease. The aim of a four year pilot proof of concept study was to demonstrate if tacrolimus instilled in the bladder is effective in treating IC/BPS. Tacrolimus dissolved in DMSO/sterile water was instilled in the bladder of 24 patients with refractory IC/BPS symptoms. In 6 to 63 months follow up improvement was shown in 13 out of 24 patients. No side

effects were reported except for post-instillation flare-up. Blood levels of tacrolimus reached similar safe levels irrespective of using either DMSO or water for preparing the solution. Intravesical tacrolimus dissolved in DMSO/water was found effective in 54% patients of intractable IC/BPS without significant side effects. (648)

XV. BOTULINUM TOXIN (BTX-A) (INTRAMURAL)

Level of Evidence: 2, Grade of Recommendation: B

Intradetrusor BTX-A, a widely used treatment for refractory overactive bladder symptoms due to both neurogenic and idiopathic detrusor overactivity, also has a role to play in treatment of IC/BPS and HLD. It is a protein that is produced naturally by Clostridium botulinum. The toxin is taken up by endocytosis at nerve terminals where it stops the vesicular release of neurotransmitters at the synapse. The therapeutic potential is related to factors beyond its known ability to temporarily inhibit the release of acetylcholine and other neurotransmitters. It also has analgesic properties and can reduce peripheral sensitization by inhibiting the release of several neuronal signaling markers, including glutamate and substance P, and reducing c-Fos gene expression (33). BTX-A disrupts fusion of the acetylcholine-containing vesicle with the neuronal wall by cleaving the SNAP-25 protein in the synaptic fusion complex. The net effect is selective paralysis of the low-grade contractions of the unstable detrusor, while still allowing high-grade contraction that initiates micturition. Additionally, BTX-A seems to have effects on afferent nerve activity by modulating the release of ATP in the urothelium, blocking the release of substance P, calcitonin gene-related peptide and glutamate from afferent nerves, and reducing levels of nerve growth factor (649). Side effects include dysuria and incomplete emptying that may require catheter drainage for an indeterminate period after therapy (650).

Reports of case series/ cohort studies

In an early clinical study, thirteen IC/BPS patients were injected with 100–200 IU of BTX-A (abobotulinumtoxin A or onabotulinumtoxin A) into 20–30 sites submucosally in the trigone and floor of the bladder. Overall, nine (69%) patients noted subjective improvement, and ICSI scores improved by 70% ($P< 0.05$). There were significant decreases in daytime frequency, nocturia and pain, and a significant increase in first desire to void and maximal cystometric capacity. However, dysuria occurred in a majority of patients and persisted in a minority for several months after initial injection. Three patients required clean intermittent catheterization for 2-3 months following therapy (651).

To ascertain effect of repeat injections a total of 13 IC/BPS patients were followed up for 2 years. Fifty-eight injections were administered with a mean of 4.8 ± 0.8 injections per patient. The mean interval between two consecutive injections was 5.25 ± 0.75 months. At 1 and 4 months follow-up, 10 patients reported a subjective improvement. Mean VAS scores, mean daytime and night-time urinary frequency decreased significantly. The three non-responders to the first intravesical treatment session underwent further treatment 3 months later with satisfactory results. At 1 and 2 year follow-up, the beneficial effects persisted in all patients (652)

Trigonal-only injection seems effective and long-lasting since 87% of patients (n = 23) reported improvement after a 3-month follow-up period in a study by Pinto *et al*. in a mixed cohort of women with IC/BPS and HLD (653). Over 50% reported continuity of the beneficial effect 9 months after the first treatment. When retreatment was needed, similar results were obtained. No cases of urinary retention were reported. The authors concluded that this treatment is safe, effective and can be repeated. It appeared to be effective in both cohorts of patients.

These results are in contrast with those in another study from Kuo of BTX-A (onabotulinumtoxin A) in 10 patients with HLD only. One hundred units were injected suburothelially into 20 sites in five patients, while 100 U were injected into the trigone in the remaining five. None of the patients became symptom-free; two showed only limited improvement in bladder capacity and pain score (654).

In a later study of IC/BPS and HLD, positive results were reported by the same group. Lee and Kuo treated patients with refractory IC/BPS and HLD, with 100 U of BTX-A injection plus hydrodistention followed by repeated injections every six months for up to two years or until the patient wished to discontinue. Of the 104 participants, 56.7% completed four BoNT-A injections and 34% voluntarily received the fifth injection due to exacerbated IC symptoms. With a follow-up period of up to 79 months, O'Leary-Sant symptom and problem indexes (ICSI, ICPI, OSS), pain visual analogue scale (VAS) functional bladder capacity, frequency episodes, and global response assessment (GRA) all showed significant improvement ($p < 0.0001$). Those who received repeated injections had a better success rate during the long-term follow-up period. The incidence of adverse events did not rise with the increasing number of BoNT-A injections (655).

A retrospective cohort study evaluated efficacy and safety after intravesical treatment with onabotulinumtoxin A (BTX-A) versus BTX-A with hydrodistension (BTX-A+HD) in 39 females and 2 males with IC/BPS ± HLD after a mean follow-up of 153 months (656). After three months, pain reduction on the Visual Analog Scale (VAS) was 4.5 points with 22 patients reporting total pain relief with better pain reduction in the BTX-a+HD group. A significant improvement was also found with regard to voiding function and night-time frequency in both groups. Half of the patients requested retreatment after fading of symptom relief, while lack of continuation was due to complete pain relief. Complications occurred in 27% of cases including UTI, voiding dysfunction and urinary retention.

Randomized (controlled) trials

Kuo and Chancellor analysed the difference between hydrodistension and hydrodistension plus intravesical, sub mucosal BTX-A in women with HLD (657). Of the 67 patients, 44 were divided in two groups: one received 200 U and the other 100 U, and cystoscopic hydrodistension was performed after 2 weeks. The remaining 23 patients received hydrodistension only. There was symptomatic improvement in all groups. However, in the hydrodistension group, 70% had returned to their previous symptoms after the first month, while in the BTX-A-treated groups, there was improvement of VAS, functional bladder capacity and cystometric bladder capacity at 3 months. At 12 and 24 months, the results in the active group were 55 and 30% versus 26 and 17% in the hydrodistension group.

In a small pilot series 20 women with IC/BPS were either treated with saline or onabotulinumtoxin A (BTX-A) injected *periurethrally* (658). At three months follow-up there were no differences for any parameters determined with a female modification of the Chronic Prostatitis Symptom Index (CPSI), AUA Symptom Index, Graded Chronic Pain Scale, Perceived Stress Scale, or symptom improvement Visual Analog Scale (VAS).

Manning et al. randomly allocated 54 women with IC/BPS to blinded treatment with either hydrodistension with saline or to hydrodistension + injection with 500 U AboBTXA (Dysport®) into the bladder wall (659). Subjective outcome was assessed with the O'Leary-Sant questionnaire consisting of problem (OLS-PI) and symptom (OLS-PI) index scores. At three months follow-up there was no significant difference in subjective IC/BPS bother between the two groups, however there was a significant improvement between pre- and posttreatment evaluation in both groups. The postinterventional UTI rate was high, affecting 12 study participants (5 in control group and 7 in BTXA group).

In a multicenter, randomized, double-blind, placebo-controlled patients with IC/BPS and HLD were randomized to hydrodistention plus suburothelial injections of BTX-A 100U or the equivalent amount of normal saline. Pain was assessed using a VAS at week 8 after treatment. Secondary endpoints included voiding diary and urodynamic variables. A total of 60 patients including 40 in the Botox and 20 in the N/S groups were enrolled. At week 8, a significantly greater reduction of pain was observed in the BTX-A group compared to the N/S group (2.6 vs. 0.9, p=0.021). The other variables did not differ significantly between groups except for cystometric bladder capacity, which was increased significantly in the Botox group. The overall success rates were 63% (26/40) in the Botox group and 15% (3/20) in the N/S group (p=0.028). Adverse events did not differ between the groups (660).

To ascertain effect of isolated BTX-A treatment only, Akiyama et al undertook a single-center, prospective, open labeled, randomized comparative study. Patients with refractory IC/BPS were randomly divided into two groups: immediate injection or 1 month delayed injection of botulinum toxin type A after allocation. The rate of treatment response and changes in symptom scores and frequency volume chart variables were compared between groups 1 month after allocation. Using subjects of both groups as a single cohort, predictive factors for treatment response at 1-month post-injection and the duration of response were explored. In a total of 34 patients the response rate was significantly higher in the immediate injection group (72.2% vs 25.0%, p = 0.01). All symptom measures showed significant improvement. When both groups were combined as a single cohort, the response rate was 73.5% at 1 month, 58.8% at 3 months, 38.2% at 6 months and 20.6% at 12 months. The mean duration of response was 5.4 months. The authors also found BTX-A to be more effective in patients with relapse after previous hydrodistension, thus enhancing its value in refractory cases (661).

Chuang et al. performed a double-blind, randomized, placebo controlled trial in patients with IC/BPS and HLD. Study participants were assigned to either intravesical instillation of lipotoxin (onabotulinumtoxinA 200 U with 80 mg sphingomyelin(n= 31)), onabotulinumtoxinA 200 U in normal saline (n=28) or normal saline alone (n=31). Decrease of pain on a VAS scale occurred in all three groups; however, there were no statistically differences between the groups in terms of the ICSI (Interstitial Cystitis Symptom Index) and ICPI (Interstitial Cystitis Problem Index OSS). Average improvement for VAS was -1.64 ± 2.52 (95% CI -2.57 - -0.71), for OSS -7.38 ± 8.75 (95% CI -10.58 - -4.17), for ICSI -4.00 ± 4.28 (95% CI -5.57- -2.42), for ICPI_-3.35 ± 5.11 (95% CI-5.23- -1.47). No hematuria or UTI was observed in the patients. Dysuria occurred in one patient in the lipotoxin group, in 2 in the onaBoNTA group and 1 in the N/S group. No serious AEs were reported (647).

The effect on injection location was analyzed by Jiang et al in women with IC/BPS and HLD. The efficacy and safety between intravesical bladder body versus trigonal onabotulinumtoxina injection in patients refractory to previous conventional treatment were tested in form of a prospective, randomized, clinical trial. In total 39 women were treated (20 in the bladder body, 19 in the trigone); all had a decrease of pain on a VAS scale without significant differences between groups (body 5.60 ± 1.50 preoperatively to 3.15 ± 2.18 postoperatively; trigonum 5.32 ± 2.24 to 2.68 ± 1.86, p=0.82) (662). Secondary outcome parameters included changes of Global Response Assessment (GRA), urinary frequency episodes, O'Leary-Sant score (OSS), and urodynamic study and showed no significant differences between groups. Side effects at two months included dysuria in 45% (bladder body) and 52% (trigonum group) of patients; one patient in the bladder body group had a UTI.

Pinto et al. performed a pilot, single center, randomized, double-blind, placebo controlled phase 2 study. Patients with IC/BPS were randomized to either intravesical OnabotulinumtoxinA 100 U (n=10) or saline as placebo (n=9). 12 weeks after the treatment patients in the treatment group had significantly less pain on a VAS scale than in the placebo group (-3.8 ± 2.5 vs -1.6 ± 2.1, p <0.05). The proportion of study participants who had a 50% or greater VAS pain score reduction was 60% in the OnaBotA group and 22% in the placebo group. The secondary end points including O'Leary-Sant scores (-9 ± 4.7 vs -7.1 ± 4.6, p <0.05), micturition frequency, and quality of life similarly improved significantly. At 12 weeks mean PVR was 5 ± 13 ml for OnaBotA vs 0 ml for placebo (663).

Despite Kuo and Chuang et al's finding of BTX-A ineffectiveness in disease with HLD (647,654), several authors reported similar results for patients with or without Hunner lesions present at treatment, indicating pain is targeted by BTX-A, regardless of cystoscopic phenotype (655,657,660,664).

RCTs have demonstrated efficacy of single and repeated injections with BTX-A with few and mild side effects in IC/ BPS and HLD. Further studies will be needed to obtain conclusive evidence for its efficacy, duration of effect, retreatment schedule, site of injection and side-effect profile. At this point it appears that a 100-unit total dose in 10 unit aliquots limited to the bladder base is as effective as injection points mapping the entire bladder mucosa.

XVI. NEUROMODULATION

Level of Evidence: 2, Grade of Recommendation: C

Sacral nerve stimulation (SNS) involves implanting permanent electrode(s) to stimulate S3 or S4 roots. As early as 1989, Tanago et al showed that stimulation of S3 may modulate detrusor and urethral sphincter function (665). FDA approved the usage of sacral neuromodulation for treating refractory detrusor overactivity in 1997 and for urinary urgency and frequency in 1999. Although the effectiveness of SNS for detrusor overactivity is largely confirmed by a good number of studies, relatively few papers report the effect of SNS in treating IC/BPS.

A possible mechanism of neuromodulation in treatment of pain is based on the gate-control theory; Non-painful input closes the gates of painful input resulting in prevention of pain sensation from traveling to the central nervous system. Another possible mechanism of action is reduction in the pelvic floor hypertonicity, as myofascial pain and hypertonic pelvic floor dysfunction is observed in majority of the IC/BPS patients (316). A potential role of urinary chemokines as a measure of treatment response has been reported (296). Percutaneous S3 nerve root stimulation improved symptoms and normalized urinary heparin-binding epidermal growth factor-like growth

factor levels and antiproliferative activity in patients with IC/BPS. Peters et al. suggested that treatment response may coincide with a decrease in the urine levels of chemokines, especially a decrease in the monocyte chemoattractant protein-1 (666).

Zerman et. al reported a case of 60-year-old woman treated for severe IC/BPS pain by SNS implant. Pain and accompanying bladder dysfunction were improved by temporary and permanent sacral nerve stimulation for up to six months (667). Siegel et al (668) assessed the postoperative outcome of sacral neuromodulation in 10 patients with intractable pelvic pain. Visual analogue scale (VAS) pain scores decreased by 55% from baseline and at a median of 19 months, 6 patients reported significant improvement in pelvic pain. Maher et al (669) showed that temporary stimulation was effective in 73% of 15 women with refractory IC/BPS. Mean voided volume during treatment increased and mean daytime frequency, nocturia and pain decreased significantly. As indicated by the Short Urinary Distress Inventory and SF-36 Health Survey, the quality-of-life parameters of social functioning, bodily pain and general health significantly improved during the stimulation period.

