Concerning bladder neck descent, it has been shown that the first delivery caused the most marked changes compared with the subsequent deliveries, with the most marked changes resulting from forceps delivery (205). This is supported by two different research groups, who have reported that an increased antenatal ultrasonographic bladder neck descent was associated with normal vaginal delivery (206-207). Furthermore, vaginal delivery was strongly associated with a larger and more distensible antenatal levator hiatus (206). The underlying reason remains hypothetical, but more antenatal laxity of the structures may allow for a smoother delivery. Women with increased bladder neck mobility also have an increased risk of de novo urinary incontinence post partum (21) but the risk can be halved by antenatal pelvic floor exercises (208). Avulsion of the levator ani muscle from the symphysis pubis, as outline above, is typically found in vaginally parous women only (Figure 9b) (150, 209-210). It has, furthermore, been shown that a higher maternal age at first vaginal delivery is strongly related to an increased risk of these avulsions (150, 210). Mode of delivery has a strong association with the incidence of levator ani injury such that vaginal delivery 15.4% are affected, 33.3% after ventouse delivery and 71.4% after a forceps delivery but there were no levator injuries detected in the Caesarean section group (211); similar findings have been reported by other groups (212-215). The timing of the levator ani damage appears to be as the head crowns (216). The levator ani hiatus has been reported as enlarging after vaginal delivery (217-218) and this enlargement being maintained for up to three years later (219) but other groups have not found it enlarged nine months after delivery compared with antenatal measurements. However, forceps delivery did lead to long term enlargement of the levator ani hiatus (220). The risk of levator ani avulsions increased with enlarged head circumference and prolonged second stage in labour (221).

In a large prospective cohort in nulliparous women, amongst which 15.1% suffered a LAM injury postnatally, the only independent risk factor after multivariate analysis of pelvic floor biometry was a smaller antenatal anteroposterior diameter of the levator hiatus (222). Other researchers have found that a combination of risk factors increase the odds for LAM hiatus injuries in primiparous women who delivered vaginally; women who had sustained a protracted labour, forceps delivery and OASIS had a 75% chance of suffering a complete or incomplete LAM avulsion (223). Fetal head circumference and length of first stage of labour have been suggested as additional risk factors for LAM injury, suggesting that the longer the pelvic floor is subjected to high stretch forces the more likely the occurrence of minor or major LAM defects (224). Conversely, greater levator hiatal dimensions in the third trimester of pregnancy had a significant association with a shorter active second stage of labor and a spontaneous vaginal delivery (225).

Another interesting concept of the relationship between vaginal delivery and LAM injury is the early postnatal ultrasound imaging findings and the subsequent changes. van Delft Ket al observed that all LAM haematomas seen on 3D transvaginal ultrasound as early as 4 days postpartum went on to form complete avulsion injuries 3 months after delivery. Interestingly, further avulsions noted at 3-month scans were not originally seen during the early asessment and, moreover, muscle haematomas, which were further away from the attachment point to the pubic bone did not evolve into avulsions (226). When these women with avulsions where further followed up, however, 1 year after their deliveries, more than 60% of the injuries had resolved (227). Similar findings were reported by an earlier MRI study (228) and recent ultrasound studies demonstrating recovery of the hiatal biometry for a significant proportion of women within 1 year of delivery, although not necessarily to pre-pregnancy (pre-delivery) levels (229-230). Such results have been contradicted by other researchers who demonstrated persistence of sonographically detected LAM defects, identified in the immediate postpartum period for months or years after delivery (231), again pointing out the huge variation and inconsistency in the classification of pelvic floor injuries and lack of standardisation in reporting those.

2.2.9 Pelvic Floor Surgery

Ultrasonography has been used during anti incontinence surgery with the aim of obtaining optimal results from surgery, for example during Burch colposuspension (232-233). On an individual basis, the bladder neck was lifted between 1 mm and 10 mm. The authors have obtained excellent results with a 94% continence rate after 1 year, but unfortunately no control group was incorporated in the study. Levator ani avulsions have been found to be associated with
persistent vaginal prolapse even after attempted surgical repair (234). Lone and co-authors compared 2D transperineal ultrasound - assisted ad hoc by additional 3D endovaginal ultrasound - with clinical examination for pelvic floor disorders and found that TPUS enhanced the differential diagnosis in the anterior compartment by distinguishing vaginal cysts and urethral diverticulae from pelvic organ prolapse (235). Perhaps the pre-operative value of TPUS is even greater when it comes to defects in the posterior compartment; improvement in diagnosis of enterocele with multi-compartmental pelvic floor scan, missed on clinical examination was demonstrated by use of TPUS of the pelvic floor. Diagnosis of enterocele and intussusception was further enhanced following primary surgical correction of the prominent prolapse in any of the vaginal compartments (235).

2.2.9.1 Slings and Meshes

Monofilament meshes, for example polypropylene meshes, are easier to visualise on ultrasonography compared with multifilament meshes, such as IVS (236). Ultrasonography has been widely used to localise the exact position of tension free midurethral tapes (Figure 15) (206, 237-242). The tape is generally easily visible as an hyperechogenic structure under the urethra and is easy to recognise, which contrasts with the poor images of polypropylene on MRI (243). Exact midurethral position of the tape is not essential for proper function (244). Despite the fact that the tape was located in the midurethra in only two-third of cases, this had no relation to postoperative continence status (245). A more recent ultrasound study, however, has challenged these findings, demonstrating a higher recurrence stress incontinence rate in cases where the suburethral sling was placed at the bladder neck in comparison to placement of the tape at the proximal and middle urethra (241). During Valsalva manoeuvre, the tape moves in a semicircle movement around the inferior margin of the symphysis pubis (246). This results in a position closer to the symphysis, which consequently leads to a certain degree of mechanical compression during Valsalva manoeuvre. Another mechanism of action is kinking of the urethra around the tape (247). A number of studies have looked at transobturator tape and compared these with retropubic tapes (236, 242, 248-251). Two studies could not detect any differences between the two types of tape (236, 242, 251), whereas in the other two studies (248,250), subtle differences with no apparent clinical consequences were found.