In their report in 2003, Comiter et al (670) prospectively investigated the effect of SNS on a series of 17 patients with refractory IC/BPS. At an average of 14-month follow-up, mean daytime frequency, nocturia and mean voided volume improved significantly. The average pain decreased from 5.8 to 1.6 points on a scale of 0 to 10 and Interstitial Cystitis Symptom and Problem Index scores (ICSI and ICPI) decreased from16.5 to 6.8 and 14.5 to 5.4, respectively. Of the 17 patients 16 (94%) with a permanent stimulator demonstrated sustained improvement in all parameters at the last postoperative visit. Whitmore el al (671) applied percutaneous sacral nerve root stimulation on 33 patients with refractory interstitial cystitis. Significant improvements were also seen in frequency, pain, average voided volume, maximum voided volume, ICSI and ICPI scores. Peters et al (672) reported a reduction of narcotic usage in 18 IC/BPS patients following SNS for a mean of 15.4 months, although the dose reduction was modest (36%) and only 4 of 18 discontinued the narcotics. However, Elhilali and colleagues (673) found that both of two patients with interstitial cystitis reported no improvement following sacral neuromodulation. Zabihi et al (674) more extensively stimulated S2-S4 by implanting electrodes into the epidural space through the sacral hiatus. 23 of 30 (77%) patients had successful trial stimulation and were permanently implanted. The symptom score was improved by 35% (p=0.005) and pain score improved by 40% (p=0.04). Patients reported an average of 42% improvement in their symptoms.

In the first prospective, single-blind, crossover trial of sacral nerve stimulation (SNS) versus pudendal nerve stimulation (PNS) for patients with IC/BPS (n =22), PNS gave an overall 59% improvement in symptoms, whereas SNS gave an overall 44% improvement (P = 0.05). Most patients who tested both, a sacral and pudendal electrode chose PNS as the better site. Follow-up showed marked improvements in voiding variables and validated IC/BPS symptom questionnaires. Over 90% of patients treated with neuromodulation stated that they would undergo implantation again (675).

Long-term results were verified in a retrospective study of 78 patients treated from 1994 to 2008. Permanent sacral neuromodulation implantation was performed in patients who showed at least 50% improvement in their symptoms with a temporary peripheral nerve evaluation test. Median follow-up was 61.5 ± 27.7 months. Good long-term success of sacral neuromodulation was seen in 72% of the patients. The explantation rate was 28% and revision rate was 50%. The most frequent reason for explantation was poor outcome (54% of the failed patients) (676). In another observational, retrospective, case-controlled review, 34 female patients underwent permanent device implants with mean follow-up of 86 ± 9.8 months. Mean pre and postoperative pelvic pain and urgency/frequency scores were 21.61 ± 8.6/9.22 ± 6.6 (p < 0.01), and mean pre-/postoperative VAS pain scores were 6.5 ± 2.9/2.4 ±1.1 (p < 0.01) (677).

In a recent systematic review of sacral neuromodulation in treating chronic pelvic pain by Mahran et al. (678) significant overall improvement in VAS pain scores was observed (weighted mean difference = -4.36%, 95% CI = -5.24 to -3.48, p <0.001). The most common adverse events were lead migration and malfunction (8%) followed by pain at the implantation site (5.4%), wound infection (4%), spontaneously resolved seroma (2.7%) and implantable pulse generator erosions without infection (1.1%). Five percent of patients were reported to have either device failure or removal and 10% of the patients underwent implant revision or replacements. Five patients required device or implantable pulse generator battery changes due to ended battery life.

SNS is still considered an investigational procedure for IC/BPS by the Consultation. Pudendal nerve stimulation has shown better results. Therapeutic benefits of both appear to be significant in selected cases. Strict patient selection and detailed discussion with patients prior to surgery is mandatory. Long-term results should be collected and reported, and trial results discussed with patients before employing this treatment modality.

Percutaneous tibial nerve stimulation (PTNS) has been also reported to treat IC/BPS (679,680). Recently, a single-arm, dual-center, pilot study reported the rate of overall symptom improvement in IC/BPS patients who were treated with PTNS. A total of 21 subjects were enrolled, 16 initiated and 10 completed the treatment course. There were no adverse events and 70% of the cohort had some degree of improvement (681). However, there is still limited data on efficacy of PTNS.

XVII. SURGICAL THERAPY

Interstitial Cystitis/Bladder Pain Syndrome (IC/BPS) is a chronic and debilitating disease. Major reconstructive surgical options should be considered only when all conservative treatment has failed. The patient should be informed of all aspects of surgery and understand consequences and potential side effects of surgical intervention. An experienced surgeon familiar with the particular surgical technique should perform the procedure.

XVIII. HYDRODISTENTION

Level of evidence: 3; Grade of Recommendation: D

Hydrodistension, alternatively known as bladder overdistension or cystodistension, was first reported in 1930 by Bumpus (682) and has been used for many years not only as a diagnostic or classification tool but also a treatment modality of IC/BPS. There is no standardized technique in hydrodistension but the basic concept is filling bladder to its maximum capacity at a fixed pressure (no higher than 80cm water) which is maintained for a set period of time (278). In 1975, Dunn (683) reported complete resolution of subjective symptoms in 16 out of 25 patients (64%) using Helmstein's method (684). Since then, various studies have used heterogeneous outcome parameters with minority of patients reporting improvement in

symptom for a relatively short period time (277,279,291,685,686). As most studies are retrospective and uncontrolled, therapeutic role of hydrodistension in IC/BPS is still controversial.

1. FULGURATION / TRANSURETHRAL RESECTION / STEROID INJECTION HUNNER LESIONS

Level of Evidence: 1; Grade of Recommendation: A

In 1914, Hunner presented his first report of eight cases of rare type of bladder ulcer in women and recommended open resection of the ulcerative lesion in the treatment of IC (43). However, unsatisfactory results soon placed open resection in disrepute. With improvement in cystoscopic technology, transurethral fulguration and resection have become popular (687). Bugbee or loop electrodes are commonly used for fulguration or coagulation of the Hunner lesion. Various studies have investigated the therapeutic role of transurethral operation on the Hunner lesion (556,688-691). Patients included in these studies experienced amelioration of symptom with different treatment response durations and frequent recurrences. Peeker et al. reported a retrospective series of 259 transurethal resection of Hunner lesion in 103 patients (692). Under general anesthesia, Hunner lesion were identified and each one was resected, including at least a half of the underlying muscular coat. Ninety-two patients experienced amelioration of symptoms with an average response duration of 23 months. Hillelsohn et al. reported a retrospective series of 106 transurethral fulgurations of Hunner lesions in 69 patients. Twelve months after initial fulguration, 13.1% of the patients required repeat treatment and the rate increased to 57.2% at 48 months. Until recently, there had been no reports on recurrence patterns of the Hunner lesion and the comparative evaluation of treatment methods (Hunner lesion coagulation versus resection). In a retrospective analysis of 91 patients with IC, Han et al. reported that the recurred Hunner lesions involved previous as well as *de novo* areas which made recurrence pattern unpredictable (693). Ko et al. first reported a single–center, prospective, randomized controlled trial including 126 patients with Hunner lesion and compared the efficacy and safety of transurethral resection and transurethral coagulation. No differences were observed in the recurrence-free time, decreased daytime frequency, nocturia, urgency episodes, pain and symptom questionnaires between the groups over 12 months (694). Several reports have described the use of Neodynium:Yag laser for ablation of Hunner lesion with small bowel perforation due to forward scatter of laser energy as the most serious complication (695-697). Transurethral resection, fulguration, coagulation or laser ablation of the Hunner lesions are recommended treatments for patients with IC/BPS ESSIC type 3X. These endoscopic surgeries are usually combined with hydrodistension. One retrospective study of 44 patients has reported that transurethral resection combined with therapeutic hydrodistension increased bladder capacity and improved voiding symptoms more than did transurethral resection alone (698). Decreased bladder capacity from repetitive transurethral resection or fulguration of Hunner lesion is a controversial issue (699,700). It would be difficult to sort out the effect of fulguration from the natural history of disease given that frequency of fulguration is guided by response to therapy. Transurethral intravesical submucosal injection of corticosteroid (triamcinolone) was also reported to have symptomatic effects comparable to the results observed after resection or fulguration in some uncontrolled studies (701-704).

2. CYSTOLYSIS – PERIPHERAL DENERVATION

Level of Evidence: 3; Grade of Recommendation: - not recommended

Hunner simply dissected bladder from surrounding tissue. Initial results were encouraging, however after 3 years of follow-up, symptoms reoccurred. Worth and Turner-Warwick attempted to do more formal cystolysis and were more successful with regard to symptoms (705). After seven-year follow-up, Worth found bladder areflexia to be a significant complication of this procedure. Patients had to use Credé technique or even be on intermittent self-catheterization (706). Albers & Geyer reported symptom recurrence after 4 years in most of the patients (707). Cystolysis, peripheral denervation of bladder is not indicated for IC/BPS.

3. AUTONOMIC DENERVATION

Level of Evidence: 4; Grade of Recommendation: not recommended

Visceral pain is transmitted in most cases by the sympathetic nervous system. Gino Pieri (708) applied this principle to the bladder pathology and suggested resection of the superior hypogastric plexus (presacral nerves), paravertebral sympathetic chain, and gray rami from S1-3 ganglia (Level 4). This was repeated by Douglass (709) a few years later. Immediate results were very good, however Nesbit (710) showed that the long term results were short lived.

Based on the contribution of S2-S4 segments to bladder innervation, Moulder and Meirowsky (711) used S3 neurectomy in 3 patients with good long term follow-up. Larger series were reported by Milner (712,713) and Mason (714) but results after five years were not encouraging. To improve results selective dorsal sacral root neurectomy, unilateral or bilateral, was introduced by Bohm and Franksson (715). The outcomes of this procedure were unclear. Both sympathetic and parasympathetic denervation is not indicated for IC/BPS.

4. SURGERIES USING INTESTINAL SEGMENTS

The global definition of IC/BPS and its phenotypes is currently under active debate. A recent report after 2018 International Consultation on Interstitial Cystitis Japan concluded that the Hunner lesion disease is pathologically and clinically distinct from the non-Hunner lesion disease, suggesting that the Hunner lesion disease and the non-Hunner lesion are separate disease entities. (22) As various aforementioned surgical treatment options are based on conventional classification system that puts together IC/BPS and HLD in a single category, this recommendation might need revision in the future.

4.1. Bladder Augmentation – Cystoplasty

Level of Evidence: Level 3; Grade of Recommendation: C

Bladder augmentation - cystoplasty has been commonly used for refractory IC/BPS for more than 60 years. First reports of ileocystoplasty from 1958 were very promising. (716) Later publications

were less sanguine with results varying from 25% (717) to 100% (718,719). Cystoplasty is usually done with or without bladder resection. Cystoplasty alone was reported as early as 1967 by Turner-Warwick and Ashken (720), advocating augmentation with removal of the diseased tissue. Several subsequent studies indicated that cystoplasty with subtrigonal cystectomy offers better results than without subtrigonal cystectomy (719,721,722). These were all retrospective studies and conclusions should be taken with reservation.

Cystoplasty with partial or total removal of the bladder requires bowel tissue substitution. Different bowel segments are used to enlarge the bladder. It is the general consensus that the intestine segment used for bladder augmentation should be detubularized (723). Experiences with different bowel segments (ileum, ileocecum, cecum, right colon, sigmoid colon, stomach) have been reported. There is no significant difference among bowels segments with regard to the outcome, except for gastric tissue substitution which is associated with dysuria and persistent pain due to production of acids. Using intestinal segments for bladder substitution is considered to be highly morbid. Recently Osman et al. reported a systematic review on 20 studies using bowel segments for IC/BPS published from 1990 onwards; 85% of included studies (17 out of 20) reported postoperative complications in 357 patients (92 cases of total cystectomy and orthotopic neobladder, 10 cases of total cystectomy and ileal conduit and 101 subtotal cystectomy and augmentation cystoplasty, and 154 procedures not identified). A total 102 complications were documented overall with the most common being sepsis of any type followed by recurrent urinary tract infection, bowel obstruction, ileus, bowel frequency, hernia, metabolic change, stomal problems. Six (1.3%) postoperative deaths were reported. Five patients died from unrelated causes and on patient committed suicide due to persistent pain, having previously undergone primary urinary diversion followed by total cystectomy for persistent pain (724).

4.2. Cystoplasty with Supratrigonal Resection

Level of Evidence: Level 3; Grade of Recommendation: C

Cystoplasty with supratrigonal resection (i.e. trigone-sparing) has been reported in various studies (717,718,721,722,725-730). Von Garrelts described excellent results in eight of 13 patients with a follow-up of 12-72 months. Bruce et al. reported satisfactory relief of IC/BPS symptoms by ileocystoplasty and colocystoplasty in eight patients. Dounis and Gow reported improvement in pain and frequency in seven IC/BPS patients after supratrigonal cystectomy with ileocecal augmentation. Kontturi et al. used segments of colon and sigmoid colon in 12 cases with 100% symptom-free outcome in five patients augmented with sigmoid colon over 4.7 years of follow-up. Two of seven cases augmented with colon required ileal conduit and cystectomy. Linn et. al followed six IC/BPS patients for 30 months, and reported that all were symptom free and voided spontaneously. The report by Nielsen et. al was less favorable. Six out of eight patients (75%) had good results. Van Ophoven et. al reported the long-term (mean 57 months) results of orthotopic substitution enterocystoplasty in 18 women with IC/BPS, using ileocecal (n = 10) or ileal (n = 8) segments with two failures. In the group augmented with ileum, three patients required self-catheterization and one a suprapubic catheter. Peeker et. al found that patients with end-stage HLD had excellent results following ileocystoplasty but not in the patients with non-HL disease. Long-term follow-up (median 89 months (2 to 258)) on this paper was published with the same conclusion for Hunner lesion disease, while both continent diversion and iliocystoplasty were unrewarding in patients with type 2X IC/BPS. There is some weak evidence that cystoplasty with supratrigonal resection may benefit some selected patients with end stage ESSIC type 3C IC/BPS. It is reasonable to consider provided patients recognize that a follow up surgical procedure may be required if symptoms do not respond.

5. CYSTOPLASTY WITH SUBTRIGONAL CYSTECTOMY — ORTHOTOPIC CONTINENT BLADDER AUGMENTATION

Level of evidence: 3; Grade of Recommendation: C

Cystoplasty with subtrigonal cystectomy — orthotopic continent bladder augmentation (i.e. with trigone removal but preservation of the bladder neck) in the management of IC/BPS has been reported less often (731-734). Because of the need of ureteral reimplantation, it is associated with some risks of urine leakage, ureteral stricture and reflux (733). Linn et al. (726) had three failures in 17 patients and half of the patients with good symptomatic response required self-catheterization. Nielsen et. al (717) had better results following orthotopic substitution with low bladder capacity (200 mL versus 525 mL, respectively).

Orthotopic continent bladder augmentation, particularly when removing the trigone, may cause incomplete voiding requiring intermittent self-catheterization. Therefore, patients considering such procedures should be advised accordingly and must be considered capable of performing, accepting, and tolerating self-catheterization. Nurse suggested that the decision on whether to do a subtrigonal or supratrigonal cystectomy be based on the results of trigonal biopsy, with the former procedure indicated in the patient with trigonal inflammation (717). There is no compelling evidence that subtrigonal cystectomy with cystoplasty has any outcome advantage over supratrigonal cystectomy, but it tends to be associated with more complications and poorer functional bladder rehabilitation.

6. URINARY DIVERSION WITH OR WITHOUT TOTAL CYSTECTOMY AND URETHRECTOMY

Level of Evidence: 3; Grade of Recommendation: B

In patients who have not responded to less invasive interventions, urinary diversion can result in major quality of life improvements. Techniques include simple conduit or continent urinary diversion. Continent diversion may be preferable for cosmetic reasons in younger patients. Simple urinary diversion with formation of an ileal conduit is the most common surgical treatment for IC/BPS (735). Initially, diversion can be done without cystectomy and only if bladder pain is persistent, cystectomy can be considered. Bladder de-functionalization alone produced symptom-relief in multiple reports (736-739). Whether or not cystectomy should be performed at the same time as urinary diversion is somewhat controversial. Nordling and Redmond et al. reported that urinary diversion for IC/BPS does not require concurrent cystectomy (739,740). About 80% of patients seem to have clinically significant improvement after urinary diversion, but secondary cystectomy does not seem to improve refractory pain. Meanwhile Osman et al. concluded that total removal of the bladder tended to result in success defined

as symptom improvement as compared with subtotal cystectomy or whole bladder in situ (724). Often diversion is performed as a next step after unsuccessful bladder augmentation. To avoid further bowel resection, a bowel segment used for cystoplasty can often be converted to a conduit (741). In some patients, chronic inflammatory changes have been observed in the cystoplasty pouch resembling interstitial cystitis (742,743) perhaps suggesting that a urinary component is an etiologic agent for the syndrome. Similar bowel changes, however, have been described when cystoplasty is performed for pathology other than interstitial cystitis, suggesting that these pathologic findings are not a direct result of the exposure of bowel to IC/BPS urine (744). Urinary diversion with and without cystectomy may be the ultimate option for refractory patients. Continent diversion may have better cosmetic and life style outcome but recurrence of pain in the pouch is a real possibility. In patients who would prefer only one major surgical procedure, a simple conduit diversion without cystectomy would be a reasonable approach. One can promise the patient that urinary frequency should no longer be a problem, and while pain may improve dramatically, if it doesn't it can be treated through pain management techniques.

XIX. OUTCOME ASSESSMENT

Level of evidence 2, Grade of recommendation C

1. STANDARDIZED IC/BPS CASE DEFINITION

A brief survey that reliably segregates IC/BPS from other urologic disorders would make the ability to diagnose the syndrome reliable, inexpensive, and available to all healthcare providers. It would aid in epidemiologic studies as well. A case definition for IC/BPS was developed by adapting the RAND/University of California, Los Angeles Appropriateness Method. (71) This involved a panel consisting of nine experts with experience in IC/BPS and related diseases, literature review of case definitions of IC/BPS, initial ratings of symptoms as indicators of the IC/BPS diagnosis, and discussion and a second set of ratings to establish criteria for diagnosis through patient reports. This resulting IC/BPS case definition **(Figure 18)** was able to discriminate between IC/BPS patients and patients with confusable disorders (overactive bladder, endometriosis,

1. In the past 3 months, have you ever had a feeling of pain, pressure, or discomfort in your lower abdomen or pelvic area -- that is, the part of your body that is above your legs and below your belly button?
   - YES
   - NO

2. In the past 3 months, have you had a strong urge or feeling that you had to urinate or "pee" that made it difficult for you to wait to go to the bathroom?
   - YES
   - NO [GO TO QUESTION 4]

3. Would you say this urge to urinate is mainly because of pain, pressure or discomfort or mainly because you are afraid you will not make it to the toilet in time to avoid wetting?
   - PAIN, PRESSURE, DISCOMFORT
   - FEAR OF WETTING

4. In the past 3 months, before you urinate, as your bladder starts to fill, does your feeling of pain, pressure, or discomfort usually:
   - GET WORSE?
   - GET BETTER?
   - STAY THE SAME?

5. In the past 3 months (when you were having symptoms), how many times on average have you had to go to the bathroom to urinate during the day when you are awake?

ENTER NUMBER OF TIMES: _____

IC/BPS Case Definition = Pain plus (Urgency or Frequency)

Pain criteria = 'Yes' answer to item 1
Urgency criteria = 'Yes' answer to item 2 plus response of 'pain, pressure or discomfort' for item 3
Frequency criteria = response of 10 times or greater on item 5

Figure 18. Rand interstitial cystitis epidemiology (RICE) IC/BPS case definitions. Berry SH, Bogart LM, Pham C, Liu K, Nyberg L, Stoto M, et al. Development, validation and testing of an epidemiological case definition of interstitial cystitis/painful bladder syndrome. J Urol 2010, May;183(5):1848-52.

vulvodynia) with adequate sensitivity and specificity. It was subsequently successful in establishing population-based estimates for IC/BPS disease prevalence (92,94). If this could be adapted for use in screening by primary care physicians, the potential benefits in early diagnosis of IC/BPS are evident.

2. CLINICAL SYMPTOM SCALES

IC/BPS symptom scales are currently utilized to measure treatment outcome and are especially valuable in clinical research studies as well as for guiding therapy for individual patients. Symptom scales have enabled patients to be categorized by symptom severity and are also valuable to follow results of treatment in patients with IC/BPS.

There are 5 published IC/BPS symptom questionnaires: the University of Wisconsin IC Scale (Figure 19), the O'Leary-Sant IC Symptom Index (ICSI) and IC Problem Index (ICPI) (Figure 20), the Pelvic Pain and Urgency/Frequency (PUF) Scale (Figure 21), the Bladder Pain/ Interstitial Cystitis Symptom Score, and the Genitourinary Pain Index (745) (Figure 22).

The University of Wisconsin IC Scale includes 8 IC/BPS symptom items which capture severity of symptom expression, as well as 17 non-IC/BPS items (746,747). It was the first published IC/BPS symptom scale, and underwent appropriate psychometric assessment. Its use has declined in recent years.

The O'Leary-Sant ICSI and ICPI indexes are validated tandem questionnaires that were originally developed by focus groups, subjected to test-retest reliability analysis, and validated by administration to IC/BPS patients and asymptomatic controls (748,749). The questionnaires each center on 3 questions related to urgency/frequency and one on bladder-associated pain. The ICSI inquires about symptom severity, and the ICPI assesses the degree of bother. The scores on the ICSI and the ICPI correlate quite highly, suggesting that the ICSI may be sufficient for clinical or research use (750).

The Pelvic Pain, Urgency, Frequency (PUF) questionnaire (751) was designed to include questions that reflect a wide variety of IC/BPS symptoms. One-third of the questions address pelvic pain, including pain anywhere in the pelvis: the vagina, labia, lower abdomen, urethra, perineum, testes, penis, or scrotum. The PUF was developed as an IC/BPS screening tool and was not subject to psychometric analysis. Higher scores were found to correlate with a higher likelihood of a positive potassium sensitivity test (PST). To the extent that the PST is suspect, the reliability of PUF data comes into question. A large study utilizing the PUF questionnaire concluded that up to 23% of United States women have IC/BPS (751); his makes one wary as to the utility and face validity of the PUF.

After a review indicated that the existing IC/BPS patient-completed measures did not meet current standards for the development of patient reported outcomes (752,753), a new measure of IC/BPS symptoms (the Bladder Pain/ Interstitial Cystitis Symptom Score (BPIC-SS)) was developed (754) . The BPIC-SS is based on defined standards for patient-completed measures, including patient and clinical input. The BPIC-SS appears to successfully discriminate IC/BPS patients from OAB patients and healthy controls. It has not been validated to discriminate IC/BPS patients from those with confusable diseases (e.g. endometriosis or UTI). The BPIC-SS appears more discriminative than the PUF or the ICSI. As a result, the BPIC- SS has been implemented into the standard sets within the FDA´s guidance for patient reported outcome development and has been used in recent IC/BPS trials (755). Finally, although developed for the purpose of screening into trials, the BPIC-SS could also potentially be used for measuring outcome results during clinical trials. The questionnaire is available free of charge (http://www.prolutssh.com).

The Genitourinary Pain Index (GUPI) is a 9-item instrument which was developed by the NIH-funded Urologic Pelvic Pain Collaborative Research Network (745). The GUPI is applicable to men and women to assess Pain symptoms, Urinary symptoms, and Quality of life as separate sub-scales, and overall as a total score (Figure 22). It was found to discriminate between men with chronic prostatitis or IC/BPS, those with other symptomatic conditions (dysuria, frequency, chronic cystitis), and those with none of these diagnoses. It also discriminated between women with IC/BPS, those with incontinence, and those with none of these diagnoses. The GUPI demonstrated good internal consistency within subscale domains, and GUPI scores correlated highly with scores on the O'Leary Sant ICSI and ICPI. The GUPI was highly responsive to change, and the change in score was similar in both male and female responders. A change of 4 points was the minimum clinically perceptible difference, and a reduction in 7 points robustly predicted being a treatment responder.

3. PLACEBO-CONTROLLED TRIALS

IC/BPS has been a difficult condition for which to assess therapeutic impact. There is a 50% incidence of temporary remission unrelated to therapy, with a mean duration of 8 months (4). In a chronic, devastating condition with primarily subjective symptomatology, no known cause, and no cure, many patients are desperate and may appear to respond to any new therapy. A skeptical view of outcomes is essential (**Figure 23**), as patients can be victims of unorthodox health care providers using unproven forms of therapy, some medical, some homeopathic, and some even surgical.

Where possible, the results of randomized controlled studies should be used for decision making. Placebo, double-blind studies are optimal in this disorder for which there is no generally effective standard therapy. Placebo effects influence patient outcomes after any treatment which the clinician and patients believe is effective, including surgery. Placebo effects plus disease natural history and regression to the mean can result in high rates of good outcomes, which may be misattributed to specific treatment effects. (132,756-759) Until recently, relatively few IC/BPS treatments have been subjected to placebo-controlled trials.

While in many diseases an argument can be made against using a true placebo control as opposed to an orthodox treatment of approved or accepted value (760), a good case for true placebo comparison can readily be made for IC/BPS. The vagaries of the natural history, the general lack of progression of symptom severity over time, and the fact that it is not life threatening, mean that there is little to lose and much to gain by subjecting new treatments to the vigorous scrutiny of placebo control. Many patients who volunteer for such trials have already run the gamut of accepted (though generally unproven) therapies. It has long been recognized in protocols that use subjective criteria for assessment that "improvement" may be expected in up to 35% of placebo-treated patients (761). As the spontaneous remission rate (though temporary) for IC/BPS is 11%

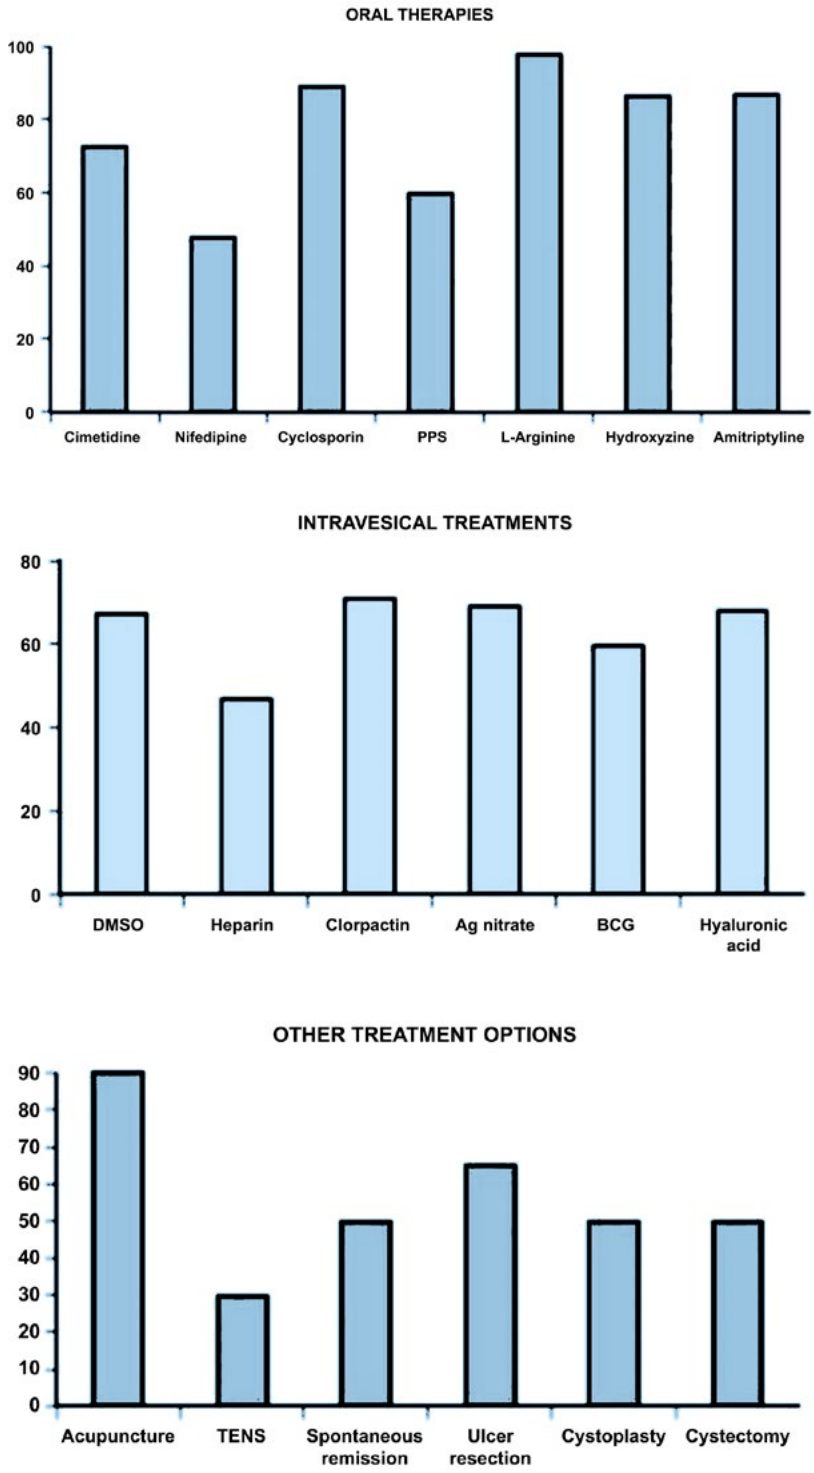

Figure 23. Selected reported treatment outcomes in uncontrolled studies in IC literature: percentage of patients initially improved.