Imaging both tension-free and transobturator tape procedures during straining show a reduction in the diameter of the hypoechoic urethral core and the diameter became significantly smaller only in the successful procedures (252) and a reduction in the symphysis pubis to tape distance led to continence (253). Other authors have suggested optimal positions of the tape being between the distal third and middle of the urethra with a tape-urethral distance of 2mm, greater than 3.9mm distance led to failure of the procedure. The tape to urethral distance can be reliably assessed using 4D ultrasound (254). Midurethral tapes impinging on the urethra has been reported as being associated with voiding difficulty and the “V” shape of the tape was the same regardless of the insertion method (ie TOT compared to TVT) (255). Tunitsky-Bitton et al. found that the RP sling angle was significantly more acute than the angles of the TOT and TVT-O slings on 3D pelvic floor ultrasound, however no difference was noted between the 2 transobturator slings (242). Tapes sited around the midurethra resulted in a reduction in flow rate compared with a distal tape position under the urethra which did not change flow rates (256) and this positional information has been used to determine the management of de novo symptoms after surgery (257). Muati and Shoebir have proposed the use of 3D pelvic floor ultrasonography intraoperatively for releasing the mid-urethral part of a sling to overcome voiding dysfunction (258).

The bladder neck is displaced during insertion of a midurethral by using a rigid guide during insertion of a tension-free vaginal tape. Ultrasound has been used to determine that the bladder neck is moved by 1.4cm by this technique (259).

Recently, ultrasonographic localisation of polypropylene mesh as used in prolapse surgery has been described (Figure 16 and 17) (260). These meshes are usually easily visible on ultrasonography. It appears that the ultrasonographic appearance of the mesh is significantly shorter and narrower than the size at implantation within six weeks of the procedure (261). It is unclear whether this is due to shrinkage of the mesh or represents difficulties in visualising the full extent of the implanted mesh. The failure of mesh to support vaginal prolapse was associated with mesh shrinkage (262-263).

The differentiation between recurrent herniation and the detachment of the mesh arms from the pelvic sidewall for example, will aid in the better understanding of the mode of action of these meshes (264).

2.2.9.2 Bulking Agents / Injectables

Periurethral bulking agents/injectables, such as microparticulate silicone (Macroplastique), various gels (e.g. Durasphere, and collagen) can be visualised by imaging techniques. For MRI, an overview of appearances of periurethral bulking agents is already available (265).
Figure 15 Perineal three-dimensional rendered image. Polypropylene mesh (TVT-O) after one-sided incision of the tape.

Figure 16 Perineal midsagittal two-dimensional view. Polypropylene mesh of the anterior vaginal wall (Prolift anterior).
On ultrasonography, the injectables appear hypoechoic after injection, and become more hyperechoic over time due to dehydrogenation. Good intra-observer variability of repeated measurements of periurethral collagen volumes have been found (266). The location in relation to the bladder neck and a circumferential distribution of collagen injectables around the urethra, as well as the height and volumes of the injected periurethral collagen bumps, were associated with the treatment success of periurethral bulking agents (266-268). Using an endovaginal probe Elia and Bergman found that optimal location of collagen implant was less than 7 mm from the bladder neck (268). It appears that optimal periurethral collagen location is a circumferential distribution around the urethra, while an asymmetric distribution is associated with a significantly smaller improvement in incontinence symptoms (267). A recent prospective study by Hegde et al confirmed these findings demonstrating that best short outcomes occur with a combination of circumferentially distributed and proximally located Macroplastique (269). Although the volume range was wide, a collagen volume of 2.8 cc on three dimensional ultrasonography has been assessed as optimum volume from a continence point of view. Poon et al. have published a decision tree, in which a combination of the patients’ symptoms after collagen injection and the configuration and volume of the periurethral collagen on three-dimensional ultrasonography, assist in the decision for further treatment of women with intrinsic sphincter deficiency (266). In this algorithm, women with asymmetric deposition and/or low collagen volumes were offered further treatment with injectables as this is associated with failure (270).

Ultrasonography has not only been used for follow-up, but also during placement of periurethral injections. Transurethral ultrasonography-guided injection of autologous stem cells has been used in women and men with stress urinary incontinence. The technique allowed precise injection of the myoblasts directly into the rhabdosphincter and was more effective in the resolution of incontinence compared with urethroscopic guided collagen injectables in the submucosa in a randomized controlled trial (271-272). The use of stem cells in the management of urinary incontinence is of great interest although the subject remains controversial and confirmatory studies are eagerly awaited.

2.2.10 Conclusions

Research in US imaging of the pelvic floor has flourished over the last decade although the clinical benefit of it remains uncertain. Standardisation of imaging techniques and terminology are eagerly awaited. Imaging of pelvic floor muscle in relation to POP is a promising area because of the possible insight into the pathophysiology of the condition and treatment outcome. Research suffers from a lack of coordination among different research groups and a more
structured approach to research on imaging of UI and POP is advisable.