(520) to 50% (4) , combined with the placebo improvement it can be difficult to prove efficacy.

Even in placebo controlled trials, it is reasonable to surmise that some degree of unblinding may occur as a result of somatic or psychological side effects of the active arm, impairing the validity of the trial results and giving the active arm a slight edge over placebo (762,763). Failure to recognize unblinding can easily bias results of a study and has not been routinely measured in clinical trials (764). When occurring late in a study after one would expect onset

of a therapeutic effect, unblinding could be the result of side effect profile or drug efficacy. Early in the trial it reflects poor placebo or study design. The degree of blinding needs to be ascertained throughout the trial. This is of specific concern in IC/BPS and any disorder where primary outcomes may be subject to patient-specific psychological and physiological factors.

The ethics and necessity of placebo-controlled trials have been questioned, especially in situations in which an effective treatment exists and also where delay in treatment has been shown to result in disease progression (765-767) . However, there are methodological concerns with equivalence and non- inferiority active agent comparison trials (768). These include an inability to determine if the treatments are equally good or equally bad, and the possibility that successive non-inferiority trials can lead to a gradual decrease in treatment efficacy. Although the use of placebo-controlled trials raises ethical concerns when proven effective treatment exists for the condition under investigation, they are ethically justified, provided that stringent criteria for protecting research subjects are satisfied (769) .

The value of placebo-controlled trials is aptly illustrated by the decisions of pharmaceutical manufacturers not to pursue FDA approval in the United States for seemingly promising intravesical therapies for IC/BPS (594,770) after placebo-controlled trials failed to establish efficacy. These include low concentration hyaluronic acid (Bioniche, Canada), high concentration hyaluronic acid (SKK, Tokyo), and resiniferatoxin (ICOS, Bothell, Washington, USA). Nalmefene, an initially promising oral therapy in the 1990's (771), also failed phase 3 trials (IVAX, Miami). Placebo trials are impractical in surgery and it can be difficult to evaluate surgical reports. The many older medications currently used off-label might not meet success if tested in the stringent manner in which new molecular entities are tested. The expense of testing therapies currently used off-label often requires dependence on the largesse of government agencies like the National Institute of Health.

4. ALTERNATIVE CLINICAL TRIAL DESIGNS

In addition to classic randomized, blinded clinical trials, there are alternative randomized and non-randomized clinical trial designs that may be considered when testing the efficacy of treatments. These include *factorial* designs, *within-group* designs, and *crossover* designs, among others (772). *Factorial* trials aim to assess two or more treatments in a single trial. The NIDDK-funded Interstitial Cystitis Clinical Research Network (ICCRN) conducted a 2X2 factorial study, in which participants were randomized to four groups: oral pentosan polysulfate (PPS) alone, oral hydroxyzine alone, PPS plus hydroxyzine, or placebo (506). This study design is efficient as it allows the investigators to test the efficacy of two treatments, and it also reduces the number of participants who receive placebo (when compared with a standard RCT with 50:50 randomization). One major disadvantage of a factorial design is that the two treatments may interact, which can reduce the study power and complicate the statistical analysis. *Within-group* designs (or time-series designs) are non-randomized studies in which measurements are made before and after participants receive the intervention. Therefore, each participant serves as his/her own control. Due to a lack of a control group, within-group designs are subject to confounding from learning effects and regression to the mean. One type of within-group study is an "N-of-one" trial, in which participants repeatedly alternate between active forms of the treatment and placebo. In order to be feasible, N-of-one studies must use treatments that have relatively quick onset of action, and with limited carryover effects after cessation. In *crossover* designs, half of the participants are randomized to start with the control intervention and switch to the active treatment, and the other half starts with the active treatment and switches to control. These study designs are attractive to study participants, as they are guaranteed to receive the active treatment at some point. However, as with within-group studies, any carryover effect from the active treatment may contaminate the results. Therefore, there is typically a 'washout' period (no treatment) included between arms of crossover trials. Another disadvantage of crossover designs is that the study length needs to be doubled to accommodate each participant receiving active treatment and placebo.

5. CHRONIC PAIN CLINICAL TRIAL OUTCOMES AND OUTCOME INTERPRETATION: IMMPACT RECOMMENDATIONS

The Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) has published recommendations for core outcome domains for chronic pain clinical trials (461,773). It is recommended that these domains should be considered in all clinical trials of treatments for chronic pain conditions, including IC/BPS. These domains include: (1) Pain, (2) Physical functioning, (3) Emotional functioning, (4) Participant ratings of improvement and satisfaction with treatment, (5) Symptoms and adverse effects, and (6) Participant disposition. In addition, IMMPACT recommends that the type of trial, the study design, the statistical analysis methods, the magnitude of the estimated effects, the risk-benefit profile of alternative treatments, the clinical importance of the reported changes, the presentation of the outcome data, and the limitations of the approaches be considered when interpreting the results of chronic pain clinical trials (774). In IC/BPS clinical trials, particular attention should be paid to the composition of the study sample. Patients with long-standing disease or compromised bladder capacity or widespread pain ("central sensitization") might be less responsive to treatments directed toward the bladder itself. In addition, the concept of statistical versus clinical significance is paramount when interpreting objective responses to treatments. Investigators should, but rarely do, point out differences between statistical improvement and what they consider to be clinically significant improvement (775). As Gertrude Stein reportedly stated, "A difference, to be a difference, must make a difference". An increase in bladder capacity of 30cc may be statistically significant but clinically irrelevant. Number needed to treat and number needed to harm data (776) may be particularly important in IC/BPS but have not typically been included in efficacy analysis.

CONCLUSIONS:

In 2022 for IC/BPS there are no accepted biologic disease markers that can be used for the assessment of response to therapy. The RICE IC/BPS case definition holds promise as a potential screening tool for IC/BPS in primary care. Multiple validated questionnaires exist to follow disease progression and response to therapy. The IMMPACT recommendations suggest that as well as symptom scores, any future study on a pain syndrome must involve more general assessments of psycho-physical functioning. International recognition of an agreed upon definition and inclusion and exclusion criteria of IC/BPS will help future studies to fulfill the highest standards available, and placebo-controlled,

double blind, randomized controlled trials, where possible, will provide the highest level of evidence to move the field forward.

XX. THE IMPACT OF IC/BPS (QUALITY OF LIFE, COST)

Many IC/BPS patients experience a long delay from symptom onset to diagnosis, due to misdiagnoses (e.g. 'recurrent UTIs', 'overactive bladder') and a general lack of familiarity with IC/BPS by the medical community. Even after a correct diagnosis, IC/BPS symptoms often prove to be refractory to treatment. The impact of these symptoms can be profound. Numerous studies have demonstrated that overall well-being/ quality of life of IC/BPS patients is significantly lower than the general population in both physical and mental aspects (93,777-779), with a similar impact as other debilitating chronic conditions such as rheumatoid arthritis and dialysis-dependent renal failure (777).

The individual and societal costs of IC/BPS are substantial. Mean annual direct medical costs for IC/BPS patients are approximately twice that for those without IC/BPS (780,781), and mean annual indirect costs (work loss, reduced productivity) are 84% higher (782). One study found that 10% of IC/BPS patients were unable to work at all due to their symptoms (783), and another found that 19% of employed IC/BPS patients had experienced lost wages due to their symptoms in the preceding 3 months (784).

XXI. PRINCIPLES OF MANAGEMENT

The information currently available in the literature does not lend itself to easily formulating a diagnostic or treatment guideline that will be acceptable to a wide range of practitioners. Different groups of "experts" would undoubtedly create different "best practices". (785) The compromise approach devised by an experienced cross-section of urologists and gynecologists from around the world at the International Consultation on Incontinence 2004 meeting in Monaco (60) and subsequently modified at the 2008 and 2012 meetings in Paris (786,787) and the 2016 Tokyo meeting (1) has been reviewed and updated by the committee and allows for significant latitude to reflect varying individual practice patterns and to account for patient preference.

An underlying principle is that, where possible, decisions on the treatment of interstitial cystitis/bladder pain syndrome (IC/BPS) and Hunner lesion disease (HLD) should be evidence based (788). Unfortunately, high level evidence of efficacy is lacking for many common treatments, either because such studies have not been done, failed to differentiate patients with HLD from IC/BPS and/or failed to demonstrate efficacy vs placebo. (789-792) . While there is no shortage of literature on treatment trials, the vast majority have small sample sizes and effects of treatments cannot be estimated with precision. (547)

Another principle is that we should be guided by patient perceived and driven outcomes. Newer symptom scores are based on this principle (745,754) and the Food and Drug Administration in the United States is asking pharmaceutical companies to develop more patient reported outcome measurements as a requirement for successful future drug development. (793)

Many patients prefer noninvasive therapies (794), and it would seem reasonable to start with physical therapy and/or oral or intravesical therapies as per patient preference if conservative non-medical interventions (i.e. education, diet, behavioral modification, stress reduction) fail to result in significant symptom amelioration. Use of surgical therapies should be approached with some caution. It has been reported that women with IC/BPS have had significantly more pelvic surgeries than controls, and the majority were performed prior to diagnosis of BPS, possibly for pain related to undiagnosed BPS. (795,796). This is one of many health disorders where patient education is critical and allows the patient to be instrumental in developing a personalized treatment algorithm that they can modify based on their ongoing quality of life.

Two major constructions may provide the foundation for the basic principles of management.

The first is the early diagnosis of Hunner lesion disease through local cystoscopy or cystoscopy under sedation with bladder distention. This changes the treatment algorithm and can provide an initial surgical option through direct treatment of the lesion that yields generally reliable good clinical results, albeit not permanent. (20,29,32) . These results may surpass those in patients with unremarkable histopathological findings on cystoscopy and biopsy. (797)

The second is the natural history of interstitial cystitis/bladder pain syndrome. Up to one half of all patients may exhibit symptom improvement with time, with or without regular follow-up and receiving a new treatment. (4,5). Symptom duration is associated with more severe symptoms only in limited populations. Symptom duration is not associated with risk for chronic overlapping pain comorbidities or mental health comorbidities (76,134). To the extent we can prevent catastrophizing we can expect less long-term pain symptoms. (133,798)

As no single treatment works well over time for a majority of patients, the treatment approach should be tailored to the specific symptoms of each patient and a multidisciplinary approach may be required with input from primary care providers, registered dietitians, physical therapists, pain specialists, gastroenterologists, and gynecologists and urologists with expertise in management. (799)

Time tends to be the ally of the patient and the provider. It does not make sense to throw a wide variety of treatments at the patient immediately upon determining the diagnosis. There is no long-term advantage, and one loses the benefit of the often-salutary natural history of the disorder, prone to symptoms waxing and waning. If your initial multimodality therapy is ineffective, the practitioner has nowhere to go but more invasive and possibly more morbid therapies that may or may not relieve symptoms. It is better to follow conservative principles, allay patient anxiety and catastrophizing, and begin a specific intervention, adding to it if necessary or substituting another therapy if it is ineffective.

Treatment strategies should proceed from conservative to less conservative in the majority of patients. Of course, symptom severity, clinician judgment, and patient preference will play key roles in the decision as to where in the algorithm to begin therapy. In the rare instance when an end-stage small, fibrotic bladder has been confirmed and the patient's quality of life suggests a positive risk-benefit ratio for major surgery, reconstructive surgery can be considered early in the algorithm. Pain management should be continually assessed in all patients.

XXII. MAJOR FINDINGS FROM THE MAPP RESEARCH NETWORK

The Multidisciplinary Approach to the Study of Chronic Pelvic Pain (MAPP) Research Network was established by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), National Institutes of Health (NIH), to study IC/BPS and chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS). For research purposes, these conditions are collectively referred to as urologic chronic pelvic pain syndrome (UCPPS) (800). The MAPP Network includes investigators with diverse clinical and research expertise, including in urology, gynecology, non-urologic chronic pain conditions, epidemiology, biostatistics, molecular and cellular biology, neurobiology, psychology and psychometrics, microbiology, and basic science pre-clinical animal models, among others. The group uses this multi-disciplinary expertise to promote a systemic characterization of UCPPS that extends beyond a sole focus on the urologic system to include a broad scope of potential physiological contributors.

During its first phase (MAPP I, 2009-2014), the MAPP Network characterized 424 UCPPS patient participants (233 females and 191 males with a clinical diagnosis of IC/BPS or CP/CPPS) in a central 12-month prospective cohort study (801). This study design was observational ('treated natural history') with the participant's physician managing clinical care, including prescribing treatment. Participants were assessed in an initial baseline "deep phenotyping" session that included numerous urologic and non-urologic patient-reported measures to determine symptom profiles, a physical exam, quantitative measures of pain sensitivity, and neuroimaging (via fMRI) to examine central nervous system structure/function, as well as collection of diverse biological samples for characterization of biomarker and microbiome profiles. UCPPS participants were followed prospectively for one year with additional in-clinic data and samples collection and on-line patient-report assessments to compare baseline factors to clinical phenotype and changes in underlying biology over time. In addition, 415 healthy control and 200 "positive control" (i.e., patients with diagnosed non-urologic chronic overlapping pain conditions [COPCs]) participants were characterized through an identical baseline deep-phenotyping visit. To complement the clinical studies investigators developed relevant animal models for UCPPS to test hypotheses on pathophysiology and provide a platform for in vivo studies based on MAPP Network clinical insights. All studies were highly-integrated to promote a systemic characterization of UCPPS and designed to address the MAPP Network's central goals of providing an improved evidence-foundation for development of future clinical studies, and ultimately to improve clinical management. In the second phase of this program (MAPP II, 2014-2022), the Network is characterizing UCPPS patient participants at baseline and during an extended 36-month observational period, as part of the Trans-MAPP Symptom Patterns Study (SPS) protocol. This study is in progress and will expand the patient phenotyping greatly from the first phase.