2.2.11 Consensus statement

- Ultrasound is not recommended in the primary evaluation of patients with urinary incontinence and/or pelvic organ prolapse (rectal prolapse is dealt with in a different section). (Level of evidence 3, Grade of recommendation C)

- Ultrasound is an optional test in the evaluation of patients with complex or recurrent urinary incontinence and/or pelvic organ prolapse. (Level of evidence 3, Grade of recommendation C)

- Ultrasound is recommended for measuring post-void residual and assessing pelvic floor muscle training (Level of evidence 2, Grade of recommendation B)

2.2.12 Future research areas

- Standardisation of terminology of pelvic floor US imaging
- Internal and external validity of techniques of pelvic floor imaging
- Confirmatory studies to validate previously published evidence on imaging of UI and POP
- Accuracy of US diagnosis of levator ani injury
- Prognostic value of preoperative US imaging and outcome of POP surgery
- Health technology assessment of pelvic floor imaging in the management of UI and POP.

2.3. MRI (The evolving role of MRI in the assessment of the female pelvic floor).

2.3.1 Introduction

The role of magnetic resonance imaging (MRI) in evaluating pelvic floor disorders has been established in recent years and continues to evolve. This technique provides unparalleled images of pelvic floor muscles, connective tissue, and organs. In addition to the detailed static picture of the pelvic organ support system anatomy, MR can also reveal the downward movement of each pelvic compartment during increases in abdominal pressure. Advances in MR imaging, equipment and software have significantly improved image quality and now MRI provides ever more detailed pictures of anatomy and function. At present active investigation is ongoing to see how this imaging might result in a better understanding of these diseases and improve their diagnosis and management.

Although women might present with symptoms isolated to one of the pelvic compartments, they often have concomitant defects in other compartments or pelvic structures. In these women, imaging can provide information to extend what can be determined on physical examination (1). Furthermore, surgical failures could result from lack of a thorough preoperative evaluation of the female pelvis and inadequate diagnosis and staging of pelvic floor deformation and dysfunction (2). Accurate diagnosis of coexisting abnormalities is therefore essential in planning reconstructive and anti-incontinence procedures. Although most diagnoses of pelvic floor prolapse are made on detailed physical exam, the sensitivity and specificity of the pelvic exam in diagnosing various forms of pelvic floor prolapse is low(3)(4)(5). Ultrasound and fluoroscopy have been used to improve diagnosis (6)(7) and the role of MRI in pelvic floor dysfunction is rapidly developing. A systematic review suggests that prolapse assessment on dynamic MR imaging may be useful in the posterior compartment, although clinical assessment and dynamic MR imaging seem interchangeable in the anterior and central compartment (8).

MRI provides detailed images of bladder neck and urethral mobility, rectoceles, cystoceles, enteroceles, and uterine prolapse, in a single non-invasive study without exposing the patient to ionizing radiation (9)(10)(11)(12)(13)(14)(15)(16)(17)(18). MRI also provides a multiplanar thorough evaluation of pelvic organs including the uterus, ovaries, ureters, kidneys, and levator muscles, as well as the urethra, that is unavailable by any other imaging modality (11)(13)(14)(15)(16)(17)(19)(20). MRI can identify ureteral obstruction, hydronephrosis, and uterine and ovarian pathology. In addition, MRI remains the study of choice for the evaluation of urethral diverticula.

The following measurements using MRI in urogynecology and female urology have been highlighted in the IUGA/ICS Joint Report on the Terminology for Female Pelvic Floor Dysfunction (21):

- Bladder neck and cervical descent/mobility:
  - Position of bladder neck and cervix at rest and on Valsalva.
  - Pubo-coccygeal line: A line extending from the inferior border of the pubic symphysis to the last joint of the coccyx. Bladder neck or cervical descent >2 cm below this line with straining indicates weakness of the pelvic floor. If alternative landmarks are used in scientific papers they should be clearly described.

- Intercurrent pelvic pathology: For example, fibroids, ovarian pathology.

- Uterine version: Anteverted or retroverted; flexion at the isthmus.

- Bladder abnormalities: For example, tumor; foreign body.

- Urethral abnormality: For example, diverticulum.
• Postoperative findings: For example, bladder neck mobility.
• Pelvic floor measurements/levator defects: Assessment of the configuration of pelvic floor muscles, in particular, the levator ani.
• Descent of pelvic organs.

2.3.2 Technique

2.3.2.1 Conventional MRI

Standard MRI consists of two dimensional image acquisitions. Usually conventional T1 images and spin echo T2 weighted images are obtained. Proton density T2 weighted scans provide excellent soft-tissue definition (Figure 18). However, the long imaging time of conventional MRI hampers its ability to evaluate the movement of organs that are characteristic of POP.

Figure 18: Sagittal mid pelvic section showing anatomical detail visible in static images made with Proton Density sequence.

2.3.2.2 Ultra Fast Image Acquisition and MR Sequences

Pelvic organ movement during Valsalva is identifiable using very fast single-shot MR sequences and the technical aspects have been summarized in a previous report (ICI 2009). (15)(16)(22)(23). These sequential images are obtained approximately once per second, either as a series of images covering the entire pelvis (static imaging) or repetitively in one plane while the patient is straining (dynamic imaging). The patients are placed in the supine position with legs slightly spread apart, and knees bent and supported by a pillow. Most pelvic floor details can be seen without the need for bowel preparation, premedication, instrumentation or contrast medium but often, especially with MR defecography, ultrasound gel or other suitable agents are used to enhance visibility of the rectum and vagina. The MRI torso coil is centered at the symphysis pubis. Images are acquired in the sagittal plane using single-shot fast spin echo (SSFSE) or half Fourier acquisition, single shot turbo spin echo (HASTE) sequences. Single, mid sagittal views are obtained during 3 seconds of apnea with the patient relaxed and during various degrees of progressive abdominal straining.

Steady-state free precession gradient-echo imaging provides an alternative T2-like imaging contrast (T2- and T1-weighted imaging) with robust signal and a rapid acquisition time of less than 1 second, thereby permitting near real-time continuous imaging. This is an improvement on the HASTE approach that requires 1–2 seconds between acquisitions to allow T1 recovery; therefore, real-time imaging is not possible. Comparisons of the degree of POP shown on dynamic true fast imaging with steady-state precession (FISP) versus HASTE sequences in symptomatic patients reveal a greater degree of prolapse in all three compartments with a dynamic true FISP sequence. Near real-time continuous imaging with a dynamic true FISP sequence may therefore be useful to evaluate pelvic floor dysfunction in addition to dynamic multiplanar HASTE sequences (24).

During a typical study of pelvic organ movement two sets of images are obtained. The first set consists of static sagittal and para-sagittal images covering the pelvis from left to right sidewall. These images are used to select the mid-sagittal plane for the dynamic second set of images. This static sequence also allows for anatomic delineation of the pelvic sidewalls and muscular and fascial components of the pelvic floor (15)(16)(22)(23). The perineal membrane and the levator ani musculature, as well as the anal sphincter anatomy, are also clearly demonstrated(25)(26). The static set consists of 17-20 sequential images independently acquired in a total of about 18 seconds.

The second set of images consists of relaxed and straining mid-sagittal images used to assess the degree of pelvic floor relaxation and organ prolapse. Images can then be looped for viewing on a digital station as a cine stack.

Dynamic MRI allows detection of POP that may not be evident on conventional static sequences, as it permits both structural and functional evaluation. For example, in women with lower urinary tract symptoms, evaluation of the urethra may be of added value.(27)
The first time a woman performs a Valsalva maneuver, she may not get the prolapse to protrude to its maximal extent. Forty per cent of women have a greater than 2cm increase in prolapse size from their first to third Valsalva attempt and 95% of women extend their prolapse further with a third Valsalva(28). As with clinical examination, several attempts may therefore be required to have maximal anterior compartment prolapse present during dynamic MRI of the pelvic floor. Delaney et al evaluated whether the use of a speculum blade modifies the evaluation of pelvic organ prolapse (POP) as assessed by dynamic MRI. Twenty-seven women with POP Quantification (POPQ) stage II or greater, scheduled for POP surgery, were evaluated using MRI. The procedure was repeated using the posterior blade of a standard plastic Grave's speculum to successively retract the anterior and posterior vaginal walls. Standard POPQ was 15% stage II (n =4), 59% stage III (n =16) and 26% stage IV (n =7). The use of a blade evidenced hidden pelvic prolapsed compartments in 59% (n =16) of cases. For 48% of patients (n =13), the variation of the leading edge of at least one additional prolapsed compartment was diagnosed as more than 20 mm. In this series, the use of a speculum blade during dynamic MRI modified the POP evaluation in a large proportion of patients with POP stage > or =II (29).

More recently, open magnetic resonance imaging (MRO) with vertical magnets, has allowed imaging in a variety of upright postures. A pilot study compared distances between the lowest point of the bladder to the pubococcygeal (PC) and pubopromontoreal (PP) lines as well as the ratio of bladder area under the PC and PP lines to the total bladder area. Significant elongation between the PC line and lowest point of the bladder was evident in women with POP comparing supine and standing images (p = 0.03), but not controls (p = 0.07). Similarly, this axis was significantly longer in women with cystocele versus controls only in the standing position. Bladder area under the PC line was significantly increased between supine and standing positions only among women with cystocele (p < 0.01), and significantly larger among the study group in the standing position (p < 0.005), less significant in the supine position (p = 0.015), and not significant in the sitting position (p = 0.3)(30).

2.3.2.3 Three Dimensional MRI

Three dimensional (3-D) MRI provides precise detail of the bony and muscular pelvic structures (Figure 20) so that 3D models can be constructed based on these detailed images. In this technique, static or dynamic images are reconstructed using consecutive planes in the axial, sagittal and coronal dimensions. Anatomic variations of the insertion and path of the pubococcygeus and iliococcygeus muscles can be seen. Fielding et al. made 3D models of the pelvic viscera and supporting muscles and bones with the marching-cubes algorithm and a surface-rendering method in nulliparous continent female volunteers and found that the muscle morphology, signal intensity and volume are relatively uniform (25). They described an average volume of the levator ani of 46.6 cc, width of the levator hiatus of 41.7 mm and an average posterior urethrovesical angle of 143.5°. In addition, these 3D models made from multi-slice scans during a maximal Valsalva have allowed direct measurements of changes in the relationship between the vagina and pelvic walls.
3D MRI enables evaluation of paravaginal defects, apical descent and vaginal widening. Larson et al (31) studied the relative contributions of "midline defects" (widening of the vagina) and "paravaginal defects" (separation of the lateral vagina from the pelvic sidewall) in women with anterior prolapse using 3D MRI models of the anterior vaginal wall and found that changes in lateral anterior vaginal wall were considerably greater than changes in vaginal width in cases vs controls. These "paravaginal defects" were also highly correlated with apical descent.

The geometry of the arcus tendineus fascia pelvis (ATFP) and arcus tendineus levator ani (ATLA) in women with unilateral levator ani muscle defects and associated "architectural distortion" has been studied using 3D MRI. In those women, the ventral arcus anatomy is significantly altered in the presence of levator defects as well as architectural distortion, resulting in change of the supportive force direction along the lateral anterior vaginal wall, thus increasing the risk for anterior vaginal wall prolapse. (32)

Luo et al (33) developed a method to evaluate changes in apical ligament lengths and lines of action from rest to maximal Valsalva using 3D stress magnetic resonance imaging (MRI). In a case-control study, 3D reconstructions of the uterus and vagina, cardinal ligament (CL), deep uterosacral ligament (USL(d)), and pelvic bones were created using 3D Slicer software. At maximal Valsalva, CL elongation was greater in cases than controls, whereas USL(d) was not; CL also exhibited greater changes in ligament length, and USL(d) exhibited greater changes in ligament inclination angle.