A detailed summary of the MAPP network findings to date has been published (802). Below is a brief summary of some of the potential clinical implications of these findings.

Multimodal Management. A high percentage of UCPPS participants had accompanying non-urologic COPCs, which suggests an important role for multimodal management and the frequent need for therapies that extend beyond the pelvic viscera. This finding also raises the question whether patients would do best managed in medical environments capable of addressing these varied needs, i.e., "Centers of Excellence."

Prognosis. MAPP Network studies have provided novel insights into symptom severity in UCPPS patients, finding that those afflicted with COPCs such as IBS, CFS, and FMS frequently endorse the highest pain severity and, perhaps not unexpectedly, have a higher risk of depression and anxiety. This information is critically important for the clinician from the perspective of identifying other "therapeutic targets" and patient counseling. Improved prognosis of UCPPS patient's symptoms over time (e.g., likelihood of worsening or improving) is one of the major clinical goals of the MAPP Network and is being further addressed in the extended observational period in the MAPP II study.

Etiological crossover. In standard urological practice, there is a tendency for men presenting with pelvic pain of unknown etiology to be classified within the general context of "prostatitis" (Prostatitis Type III, CP/CPPS), a condition associated with limited effective therapies. Data generated within the MAPP Network reveal a strikingly high prevalence of painful bladder filling and/or painful urinary urgency in male participants, suggesting a clinical and perhaps etiological crossover between IC/BPS (predominately female) and CP/CPPS (male). This finding illustrates the importance for clinicians to query male patients with chronic pelvic pain about bladder symptoms, as an affirmative response may lead to a change in diagnosis and subsequent therapy.

Urological Pain & Urinary Urgency-Frequency Outcomes. To date, it has been common to combine pain, irritative voiding symptoms, and other measurements, such as quality of life, together to derive a composite score and use that to assess outcomes of clinical trials and track clinical progress. One of the most important findings of MAPP I is that this approach may not be appropriate. The MAPP Network has shown urological pain and urinary urgency/frequency each have a different impact and severity pattern over time, and thus should be assessed separately in UCPPS patients in both a research and potentially clinical setting. This has major implications for the design of research studies and in terms of how clinicians follow patients in standard practice. Just as important, new instruments based upon these findings may impact how outcomes (i.e., improvement) are assessed and patient cohorts screened in future clinical trials.

Symptom Flares. Once a diagnosis of UCPPS has been made, clinicians typically begin therapy to treat pain that is known to be chronic, but is often assumed to be stable in severity and character. MAPP Network symptom flare data has dispelled this traditional notion by demonstrating that flares occur in almost all patients with widely differing frequencies, severities, durations, symptoms, and triggers. The finding that flares are common and can have a very profound psychosocial impact strongly suggests they need to be a priority in clinical evaluation and management. An understanding of flare characteristics can be helpful to selection of therapy emphasizing mitigation of flare-specific symptoms. For example, factors that trigger symptom flares (e.g., foods, beverages, physical activity) may need to be modified in a patient-centric manner and as part of a systemic approach to management. In addition, individualized strategies for addressing flares need to be developed based on an understanding of the patient experience rather than preconceived approaches. These therapies may be as simple as a warm bath or control of constipation to more aggressive interventions such as intravesical instillations.

Psychosocial Dysfunction. One of the primary clinical goals for UCPPS patients is to improve their quality of life. Many clinicians (and patients) make the assumption that once symptoms improve, the quality of life will similarly improve. MAPP Network findings

have demonstrated that this may not be the case if the patient has substantial coexisting psychosocial comorbidities or severe non-urologic pain. Furthermore, psychosocial dysfunction (i.e., depression, anxiety, catastrophizing behaviors) was more commonly identified in patients with co-morbid non-urological symptoms and was associated with more severe UCPPS symptoms. Therefore, we may need place greater emphasis on early identification and treatment of non-urologic symptoms and psychosocial dysfunction as separate and exacerbating clinical factors in UCPPS.

Pain – Centrally acting Therapies. MAPP Network insights into structural and functional brain changes in UCPPS have revealed similarities to other chronic pain syndromes and confirm that the pain some UCPPS patients experience is more complex than simply neuropathy localized to the pelvis. Importantly, these observations may explain the frequent favorable response to centrally acting therapies for some UCPPS patients (being investigated further in ongoing MAPP II studies) and provide potential new targets for future medical or even surgical interventions. In MAPP I studies quantitative sensory testing (QST) has demonstrated global pain processing abnormalities in UCPPS patients, particularly notable in those UCPPS patients with concomitant pain beyond the pelvis. While the potential utility of neuroimaging approaches in clinical management (versus research studies) will need to be further weighed, QST is relatively simple to apply and may ultimately be useful for clinical use to phenotype patients for selective therapies.

Biomarker anomalies for diagnostic algorithms. Although not yet validated for clinical use, the development of biomarkers for UCPPS in the MAPP Network is showing promise with initial studies showing correlation between markers (such as toll-like receptors) and distinct clinical features. Identification of subgroup of UCPPS patients who over- or under-express specific biomarkers (or a panel of biomarkers) may help us understand underlying mechanism, identify new molecular targets, predict responsiveness to therapies, and may add predictive value to UCPPS diagnostic algorithms in the future.

Antibiotic Stewardship. The majority of UCPPS patients have had multiple unsuccessful empiric courses of antibiotics throughout their clinical history without improvement in symptoms. Therefore, routine use of antibiotics in the absence of an identified infection is discouraged. Newer molecular-based techniques used in the MAPP Network have the potential to uncover a wide range of organisms in UCPPS patients that would be missed using standard culture methods. The identification of new bacterial genre, as well as any changes in microbial diversity between patients and healthy individuals or between patients with distinct symptom profiles holds great promise in characterizing new host-microbial relationships in UCPPS. These insights may promote new approaches to treatment or prophylaxis in some patients.

XXIII. FUTURE DIRECTIONS IN RESEARCH

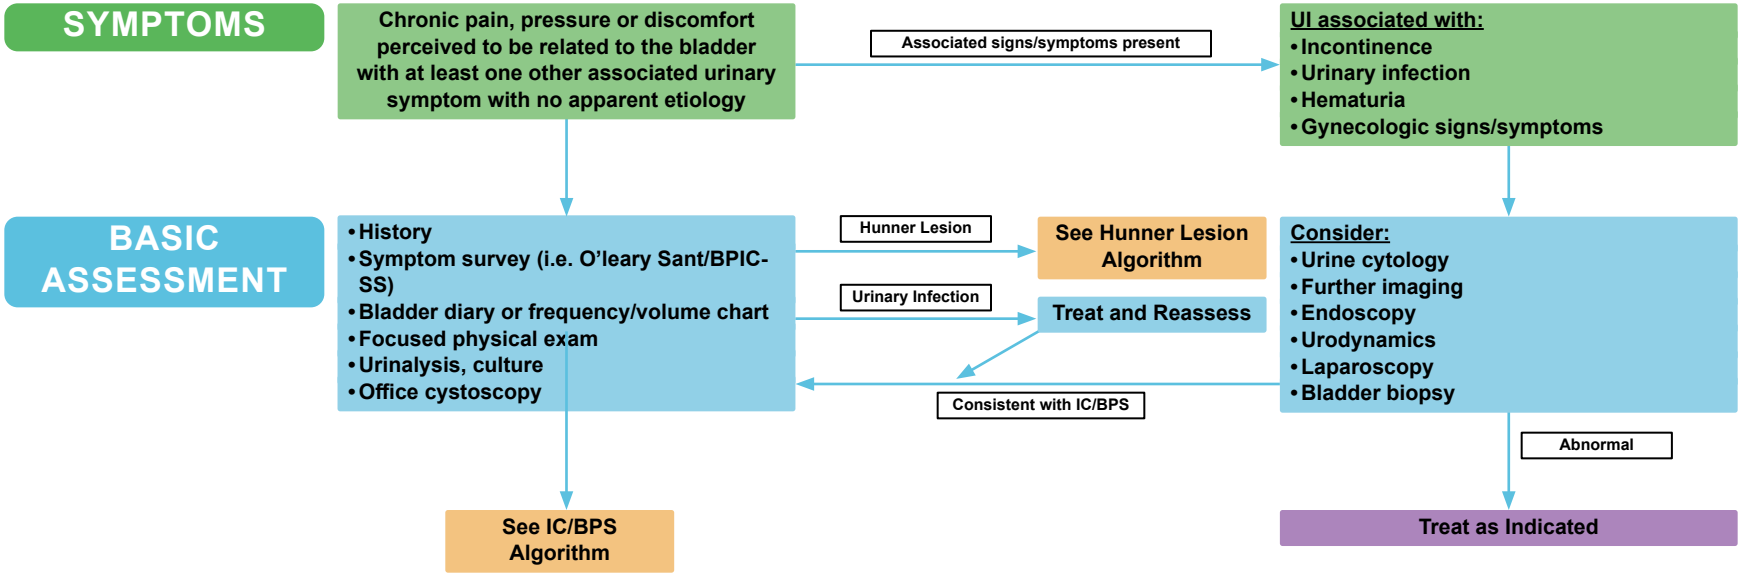
The committee believes that further research is needed in many broad areas:

1. Pathology of IC/BPS
2. Biomarker development
3. Immunology of IC/BPS
4. Neurological aspects with particular attention to the relationship of IC/BPS to overactive bladder
5. The relationship of IC/BPS to chronic prostatitis/ chronic pelvic pain syndrome in men

The following specific issues would benefit from major research initiatives:

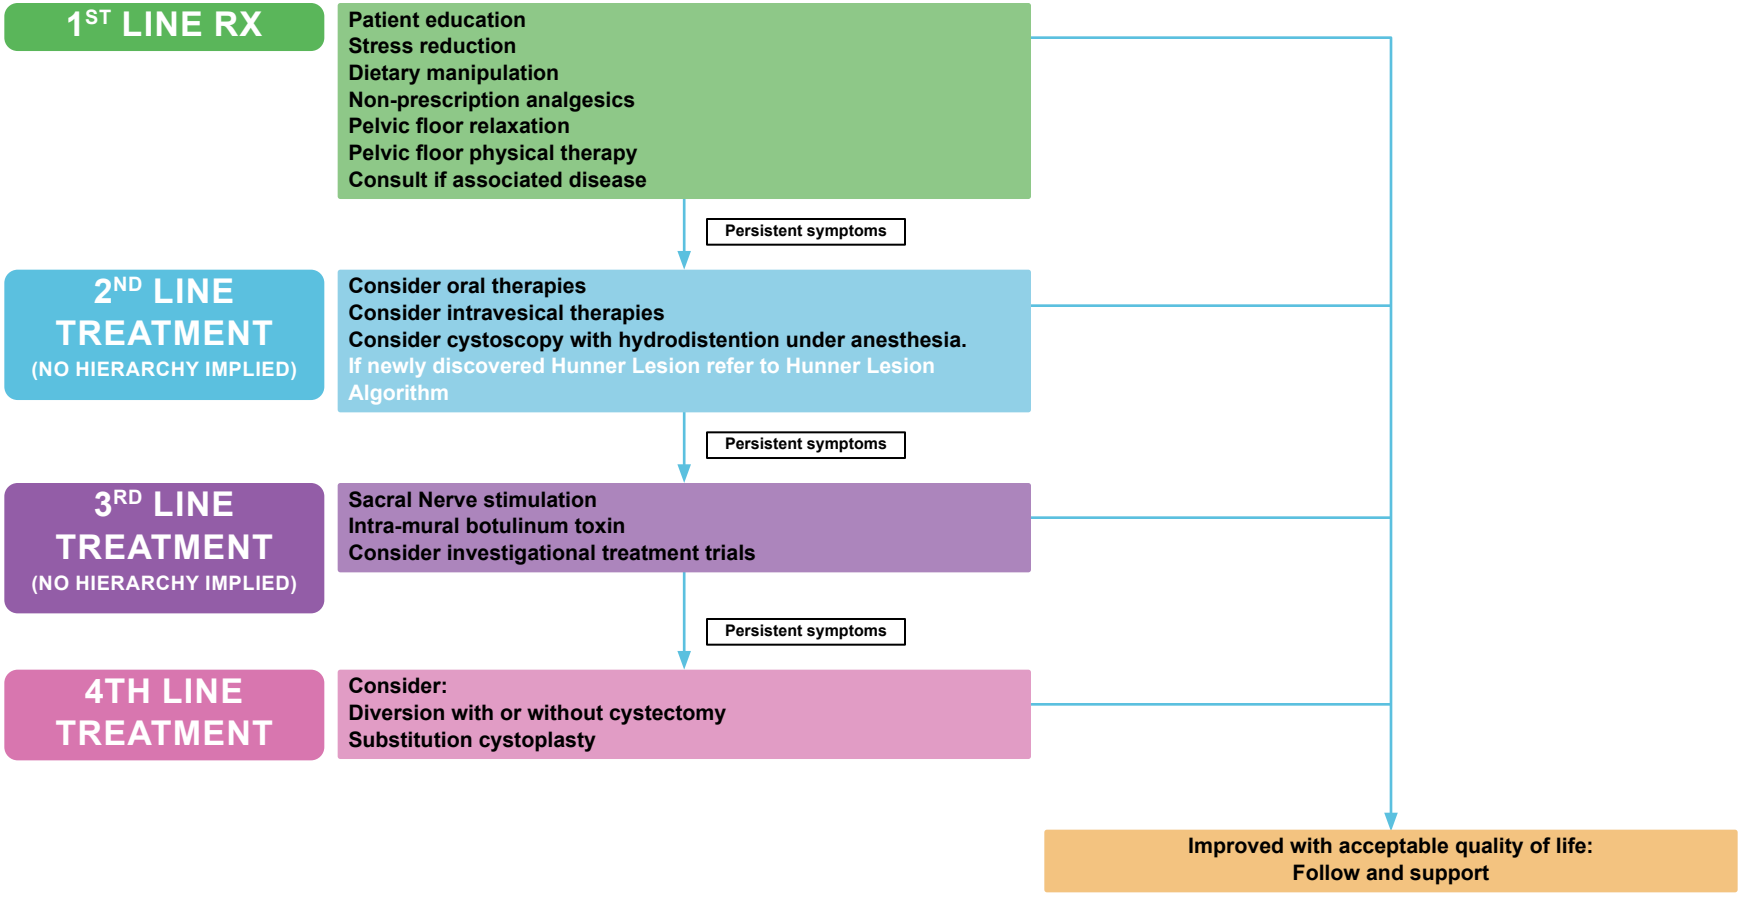
1. To improve symptom-based classification to identify the degree of bladder and non-bladder symptoms.
2. To identify bladder-specific pathology (urothelial changes, ulcer, hypervascularity and the potential role of narrow band imaging (803). Does the degree of true bladder inflammation correlate with results from specific treatments? Are there other markers that could be used to segregate therapeutic approaches? For the diagnosis of a Hunner lesion, using a cystoscope is indispensable. Checking for Hunner lesions using narrow band imaging has been reported to be useful and could improve diagnostic accuracy of Hunner lesions.
3. Further consensus to bridge the Asian concept of the hypersensitive bladder with the Western concept of bladder pain syndrome must continue.
4. To identify a bladder pain syndrome-specific biomarker (NGF or other neurotrophic factors, angiogenic growth factors, urothelial markers such as antiproliferative factor, cytokines/ chemokines profile, uroplakin [antibody, splice variant]).
5. To identify bladder-specific or systemic immunological processes (cytokines/chemokines profile). Such research may also help to identify the difference in the disease process between bladder pain syndrome and over active bladder (lower urinary tract symptoms with and without pain, respectively).
6. If we can identify the “bladder-related” and “nonbladder” (=outside the bladder) components that contribute to the symptoms, we should be able to develop the agent(s) to control bladder pain based on its pathology.
7. Establish patient data bases in different regions and conduct longitudinal follow-up to understand the natural history of the disease and to examine the differences in disease natural history among regions.
8. Develop an easy-to-use tool for non-specialists to readily identify co-morbid conditions that may impact on the need for additional consultation and suggest specific treatment pathways.
9. Develop a simple, non-invasive diagnostic test for IC/BPS.
10. Develop a practical multi-disciplinary care model and test it in various settings. This would include psychological interventions for those with psychological comorbidities, dieticians, physiotherapists, pain specialists, and patient support groups in addition to a specialist for any associated non-bladder related disorders.
11. Study the clinical utility of psychological screening tools in phenotyping and how this might impact clinical outcomes
12. Develop a screening tool to accurately identify HLD based on clinical and non-invasive factors.
13. Establish what role if any intravesical lidocaine has in diagnosis and phenotyping
14. Develop science-based recommendations to maximize the benefit of dietary modification in preventing and alleviating symptoms.