Following studies that reported diffusion tensor imaging (DTI) as a method for detecting alterations in tissue organisation of injured striated skeletal muscles, the clinical application of DTI and fibre tractography in pelvic floor imaging was assessed by Zijla et al. (34) A two-dimensional (2D) spin-echo (SE) echo-planar imaging (EPI) sequence of the pelvic floor was acquired. Offline fibre tractography and morphological analysis of pelvic magnetic resonance imaging (MRI) were performed. Inter-rater agreement for quality assessment of fibre tracking results was evaluated. DTI with fibre tractography seems to enable 3D visualisation and quantification of elements of the female pelvic floor.

2.3.3 Normal Pelvic Floor Functional Anatomy

2.3.3.1 MR Imaging of Normal Pelvic Support Structures

MRI studies of normal subjects have improved our understanding of normal pelvic anatomy, its variations(25)(26)(35) as well as anatomic changes in pelvic floor dysfunction (20)(36)(37).

In the supine position the female pelvic floor is dome shaped at rest (37)(38). During voluntary pelvic floor contractions the levator musculature straightens and becomes more horizontal. With bearing down the muscle descends, the pelvic floor becomes basin-shaped, and the width of the genital hiatus widens.

With MRI the specific structures are identified and their normal variations described (Figure 21). Tan (36) demonstrated the anatomy of the female pelvic floor with MRI. The pelvic and the urogenital diaphragm were well depicted as were urethral supporting structures—the peri-urethral and paraurethral ligaments, and the zonal anatomy of the urethra. The MRI findings in volunteers correlated with the endovaginal MR findings and gross anatomy in cadavers. Chou (39) studied the urethral support structures relative to the arcuate pubic ligament including the arcus tendineus fasciae pelvis, the perineal membrane, the pubococcygeal levator ani muscle and its vaginal and bony attachments, and the pubovesical muscle. Tunn et al (40) showed that 2-to 3-fold differences occur in distance, area, or volume measures of continence system morphologic features in continent nulliparous women with normal pelvic organ support and urodynamics. The uterosacral ligaments also exhibit greater anatomic variation than their name would imply(41). Three dimensional simplified biomechanical models constructed from MRI scans showed that the CL is parallel to the body axis. The US ligament is dorsally directed. The tensions on these ligaments seem to be affected by their orientations according to this study (42).
Figure 21: Axial images according , in 22-year-old (A, D, G, and J), 24-year-old (B, E, H, and K), and 34-year-old (C, F, I, and L) nulliparous women without urogynecologic problems. A-C, Level of cervix (Cx) and ischial spine (IS); uterus (Ut) with bright endometrium is also seen. Paracolpium and parametrium suspend (open tips) vagina and cervix from lateral and posterior pelvic sidewall. Smooth muscle of uterosacral ligament (open tips) is best seen in C. GM, Gluteus maximus muscle. D-F, Level of bladder (B) base. Upper vagina between bladder and rectum (R) and its attachment to pelvic sidewall by vascular and connective tissue mesentery (small arrow) are seen. Levator ani muscle (iliococcygeal part, filled arrowhead) arises from arcus tendineus of levator ani muscle (filled arrow). OI, Obturator internus muscle. G-I, At level of proximal urethra, levator ani muscle (pubovisceralis part, filled arrowhead) arises from pubic bone (open arrow). Pubovesicalis muscle (open arrowhead) is clearly seen in H. Vessels (white gap) are visualised between smooth muscle layer of lateral vaginal wall and levator ani muscle at this level. J-L, At level of middle urethra, pubovesicalis muscle is seen as shown in J (open arrowhead). Vessel layer (white gap) between lateral vaginal wall and levator ani muscle (filled arrowhead) has disappeared; direct connection between vagina and levator ani muscle is seen at this level. Small white gap in levator ani suggests fascia between puborectalis and pubococcygeal muscles (especially in J and L). (123)

Characteristic anatomic features of the posterior compartment and perineal body have been studied with MR cross-sectional anatomy and can be further elucidated and integrated with 3-D anatomy. In nulliparous asymptomatic women the posterior compartment’s upper, mid, and lower segments are best visualized in MRI in the axial plane. It is bounded inferiorly by the perineal body, ventrally by the posterior vaginal wall, and dorsally by the levator ani muscles and coccyx. In the upper portion, the compartment is bordered laterally by the uterosacral ligaments, whereas in the middle portion, there is more direct contact with the lateral levator ani muscles. In the lower portion, the contact becomes obliterated because the vagina and levator ani muscles become fused to each other and to the perineal body (43)(figure 22). The perineal body anatomy has been possible to study using 2mm MR images. Visualisation of perineal body anatomy in living women and development of 3-D models enhanced our understanding of its 3 different regions: superficial, mid, and deep (44). The three distinct perineal body regions are (1) a superficial region at the level of the vestibular bulb, (2) a midregion at the proximal end of the superficial transverse perineal muscle, and (3) a deep region at the level of the midurethra and puborectalis muscle. Structures are best visualised on axial scans, whereas craniocaudal relationships are appreciated on sagittal scans. In the superficial portion at the level of the vestibular bulb (VB), the bulbospongious (BS) inserts into the lateral margins of the perineal body, whereas the superficial transverse perineal muscle (STP) and external anal sphincter (EAS) traverse the region. In the perineal body’s midregion at the proximal end of the superficial transverse perineal muscle, the puboperineales muscle inserts into the lateral margins of the perineal body and in some individuals can be seen to cross the midline. This region also contains the distal internal anal sphincter. The puboanalis muscle is also visible as it inserts in the intersphincteric groove between internal and external anal sphincters. The puboanalis muscle and internal anal sphincter extend into the perineal body’s most deep region at the level of the midurethra. Here the pubovaginalis muscle also becomes visible as it fuses with the vaginal side wall, sending fibres posteriorly to the perineal body. In this location, the longitudinal muscle of the rectum may be visible in the midline. The puborectalis muscle forms a loop behind the rectum at this level but does not contribute fibers to the perineal body. (Figures 23&24)

One of the key anatomical contributions MRI has made to the understanding of normal pelvic floor structure, regards the ability to make images of a wide variety of normal living women. The pelvic floor is greatly distorted in cadavers due to loss of muscle tone and pressures during embalming. Otcenasek et al have used MR images of a normal nulliparous woman to establish geometry and then added details from dissection to produce an anatomically based topographically normal 3-D model that displays the features of pelvic floor anatomy (Figure 25) (45).

Nardos et al (46) compared levator hiatus measurements between pelvic magnetic resonance imaging (MRI) and 3-dimensional pelvic ultrasound (US) in 37 asymptomatic nulliparous women.
Figure 22: The outline of the midsagittal pubic bone (P) is shown. The bladder (B) is yellow; the uterus (U) and vagina (V) are pink; the uterosacral ligament (USL) and perineal membrane (PM) are turquoise blue; the levator ani muscle (LA) is red; the perineal body (PB) is royal blue; the external anal sphincter (EAS) is dark red; and the posterior compartment (PC) is gray. Image A, All organs are shown. B, Levator ani muscles have been faded to show the underlying structures. C, Levator ani muscles have been removed. The locations of the upper, mid, and lower axial cross-sections are shown(39). Reprinted with permission from John O. L. DeLancey.

Figure 23: 3D Model of the perineal body (40)

Figure 25: Left lateral view from above the female pelvis. The vagina, endopelvic fascia, and levator ani muscle are cut in the sagittal plane. Urethra, urinary bladder, and rectum have been removed. OIM, obturator internus muscle; PCF, pubocervical fascia; ATLA, arcus tendineus levator ani; LA, levator ani muscle; ATFP, arcus tendineus fasciae pelvis; PS, pubic symphysis; VW, vaginal wall; RVF, rectovaginal fascia; ATFR, arcus tendineus fasciae rectovaginalis; PM, perineal membrane; PB, perineal body; EAS, external anal sphincter; SC, space of Courtneyn; ACR, anococcygeal raphe; ACL, anococcygeal ligament; PM, piriformis muscle; CL, cardinal ligament; USL, uterosacral ligament; C, cervix of the uterus; CM, coccygeus muscle; Co, coccyx; SP, sacral plexus. Illustration: Ivan Helekal (41).
They found that the MRI measurements obtained from the sagittal images were consistently greater than the ones obtained by US. However, there was no such difference between MRI and US for the axial images. The authors attributed this observation to acquisition planes for axial images or interpretation of landmarks for the sagittal images.

2.3.3.2 Levator Ani Muscle Functional Anatomy

Evidence from MR and CT images in volunteers and cadavers shows that the anterior transverse portion of the levator muscle is basin-shaped; the middle transverse portion funnel-shaped, while the posterior transverse portion dome-shaped. The puborectalis appears u-shaped outside the vertical portion(47). On MR images of the five Terminologia Anatomica-listed levator ani components: pubovisceral (pubovaginal, puboperineal, and puboanal), pubopectral and iliococcygeal portions of the levator ani muscle muscles in women with normal pelvic support, the puborectalis muscle can be seen lateral to the pubovisceral muscle and decussating dorsal to the rectum in the axial plane. The course of the puboperineal muscle near the perineal body is also seen best in the axial plane. The coronal view is perpendicular to the fibre direction of the pubopectral and pubovisceral muscles and shows them as "clusters" of muscle on either side of the vagina. The sagittal plane consistently demonstrates the pubopectral muscle passing dorsal to the rectum to form a sling that can be seen as a "bump". This plane is also parallel to the pubovisceral muscle fiber direction and shows the puboperineal muscle(48)(Figure 26).

Betschart et al (49) described a technique to quantify muscle fascicle directions in the levator ani (LA): Among levator subdivisions, significant angle differences were observed between PVM and PRM (60 degrees), and between ICM and PRM (52 degrees). An 84 degrees difference was observed between PVM and EAS. The smallest angle difference was between PVM and ICM (8 degrees). The difference between PRM and EAS was 24 degrees.

2.3.4 Pathophysiology of Pelvic Floor Disorders

2.3.4.1 Levator Ani (LA) Muscle Defects

Lammers et al (50) assessed the inter- and intraobserver reliability of the diagnosis of pubovisceral muscle avulsions and measurements of the levator hiatus on MRI and confirmed that pubovisceral muscle avulsions and levator hiatus measurements can be assessed with good to excellent reliability on MRI.

In (51) a case-control study with group matching for age, race, and hysterectomy status, women with prolapse (cases) were compared to those with normal support (controls). Major defects were those that lost more than 50% of the muscle bulk. Cases were more likely to have major levator ani defects than controls.
(55% compared with 16%), but equally likely to have minor defects (16% compared with 22%) (Figure 27,28). Women with defects generated less vaginal closure force during a pelvic muscle contraction than women without defects (2.0 Newtons compared with 3.1 Newtons) and women with prolapse also generated less vaginal closure force during pelvic muscle contraction than controls (2.0 Newtons compared with 3.2 Newtons). This confirmed earlier uncontrolled observations with ultrasound (52).