DIAGNOSIS: INTERSTITIAL CYSTITIS/ BLADDER PAIN SYNDROME (IC/BPS), HUNNER LESION DISEASE (HLD)



Algorithm for Diagnosis/C/BPS and HLD symptom complex: 2023 International Consultation an Incontinence.
Early cystoscopy is recommended to differentiate IC/BPS syndrome from MLD.

TREATMENT: INTERSTITIAL CYSTITIS/ BLADDER PAIN SYNDROME (IC/BPS)



- Pain management is a primary consideration at every step of the algorithm
- Patient enrollment in an appropriate research trial is a reasonable option at any point
- Consultation with a provider experienced in treating IC/BPS and Hunner lesion disease should be considered
- Only DMSO and pentosan polysulfate are approved by FDA for IC/BPS Indication

HUNNER LESION DISEASE

A. INTRODUCTION

Not all bladder or bowel incontinence problems can be cured completely, and the challenge for those whose symptoms persist is to discover how to deal with incontinence to minimise its impact on their quality of life. This usually includes using continence products.

Our definition of products for the management of continence are those that that either enable the containment of bladder or bowel leakage (either inside or outside the body) or drain the bladder, including associated accessories and strategies to optimise use or reduce harm. Conservative interventions designed to **treat** symptoms (e.g., pelvic floor trainers) are included in Chapter 8 and in other chapters relevant to the patient group e.g., Frail Older Adults.

Even those whose incontinence is ultimately treated successfully may have to live with symptoms for a time - for example, while they wait for surgery or pelvic floor muscle training to yield its benefits – and they may temporarily use continence products during this waiting period. Others may use them as an adjunct to a treatment that reduces their leakage without eliminating it. Still, others may use products intermittently, limiting their use to periods or activities associated with troublesome leakage. However, some use products permanently, either following treatment that has not been (completely) successful or depending on their frailty, severity of symptoms and personal priorities – they are not candidates for treatment aimed to cure.

Successful incontinence management with products is often referred to as contained incontinence, managed incontinence or social continence, in recognition of the substantial benefits it can bring to quality of life even though a cure has not been achieved (1). A complete cure is not possible for many people who may continue to rely on containment products (2).

A wide variety of continence products exists, and the choice can be confusing. In this chapter, the goal is to provide the current evidence for healthcare professionals to make informed decisions as they choose – or help product users choose - between continence product categories and the most appropriate product(s) within a category. We have also aimed to make this information directly accessible to users.

In Section B this chapter provides overall guidelines for selecting products to assist with toileting, prevent or contain leakage, or address urinary retention, as well as those for incontinence-related skin and odour problems. The key elements of patient assessment are described, and classification of people into broad groups is suggested based on sex and gender , adult or child and the nature and severity of their incontinence. Each of the major product categories is then addressed (Sections D-P), and where possible - evidence-based recommendations for product selection and use are given. When little or no published data are available, expert opinion forms the basis of recommendations. Tables are provided summarising the user characteristics, priorities and contexts that commonly favour or discourage the use of each of the major product categories available. The chapter also includes (Section C) a review of the methodological challenges of conducting continence product evaluations and interpreting the results. The literature search strategy adopted for the chapter is described in Appendix 1.

In most product categories there are numerous different product designs for which there are no published data. Many are available for purchase by consumers without input from a healthcare professional. Even products that have received regulatory approval and are available through healthcare systems may have only been assessed for manufacturing processes and/or safety, depending on regulatory body requirements. Many products are therefore available without evidence of efficacy

Overall recommendation

- Our main message is that continence is often best managed by a 'mix' of different products – often used at different times or for different activities (day/night/home/away/sport). One product is unlikely to be effective for all occasions.
- To assist this, the International Consultation on Incontinence and the International Continence Society (ICS) have collaborated to make the material more accessible via a website hosted by the ICS at http://www.continenceproductadvisor.org. This interactive website provides current evidence to healthcare professionals and users to facilitate informed choices in selecting appropriate products and accessible, evidence-based advice on how to use them to best effect

B. OVERALL GUIDELINES FOR SELECTING CONTINENCE PRODUCTS

Suitable continence products are critical for the well-being and quality of life of product users and their caregivers. Sufficient concealment enables people with incontinence to protect their public identity as a "continent person" and avoid the stigma associated with incontinence (3, 4). Failure to do so can result in limited social and professional opportunities, jeopardise relationships and detrimentally affect emotional and mental well-being (5). Importantly, caregivers need to feel confident that the person(s) they care for will not be embarrassed publicly. Good product choice / use also

reduces the care level required to maintain hygiene, skincare, and laundry (6).

The intimate and stigmatised nature of incontinence means that issues relating to self-image can affect users' preferences when selecting products. This may be marked in younger people for whom body image may be significant and for whom disruption to normal social and interpersonal development may result in isolation or lack of access to normal experiences (7) (8). A key measure of product success is the ability to conceal the problem (9), and concealment may involve compromises: at times, the added reliability of products with a larger capacity than is strictly necessary may be preferred even though they may be less discreet when worn.

The range of products available can vary enormously between and within countries, depending on the funding available, healthcare policy, and supply logistics. In publicly funded healthcare systems, some products may be provided free of charge, based on cost-sharing policy, or reimbursed by insurers, whereas, in others, no support is available, and consumers must pay out-of-pocket. Additionally, the provision of continence services is not considered a priority by health system administrators in most countries, and this is especially true in developing countries (10) (11) (12) (13). In this context, this chapter and accompanying website form a useful resource that can foster greater awareness of product choice and help clinicians and users identify products that, although not readily available locally, may be sourced elsewhere.

1. PRODUCT CATEGORIES

Apart from those for addressing incontinence-related skin and odour problems, all the products described in this chapter can be categorised as in Fig B-1, according to whether they are designed to: (i) assist with toileting; (ii) help manage urinary retention; or (iii) prevent/contain urinary or faecal incontinence.

All toileting products can be useful for dealing with urine and/ or faeces except for handheld urinals which are just for urine. Containment/control products are subdivided into three overlapping classes: for urinary retention, urinary incontinence, and faecal incontinence. For example, someone with urinary retention is most likely to benefit from one of the products in the red ellipse (Fig B-1), while someone with urinary incontinence will most likely benefit from one in the blue ellipse. A patient experiencing both problems will need two products (one from each ellipse) or one product from the intersection of the two ellipses.

2. ASSESSMENT FACTORS

Assessment of a user's physical characteristics - such as anthropometrics, level of independence, mobility and dexterity, level of cognition and the underlying nature of the incontinence - will help determine the best product(s) for them. In addition, other practical and psychosocial considerations include user participation in selection (14), provision of adequate instructions for use (15) and the need for products to fulfil their function reliably and easily (7) (15) (16). The nature of the environments in which the products will be used, and the availability of caregivers are other important factors. Table B-1 summarises the key assessment elements although no evidence-based assessment tool exists. Specific guidance on assessment is provided within the subsections of this chapter.

Personal preference is known to play a substantial role in product selection (e.g. (17) and (18)), and information on the range of products that may suit an individual is important so that appropriate choices may be made. Education of users and / or caregivers is key to ensuring product use is optimal; this may range from straightforward instruction in the effective fitting and changing of absorbent products to more in-depth training in the ongoing care of, for example, a suprapubic catheter.

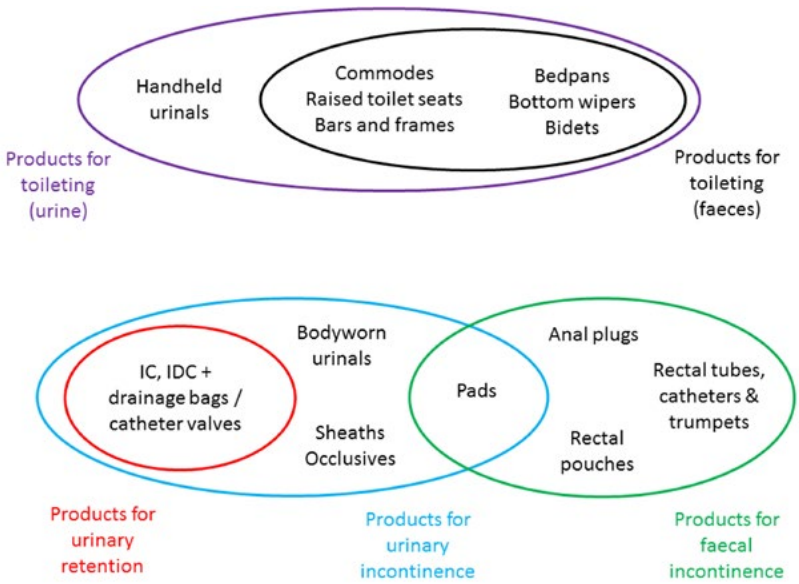

Fig B-1: Products for toileting (top) and for managing incontinence and / or urinary retention (bottom).

Table B-1: Key elements of assessing a patient and his / her environment

Element	Rationale
Nature of the continence problem	The frequency, volume, and flow rate of the incontinence influences product suitability.
Sex & Gender	Males may consider and prefer sheaths as a more masculine option to pads. Females may be attracted to products that are more feminine in design and presentation. Some 'unisex' products like absorbent pads have different designs that work better for men (or women).
Physical characteristics	Anthropometrics (e.g., height and waist, thigh, penile circumference) will influence the comfort and effectiveness of a product.
Cognition	Cognitive impairment can affect the person's ability to manage the product. Products that resemble usual underwear (e.g., some absorbents) may be easiest to manage. Products that have health implications if used incorrectly (e.g., mechanical devices or catheter valves) should be avoided if cognitive impairment is likely to preclude correct and safe use.
Mobility	Impaired mobility may make some product choices impractical or require toilet or clothing modification to use the product effectively.
Dexterity	Problems with hand or finger movement can make it challenging to use some products (e.g., taps on leg bags, straps with buttons).
Eyesight	Impaired eyesight limits effective application and management of some products
Leg abduction problems	Difficulty with abduction can make the use of some products impractical or ineffective.
Lifestyle and environment	Daily activities and environment can influence product choice; a mixture of products may provide optimum management. Different products may be most satisfactory for daytime and going out (when discreetness may be a priority) and night-time or staying in (when comfort may be a priority), for holidays (when laundry and / or large quantities of disposables may be a problem) or for use at work. The proximity and accessibility to a toilet may be key.
Independence / assistance	If a caregiver is required to apply or change the product, it may be important to involve them in selecting it and establishing their willingness and ability to use it.
Laundry facilities	Washable pads and bed linen may be very heavy when wet and take a long time to dry. It is important to check that the person doing the laundry has the ability and facilities to cope.
Disposal facilities	The ability to dispose of the selected products appropriately, safely, and discreetly needs to be considered.
Storage facilities	Some products – notably, pads for heavy incontinence – can be bulky. Adequate space to store supplies between deliveries / purchases needs to be available.
Personal preferences	Different people like different products, and where possible, patients should be given a choice of products with which to experiment to determine the most satisfactory product.
Personal priorities	Everyone wants to avoid leakage, but other factors such as discreetness may be more or less important to individuals or vary according to different contexts and activities.

3. MAIN USER GROUPS

Seven primary user groups are identified in this chapter:
- People with urinary retention.
- People who need help with toileting / toilet access.
- Females with light urinary incontinence.
- Males with light urinary incontinence.
- Females with moderate / heavy urinary incontinence.
- Males with moderate / heavy urinary incontinence.
- People with faecal incontinence.

An individual may belong to more than one group. Each group includes children and young people: their products are broadly similar to those for adults.

4. CHOOSING BETWEEN PRODUCT CATEGORIES

Tables summarising the user characteristics, priorities, and contexts that favour or discourage using each of the product categories for six of the seven user groups are available in the 6th edition of ICI (19) and a user-friendly format on the www.continenceproductadvisor.org website. Assistance with choosing appropriate products for the first group (people with urinary retention) is given in Section L - indwelling catheters and Section M - intermittent catheters.