It is important to distinguish between muscle thickness and muscle damage. A woman with a normally thin but intact muscle may have less muscle substance than a woman with naturally bulky muscles who has a defect that has involved 25% of her muscle bulk. The issue of muscle damage is relevant to seeing who is injured, while that of muscle bulk, with the capability of the muscle to close the hiatus. Hoyte et al (53) examined 10 women with prolapse, 10 with urodynamic stress incontinence, and 10 asymptomatic volunteers. Mean 3-dimensional parameters in the 3 groups showed levator volumes of 32.2, 23.3, and 18.4 cm³ (P <0.005); hiatus widths of 25.7, 34.7, and 40.3 mm (P <0.005); left levator sling muscle gaps of 15.6, 20.3, and 23.8 mm (P =0.03), right levator sling muscle gaps of 15.6, 22.5, and 30.8 mm, (P =0.03), and levator shape (90%, 40%, and 20% dome shaped; P <0.005).

Subsequently, using a novel thickness mapping (54), they found thicker, bulkier anterior portions of the levators in asymptomatic women, compared with women with prolapse or urodynamic stress incontinence while the more posterior portions of the muscle were not affected.

Hsu and colleagues quantified levator ani muscle cross-sectional area as a function of prolapse and muscle defect status (55). Using muscle cross-sections from 3-D reconstructions they found that women with visible levator ani defects on MR have less muscle ventrally compared with women with intact muscles. Women with major levator ani defects had larger cross-sectional areas in the dorsal component than women with minor or no defects indicating a compensatory hypertrophy in this area. Furthermore, after controlling for prolapse, women with levator defects appear to have a more caudal location of their perineal structures and larger hiatuses at rest, maximum contraction, and maximum Valsalva maneuver (56).

Among women with POP, those with major LAD appear less likely to experience stress incontinence when "coughing, laughing, or sneezing" (odds ratio (OR) 0.27) and when "twisting, reaching, lifting, or bending over" (OR 0.26) than women with normal muscles. They are less likely to have obstructive symptoms characterised by assuming an "unusual toileting position" or "changing positions...to start or complete urination" (OR 0.27). Women with minor LAD appear more likely to experience stress incontinence with exercise (OR 3.1) and urge incontinence (OR 4.0) than those with normal muscles. Lower urinary tract symptoms are therefore less common among women with prolapse and major levator ani defects and more common among those with minor defects (57). This may be explained by the fact that the women with major LA defects have larger prolapses than those who do not have major LA defects. It is a clinical observation that prolapse often reduces the occurrence of stress incontinence (urethral kinking?) and this hypothesis is consistent with the observations mentioned above.

Cai et al (58) evaluated levator ani morphology and function in healthy nulliparous women using static and dynamic MRI. They found no morphologic abnormality in healthy nulliparous women. However, in 15% (12/80) of women, pelvic organ descent below the pubococcygeal line was observed. In these women, the width of the pubic portion of the levator ani was significantly reduced during straining, whereas the levator plate angle, the levator hiatus area, and the H and M line lengths were enlarged. These changes were associated with weakened levator ani function and pelvic floor laxity.

2.3.4.2 Identifying the Injury Zone within the Levator Ani Muscle Most Often Involved by Injury

MRI based 3D models show that in women with bilateral puborectal muscle avulsion after vaginal delivery, the damage affects the pubic origin of the muscle. This structural change alters the support to the whole endopelvic fascia and destabilises both the anerior and the posterior vaginal walls(59). In women with significant muscle on one side and damaged muscle in the same individual(60) the injury involves the muscle’s origin from the posterior pubic bone (Figure 29). Distortion of the surrounding connective tissue with lateral spilling of the vagina towards the obturator internus muscle is observed in 50% of women. The defect is right sided in 71% of patients. The average difference of the amount of muscle lost in these types of injury between the normal side and the defective side is up to 81% at locations nearest the pubic origin(61). Almost all of the volume difference (13.7%, P=0.0004) is attributable to a reduction in the pubic portion (24.6%), not the iliococcygeal portion of the muscle.
Figure 26: Three-dimensional model of levator ani subdivisions including the pubic bone and pelvic viscera. This model was created by using the magnetic resonance images shown in Figures 2, 3, and 4. The pubovaginal, puboperineal, and puboanal muscles are all combined into a single structure, the pubovisceral muscle. Inferior, left 3-quarter view. B. The same model without the pubic bone. PB, pubic bone; V, vagina; U, uterus; Ur, urethra; B, bladder; IC, iliococcygeus muscle; PR, puborectal muscle; PVi, pubovisceral muscle; EAS, external anal sphincter. © DeLancey 2006. 2.3.4.3 Changes in the Hiatus Size and Levator Plate Angle with Prolapse

The levator ani muscle’s constant activity closes the genital hiatus. In addition to evaluating defect status and muscle bulk, MRI has revealed changes to the levator hiatus and angle of the levator plate (that midline portion of the muscle between the anus and the coccyx) which is presumed to be influenced by muscle action. Hsu and colleagues (62) studied 68 women with pelvic organ prolapse and 74 normal controls. During Valsalva, controls had a mean levator plate angle of 44.3 degrees. Cases had 9.1 degrees (21%) more caudally directed levator plate angle compared to controls (53.4 degrees vs. 44.3 degrees), 15% larger levator hiatus length (7.8 cm vs. 6.8 cm), and 24% more caudal perineal body location (6.8 cm vs 5.5 cm). Increases in levator plate angle were correlated with increased levator hiatus length ($r = 0.42$) and perineal body location ($r = 0.51$). The bladder neck descent at straining is also correlated with the levator plate angle at rest, hiatus length at rest and at straining(63). Uterine cervix descent at straining is correlated with increased hiatus length and width at straining, and greater levator plate angle ($p=0.007$) at straining. Paradoxically anterior rectal bulging at straining is inversely correlated with the hiatus width at rest ($p = 0.04$).