The same product will not necessarily suit all people, even if the result of their assessment is similar. Thus, providing access to a range of products to test will help determine the most satisfactory choice. Similarly, priorities vary between users; for example, some will opt for a bulky, less discreet pad to achieve an acceptably low risk of leakage, while others will see the balance differently. Choosing between products or strategies can be complex. A product decision aid to help users and healthcare professionals choose between products has been developed (20) and incorporated into the continence product advisor website. Other relevant aids to decision-making include a support tool, developed through expert consensus, to assist non-specialist healthcare professionals to identify factors to help identify appropriate incontinence care options (19).

A mix of products drawn from more than one category may provide the best solution; for example, needs may vary between day / night or home / away.

5. SUMMARY

Continence products can play an important role in enhancing the quality of life and reducing the stigma of incontinence of those who are awaiting treatment; are waiting for treatment to take effect; elect not to pursue cure options; are unable to be fully cured and are living with an ongoing bladder / bowel problem.

6. RECOMMENDATIONS

- Users often require / prefer a mix of different products for use at different times and for different activities to achieve optimum management **Grade of recommendation C**
- Incontinence should be actively managed with products to minimise the impact of incontinence on quality of life **Grade of Recommendation C**.
- Users should be carefully assessed (and reassessed periodically) to select the most appropriate products **Grade of Recommendation C**.
- Users should be offered a range of products that are appropriate for their needs so that they can make informed choices. **Grade of Recommendation C.**

C. PRODUCT EVALUATION METHODS

This section aims to assist those planning clinical trials of products. There have been relatively few large clinical trials of continence products, and for most product categories, research evidence to guide the selection of individual products / designs / features is limited and, in some cases, absent.

Measuring the performance of continence products is challenging. Manufacturers modify and change their products regularly - in terms of both materials and designs - and this limits the long-term validity of research results. There are also complex issues regarding research questions, study design, product representation, blinding, and sample size (20), which are discussed below.

1. METHODOLOGICAL CHALLENGES

Part of the complexity of product evaluations stems from the sheer number of product categories and brands available, meaning that many different comparisons could be made. Table C-1 illustrates the problem using a hierarchy of questions relating to absorbent products. So, in this example, once the decision is made to choose an absorbent product in response to question 1, successive further questions can be used to narrow the choice to a specific product brand. Questions at any of these levels may form the basis for research projects.

In the field of absorbent products, the practitioner and / or patient wishes to know whether to use an underpad or a bodyworn product, a reusable or a disposable, a diaper or an insert (if they select a bodyworn), a diaper with internal elastication (standing gathers) or without and, finally, which of the many diaper brands is likely to suit them best. This final question is the most pertinent for the practitioner (who may already have made decisions about questions 1-4, Table C-1), but it is particularly problematic because of the high rate of product change. By the time the results of a clinical trial of product brands are known, many test products will have been modified, and the results will have limited value for selection. However, these 'single design' studies do have value in demonstrating the range of performance between the brands within a product design category, and where objective measurements can be made (for example, of leakage performance), they can allow for comparisons to be made. Single design studies are also helpful in promoting product improvement by revealing common problems experienced by patients and exposing particularly poor products or poor product features which are amenable to change by manufacturers.

Table C-1: Levels of research questions

1. Which product category (e.g. catheter, sheath, absorbent pad)?
2. Which design of product design (e.g. pull-up or diaper design of pad)?
3. Which material type (e.g. reusable or disposable)?
4. Which features (e.g. with / without elastic gathers)?
5. Which product brand?

Overall product designs, generic features and classes of materials change much less frequently and attempting to answer questions 1-4 (Table C-1) is likely to lead to more long-lasting results with value beyond the lifetime of the brands tested. Many researchers have attempted such studies, but these have frequently been confounded by problems with product representation.

The single greatest (and most frequently overlooked) threat to the validity of clinical trials of products is the selection of the brands entered into the study to represent the various designs. Evaluations of several product variants of a similar design (e.g. different brands) have shown that patient 'overall opinion' scores can vary by as much as 70 percentage points between apparently similar products (21). Accordingly, in an evaluation to compare different designs, the selection of one or more products to represent each design is crucial. Studies that have purported to compare different designs or materials have often included a small number (most often just one) of arbitrarily selected product(s). Generalising the results of such studies to whole product groups (e.g. reusable underpads, or disposable bodyworns) is meaningless and misleading. It is perfectly possible to select (either by accident or design) a particularly 'good' product from one group and a particularly 'poor' product from another. Therefore, a well-designed study will be seriously flawed if there is no clear process or pilot study to determine and justify the choice of particular brands. Even with a systematic process of product selection (or preferably a pilot study), it is unwise to select a single brand to represent a whole group of products, and selecting a small group of brands (e.g. three) is preferable. This allows for any 'within group' differences to be detected and helps to demonstrate the 'representativeness' of the products selected.

The most controlled method of testing different designs, materials or features of products is to make up experimental batches that differ only in the aspect of interest (e.g. the material or the feature), and a small number of studies have attempted this (21) (22). However, experimentally made products are not usually identical to those available on the market, limiting their product selection value.

It is common for practitioners to be asked (by their employers or companies) to do a small evaluation or trial – sometimes to 'test out' a new product and sometimes to help choose between competing brands for bulk buying. Such trials should be approached with caution; they can be very demanding, and their results may be of very limited value, even for local use. The methodological challenges identified above still apply but are compounded by the small sample size and restricted product selection. These studies are likely to be helpful only for identifying gross product shortcomings or benefits.

2. RESEARCH DESIGN

A randomised controlled trial is not possible for clinical trials of products in most categories simply because a 'control' product does not usually exist. Nor is there a 'standard or reference' product to act as a control, and comparisons with 'standard practice' (i.e. the product currently in use) are prone to bias.

Although it is methodologically simpler (and more robust) to compare only two different product groups, it is more clinically relevant to compare several competing groups using a multiple cross-over design, with valid comparisons. For example, there are four main design groups of disposable bodyworn pads for moderate / heavy incontinence (inserts, diapers, pull-ups and T-shaped). Evaluation of all four groups together is much faster (and therefore gives more long-lasting results) and more cost-effective than several serial studies. Cross-over trials are vulnerable to order effects, and randomisation of the testing order should be carried out using Latin squares (23) to ensure balance.

It is important that clinical trials of single designs of products (which aim to enable selection of particular product brands) are comprehensive (i.e. cover all the available products) because otherwise, manufacturers can justifiably claim that, although their product may be similar to one of those tested, even subtle distinctions may lead to clinically important differences.

A further problem with research design is the blinding of products. Different products have different appearances, and it is impossible to blind subjects or staff to the product in use. Products can be repackaged to assist anonymising, but this may have unwanted effects on the products and is expensive.

Previous product experience can also affect study results, particularly if a substantial proportion of subjects are currently using one of the brands included in the study. Therefore, it is important to record which products are in current use to add this data to the model used in the analysis.

2.1. Sample size and study power

Studies that include more than two products (or two small groups of products) will need to be powered to make multiple comparisons. As the number of products included in the study increases, the number of possible comparisons of pairs of products rises. This requires a corresponding reduction in the significance level (e.g., using the Bonferroni method for each pair-wise comparison to retain the overall level of significance - usually $p<0.05$). Thus as the total number of pair-wise comparisons increases, the likelihood of a type 2 error (accepting the null hypothesis when it is false) also increases.

Sample sizes, therefore, need to be calculated to allow for each pair-wise comparison. Sample size requirements rise rapidly if each subject does not test each product, and the number of products entered into a study must therefore be limited to avoid subject fatigue. As an example, a clinical trial of four product groups where the primary outcome variable will be binary (e.g. satisfactory / unsatisfactory) will require a sample size of approximately 80 subjects with an alpha of < 0.05 and d (difference) of 20%.

2.2. Outcome variables

Studies of product performance have most frequently used self-report questionnaires at the end of the product test period to assess participant ratings of product performance. Diaries of product-related events such as leakage, laundry generation and product consumption are also commonly included. Users in some absorbent pad studies have been asked to identify and prioritise aspects of product performance (24) (25) (26) to inform questionnaires, and Table C-2 shows the most common aspects of high priority to women with light urinary incontinence (25).

Outcome variables in studies designed to compare catheterisation strategies and / or catheter materials or other design features commonly encompass measures of urinary tract infection, tissue trauma and recurrent catheter encrustation leading to blockage (Section L).

Table C-2: Most common high priority items to women with light incontinence using absorbent products (25).

Daytime: % women (N=99)		**Night-time: % of women (N=81)**	
Hold urine without leaking	83.8	Hold urine without leaking	93.8
Contain smell	75.8	Stay in place	77.8
Stay in place	54.5	Contain smell	54.3
Discreetness	41.1	Comfortable when wet	54.3
Comfort when wet	40.4	To keep skin dry	48.1

Questionnaire items vary depending on the products being tested. For product groups where few studies have been carried out, it is particularly important to tailor questionnaires to user needs by asking study subjects to prioritise items and assess final questionnaires for content and face validity. One study has measured the test retest reliability of a questionnaire to assess sheath performance and found moderately good Kappa scores (around 0.7) when assessing the same sheath twice with four weeks between measurement periods (20).

Skin health, urinary tract infection, pain or discomfort are the main physical health consequences for containment products. Skin health (which can be rated by self-report or by skin inspection) has sometimes been used as the primary outcome variable (e.g. (27)). Urinary tract infection is an important outcome for invasive devices such as catheters, and it has also been used for pads (28).

Although leakage performance is frequently rated as a high priority by product users, good leakage performance is not adequate as a sole measure of patient satisfaction with performance. A single (or multiple) fatal flaw such as poor comfort, bulkiness, or poor fit may cause a product that performs well for leakage to be unacceptable to the patient for other reasons. Accordingly, aggregate measures - which assume that the overall performance of a product can be calculated using a weighted sum of the scores for specific aspects of performance (like comfort and freedom from leakage) -

are ill-advised. Therefore, patient overall opinion or satisfaction with the product should be used as the primary outcome variable (20).

Most incontinence-specific quality of life tools are designed to measure change after interventions to improve incontinence and include urinary symptoms. Therefore, these tools are likely to be insensitive to changes in the quality of life brought about by products designed to contain incontinence rather than reduce or prevent it. However, three quality of life measures have been developed specifically for trials of continence products or long-term catheters; one for absorbent products (29), one for intermittent catheters (30) and one for long-term catheters (31).

3. SUMMARY AND RECOMMENDATIONS

There is little published evidence on which to base summary and recommendations regarding methodology, and so the following summary points are all Level of Evidence 3 / **Grade of Recommendation C**.

- Evaluation of continence products is methodologically complex, and methodological weaknesses have hampered many attempts to provide robust product selection evidence.
- Product representation is critical to providing robust and generalisable data. The selection of products for inclusion in a study should be transparent and systematic. Several products should be included to represent a product group. In particular, care should be taken not to select a particularly good or a particularly poor product to represent a whole class of products.
- Multiple crossover designs are likely to be more efficient than randomised controlled trials for many products (e.g., pads), and therefore sample size estimation needs to consider the multiple comparisons that will be made.
- Outcome variables should include a patient (or caregiver) questionnaire including items that have been established as important to users.
- Diary data should be included to determine leakage performance, skin health, laundry, and product consumption.
- Incidence of urinary tract infection should be included when testing invasive devices such as catheters, but “significant” UTI/ bacteriuria must be carefully defined (Section L).
- The primary outcome variables should be patient overall opinion / satisfaction and patient preference.
- Health economics should be measured alongside product performance

4. PRIORITIES FOR RESEARCH

- The development of Quality-of-Life tools for users of continence products.
- Consistent use of a validated product assessment scale.
- Impartial product assessment that compares several products in the same category.

D. HANDHELD URINALS

Handheld urinals are portable devices designed to allow individuals to empty their bladder in circumstances where gaining access to a toilet is not possible or is inconvenient, often due to limited mobility or joint range of motion. To function effectively, handheld urinals must enable the user to empty his/her bladder comfortably, confidently, and without spillage during filling and emptying. Excessive physical effort should not be required. The main factors influencing a user’s capacity to successfully utilise a handheld urinal are listed in Table D-1.

Table D-1: The main factors influencing the capacity of a user to successfully utilise a handheld urinal.

• The position in which it will be used (e.g. lying in bed, sitting on the side of a bed, sitting back in a chair or on its front edge, standing, kneeling, crouching) together with the nature of the surface upon which the individual is being supported.
• The ability of the urinal user to move (with or without aids or assistance) into the required positions.
• Postural control in those positions, together with a hip range of motion, particularly abduction.
• The optimal direction of approach for positioning the urinal (e.g. anterior, posterior, lateral).
• Manual dexterity and strength to adjust clothing, initially position the urinal, maintain its position during voiding, remove the laden urinal post-void and empty or store it somewhere safe to avoid spillage.
• The ability to initiate a void, together with the volume typically voided.
• Cognitive functioning.
• Personal preferences and, where appropriate, the availability of assistance.

Handheld urinals are frequently made from moulded plastic, although single-use cardboard options are available. Some are equipped with handles to facilitate positioning and handling, and some are fitted with drainage bags to collect urine. Urinals designed for women are available in various shapes and sizes (some are quite small and portable), incorporating an interfacing opening that is often anatomically shaped to fit snugly against the woman’s body.

Those intended for men tend to vary less in design, typically having a narrow neck opening to accommodate the penis, and some are fitted with integral non-spill valves or adaptors to prevent the backflow of urine following use (32) (33) (34).

Some men may find that they can make their urinal by recycling household bottles or containers (33). Small, discrete, disposable and re-useable ‘travel’ handheld urinals are available for both men and women (32) (33).

As spillage is not always avoidable during the use of handheld urinals, particularly if supine, the use of absorbent pads to protect furniture, bedding and clothing can be a useful addition (35).

An example selection of products is shown in Fig D-1, Fig D-2 and Fig D-3.

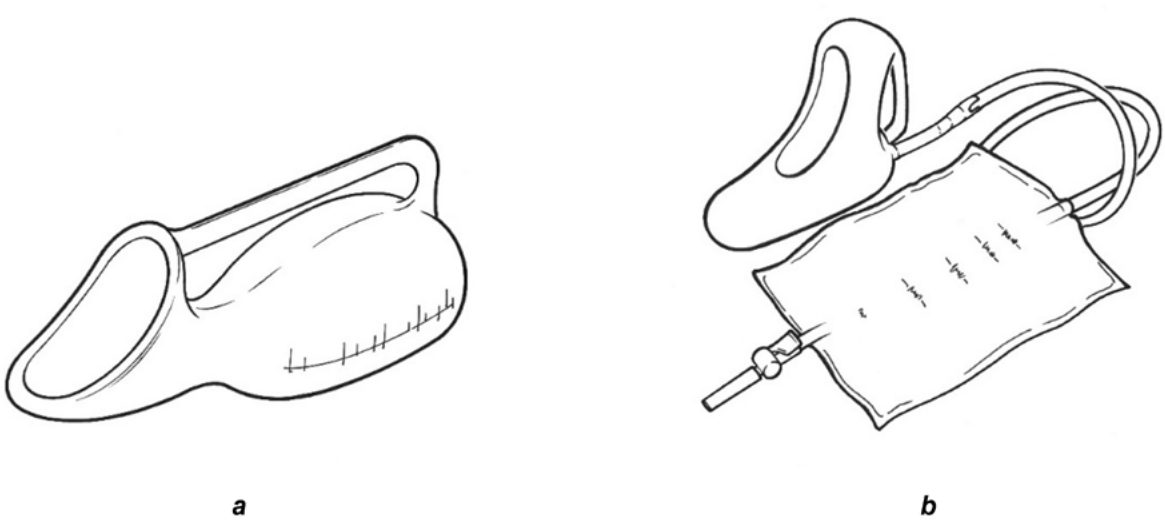

Fig D-1: Female handheld urinal (a) with drainage bag attached (b).

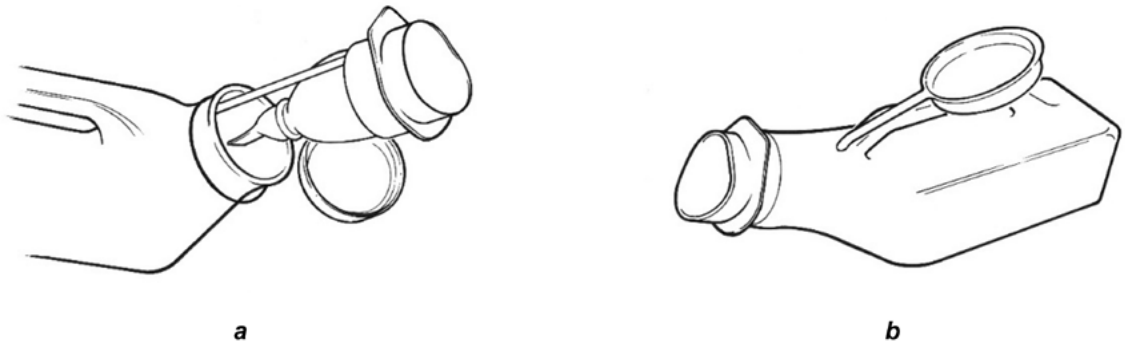

Fig D-2: Male handheld urinal with non-return (anti-spill) valve (a) and without (b).

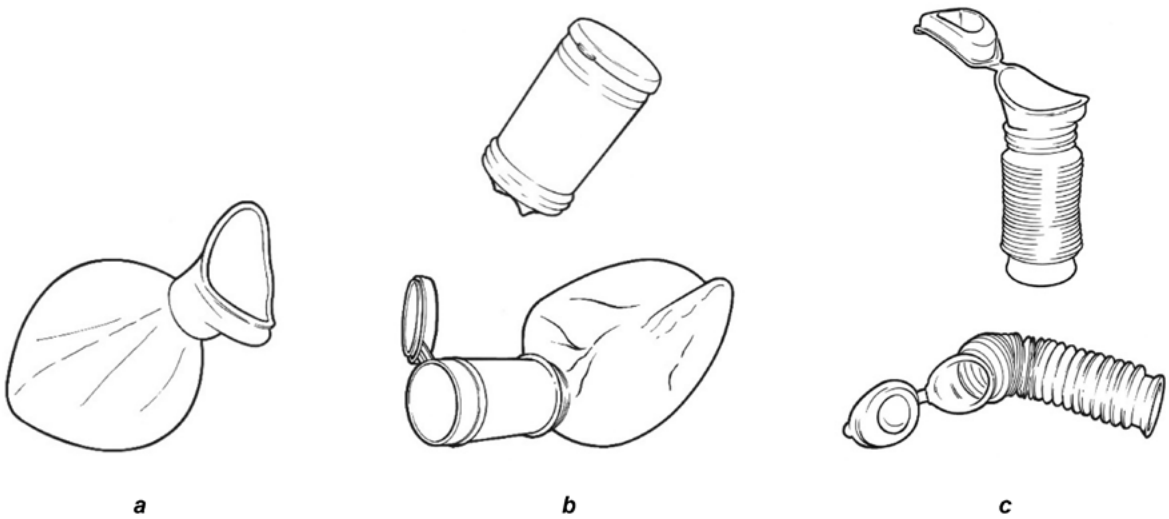

Fig D-3: Collapsible, handheld travel urinals: female (a); male (b) and unisex (c). The male and unisex designs are shown collapsed for storage (top) and ready for use (bottom).

1. EVIDENCE

The 6th International Consultation (36) highlighted a paucity of clinical trials examining the effectiveness of handheld urinals. There were no published trials of male handheld urinals at the time. The single-trial identified (37), involving a multi-centre cross-over evaluation of 13 female urinals, found that no single product suited all users. Many were successfully used when standing, crouching or seated at the edge of a bed/chair/wheelchair, but fewer were successful when seated back in a wheel/chair, and only one was identified to be reasonably effective in a lying / semi-reclined position. Of note, this study highlighted that there were fewer products to meet the needs of women with higher levels of dependence. Other work to develop and evaluate a novel, power-assisted female urinal that pumps urine into a holding reservoir highlighted mixed results in terms of reliability, size, weight, noise and aesthetics (38).

One exploratory study has been identified for inclusion in the current consultation. Farrington *et al.* (39) tested a disposable (pulpable) urinal, the 'Vernafem' with healthy volunteers (n=11), inpatients receiving palliative care on an oncology ward in hospital (n=9) and healthcare professionals (nurses or healthcare assistants) caring for inpatients receiving palliative care on an oncology ward in hospital (n=7). Data were collected through qualitative interviews to explore participant experiences of the urinal. The urinal was found to be acceptable, safe and effective, with many (but not all) participants preferring it to a conventional bedpan. Some design limitations were identified, including the urinal volume's adequacy and difficulties with correctly positioning the urinal. The authors concluded that while unlikely to be suitable for all patients, hospitals should consider offering a female urinal to patients receiving palliative care.

2. SUMMARY

- A super-absorbent polymer can be added to urinals prior to use to absorb and solidify urine (32) (35) (40) **(Level of Evidence 1).**
- Experimentation is often required to identify the optimal urinal for an individual (32) (34) (35) (37) (40) **(Level of Evidence 2).**
- Cleaning of handheld urinals is an important consideration. Cleansing with soap and water may be appropriate between episodes of use by a single individual at home. However, more robust methods that comply with the manufacturer's recommendations and local infection control policies will be necessary where users are multiple (34) (37) (40) (41) **(Level of Evidence 2)**.
- Men with a retracted penis may find that urinals developed primarily with women in mind can work well for them if they can tuck their whole penis and scrotum inside the urinal during use (33) **(Level of Evidence 3)**.
- The careful selection and adaptation of clothing can assist quick and easy use of urinals for both men and women (32) (33) (34) (35) (41) **(Level of Evidence 3)**.
- Expanding the toileting devices available to those in acute care settings to include a wider range of handheld urinals suitable for use by both men and women is recommended (35) (40) **(Level of Evidence 3)**.

3. RECOMMENDATIONS

Recommendations relating to handheld urinals are summarised in Table D-2.

Table D-2: Recommendations relating to handheld urinals.

- Handheld urinals should usefully form one of a range of options available to both men and women to manage their toileting needs, enhancing the quality of life of both the user and (where relevant) their carer(s) **(Grade of Recommendation C)**.
- Experimentation should be allowed to select the most appropriate urinal to meet individual needs and individual circumstances **(Grade of Recommendation C).**
- An individual should be offered different types of handheld urinals to manage in different situations **(Grade of Recommendation C).**

4. PRIORITIES FOR RESEARCH

- Evaluation of currently available male and female urinals to guide users, caregivers, and healthcare professionals.
- Development of the range of female urinals, particularly to meet the needs of those who are less physically able, unable to move to the edge of a bed/chair/wheelchair, and/or need to use a urinal while supine.

E. COMMODES, MOBILE SHOWER-CHAIRS AND BEDPANS

Toileting is a fundamental aspect of continence and personal care. Using conventional toileting facilities is a complex undertaking requiring, for example, core stability, balance, strength, range of movement and cognitive, sensory and perceptual skills to transfer to and from the toilet, adjust clothing, grip and manipulate toilet paper and other menstrual and bowel / bladder management products and adequate wiping or rinsing of the perineal area. Using toilets in public spaces requires locating and arriving at the facility in a timely manner. Gaining access to,and safely utilising, toileting facilities can represent a significant challenge for people with limited or impaired mobility and / or a range of other disabilities. Various strategies, assistive aids, and equipment exist to facilitate ease of access, independence in toileting and continence, and privacy and dignity. These include toilet seat raisers, toilet frames / surrounds, padded toilet seats, grab or support rails, bidets or personal cleansing/drying systems, bottom wipers, etc. (Table E-1), adaptations to clothing (e.g., use of Velcro instead of buttons), and the physical layout of toileting facilities.

Installation of these toileting aids or their latest designs may be lagging in health care facilities, however. A recent analysis of the environment of 20 contemporary nursing homes in Norway (42) revealed that their designs do not facilitate privacy and pose risks for safety; for example, the heights of toilets and sinks were not adjustable, there was inadequate space to place assistive devices such as walkers and canes, and soap, toilet paper holders, and handrails were often out of reach.

Although there is limited research examining the effectiveness of many of these assistive options for promoting continence, occupational therapists are well-positioned to offer individual assessments, including for those in the home setting (43) (44) (45) (46). Furthermore, occupational therapists can make appropriate and reliable prescriptions for the toilet and bathroom areas of patient homes

without the need for an actual home visit, using digital photographs taken by family members, clinical information about the patient, and an equipment list (47). The results of this study completed prior to the community lock-downs during the COVID-19 pandemic are timely and relevant given changes to remote home assessments that were necessary during the pandemic and may continue.

Where an individual cannot access a toilet quickly and safely, conventional, or adapted alternatives - such as commodes, mobile shower chairs and bedpans - may be appropriate. In lieu of a toilet, commodes are static or mobile pieces of equipment that comprise a chair-like frame incorporating a toilet seat under a removable pan (disposable or washable) which is positioned to receive urine and faeces. Mobile shower-chairs (sometimes called sani-chairs) are also available. These are waterproof chairs on wheels that incorporate a toilet seat and are designed to be manoeuvred over the top of a conventional toilet once an individual is seated on them (48) (49).

Previous research highlighted concerns with the stability and - therefore - safety of some commode designs and their limitations in terms of aesthetics and comfort (48) (50) (51) (52). The appearance of a commode and the invisibility of its collection container are features particularly important in a home environment (48) (52) (53). Additional considerations when using these devices in the home setting are lingering unpleasant odour and the availability/willingness of someone to empty and clean it as a caregiver, rather than the commode user, typically empties and cleans a commode used in the home (53). Odour reduction is addressed in section P.

For persons with a spinal cord injury (SCI), there is a complex array of sometimes competing factors that need to be considered when prescribing shower-chairs/commodes (54); for example, the need for large rear wheels to facilitate propulsion may complicate sliding transfers to and from the equipment. While folding frames permit portability, they are heavier than fixed frames. Additionally, commodes pose a risk of pressure injuries for these individuals (55) (56-58). Assessment for toileting assistive devices for SCI should include a review of current bowel care routines, functional capacity to undertake toileting and bowel care, postural stability and transfers to and from the shower chairs/commodes, and risk for pressure injuries skin integrity and interface pressure mapping. However, the quality of evidence about the design and performance of mobile shower-commodes used by adults with SCI is fair to poor, lacking randomised control trials (54).

Bedpans are receptacles designed to be positioned beneath an individual who needs to empty their bladder or bowels while in bed or perhaps while seated on a conventional chair. Bedpans can be broadly categorised into concave pans (rounded, triangular-shaped with a curved base and sloping front to back), cut-away pans

Table E-1: Main categories of assistive aids and equipment for toileting

Toilet seat raisers	• Contoured toilet-seat shaped extensions that fit directly onto toilet bowls once lid/ seat have been raised. • Range of heights available. • Usually fitted with brackets for secure fixing. • Some are available with integral lids.
Toilet frames/surrounds	• · Metal frames positioned around the toilet to provide armrests to assist transfers. • May incorporate a toilet seat raiser or a conventional toilet seat and lid. • May be height and width adjustable. • Freestanding or fixed to the floor.
Grab or support rails	• Fixed to an adjacent wall, floor and/and ceiling. • Wide variety of styles, including fixed and fold-away designs. • Help improve stability and confidence during transfers and adjusting clothing. • Research examining the most effective configuration of rails concluded that the use of two vertical bars resulted in the least anterior-posterior displacement (and therefore greatest stability during transfers) and was rated highly by healthy older participants as well as those living with hip replacements and strokes (54) **(Level of Evidence 3).**
Bidets and personal cleansing systems	• Combined with, or integral to, a toilet, it may enable those without sufficient hand function or balance to reach the perianal area to cleanse without the need for assistance (55) (56) **(Level of Evidence 4).**
Bottom wipers	• Grip toilet paper or wet wipes on an ‘arm’ to assist those who are unable to reach to cleanse the perianal area. • Designed to be used from the front of the toilet. • Available in various designs, including folding for discrete transportation outside the home (may include a carry case). • Some have buttons to release the paper/wipe after use.

Table E-2: The main factors influencing the appropriateness of a commode, shower-chair or bedpan as a solution for individual needs.

- The physical characteristics of the individual such as size, weight, postural stability and functional capabilities.
- The mobility of the individual (including in bed) and approach to transfers (e.g. to commode or shower-chair).
- The cognitive status of the individual (e.g. capacity to recognise the purpose of the equipment).
- Availability of and access to brakes (where appropriate).
- Likely duration of individual episodes of use of the equipment.
- The level of assistance and / or supervision required to use the equipment safely and the burden that represents to any caregiver involved.
- User access to the perianal area for cleansing.
- Comfort and need for pressure relief during use.
- The environment in which the equipment will be used and its impact on privacy and dignity.
- The proximity of the area of use to waste disposal and storage facilities.