Perineal descent and localised outward bulging of the levator ani during Valsalva was evaluated by Gearhart and colleagues (64). In this study, dynamic MRI of symptomatic patients with pelvic floor prolapse demonstrated unsuspected levator ani hernia. Patients with POP, fecal and/or urinary incontinence, or chronic constipation were evaluated. Fifteen percent of patients (12/80) had unilateral (n = 8) or bilateral (n = 4) levator ani hernias on MRI. Perineal descent on physical examination was associated with a levator ani hernia in nine patients.

2.3.4.4 MRI and the Bony Pelvis

Studies of the bony pelvis dimensions and their associations with POP, levator ani defects and stress incontinence have recently been undertaken. Stein et al showed that bony pelvis dimensions are similar at the level of the muscular pelvic floor in white women with and without POP (65). Further evaluation of the bony pelvis using MRI scans has also improved our understanding of the natural history of stress urinary incontinence as well as the associations of the bony pelvis dimensions with the prevalence of levator defects (66). Other studies investigating the role that different pelvis shapes play for specific diseases will be described in subsequent sections of this review.

2.3.4.5 MRI of Pelvic Floor After Vaginal Delivery

There are changes observed in the levator ani and pelvic floor musculature immediately after delivery, which change over time. Boreham (67) evaluated the normal visibility of the levator in post term nulliparas using 3-dimensional (3-D) MRI. LA insertion into the symphysis was visible in 93%, and the iliococcygeus muscle assumed a convex shape (arch) in 92% of 84 nulliparas. Mean LA volume was 13.5 (3.7) cm$^3$. Interestingly there was a positive association between LA volume and higher fetal station with increasing BMI. The muscle signal intensity appears
increased at 1 day postpartum on T2 weighted images, but normal by 6 months. The urogenital and levator hiatus decreases significantly by 2 weeks postpartum (68). Lienemann (69) found thinning of the puborectal muscle in primiparous women after vaginal delivery (0.6 cm vs. 0.8 cm) and increased descent of the bladder, vaginal fornix, and anorectal junction during straining compared to healthy asymptomatic nulliparous volunteers.

The descent of the bladder and cervix on straining appears greater in women who delivered vaginally compared to those who had cesarean delivery and to nulliparous women. There is a positive correlation between the duration of labor and the area of the levator sling and also between birthweight and the descent of the cervix on straining (70).

The role of levator ani muscle damage and stress soon after birth has also been studied. An investigation of 80 nulliparous asymptomatic women and 160 vaginally primiparous women half of whom had new stress incontinence after their first birth was conducted 9 months after delivery. A visible defect in the levator ani muscle was identified in 32 primiparous. Twenty-nine of these 32 defects were in the levator ani muscle was identified in 32 primiparous. Twenty-nine of these 32 defects were in the pubovisceral portion of the levator and three were in the iliococcygeal portion. None of the nulliparous women showed these abnormalities (71). In a further study of this cohort (72) evaluation of obstetric factors associated with levator ani injury after first vaginal birth showed increased odds ratios for levator defect: forceps use 14.7, anal sphincter rupture 8.1 and episiotomy 3.1 but not vacuum delivery (0.9) epidural use (0.9) or oxytocin use (0.8). Women with levator injury were 3.5 years older and had a 78-minute longer second stage of labor. Differences in gestational age, birth weight, and head circumference were not statistically significant.

Dannecker (73) compared women after spontaneous vaginal delivery to those delivered by vacuum extraction and a control group of healthy nulliparous volunteers. Significant differences for individual POPQ component measurements were noted for points Aa and Ba, TVL, and GH (spontaneous delivery versus control) and in addition for Ap, Bp, and D (vacuum extraction versus control). Significant differences were observed for the position of bladder base, bladder neck, posterior vaginal fornix, anorectal junction, hiatus perimeter and depth of rectocele. Looking into comparisons with the spontaneous vaginal delivery group, on clinical examination, there was more evidence of anterior vaginal wall descent after vaginal delivery, and TVL and GH. Differences between the groups with regard to points Ap and Bp reached only marginal significance. With MRI measurements primiparous women who underwent spontaneous vaginal delivery as compared to nulliparous women showed considerable and statistically significant descent of almost all assessed structures at rest and on straining. Bladder base, bladder neck and the anorectal junction descended even below the respective reference lines. The bladder neck showed considerably increased mobility, and the genital hiatus showed an increased change on straining. The depth of rectocele increased more than three times. One of 26 women (4%) had a rectocele >3 cm. POPQ measurements that differed significantly between primiparous women after vacuum extraction and nulliparous women of the control group indicated more evidence of anterior and posterior vaginal wall descent after vacuum extraction. In addition TVL and GH was increased and PB was decreased after vacuum extraction. MRI measurements after vacuum extraction, showed considerably increased descent and mobility of the bladder base and bladder neck on straining, and descent of the anorectal junction was prominent. The mean depth of rectocele was four times bigger than in the nulliparous group. Four of 49 women (9%) had a rectocele >3 cm.

Branham and colleagues (74) evaluated postpartum changes in the levator ani muscle in relation to obstetric events. In those subjects recovering to normal MR by 6 months an average of nearly 60% increase in right puborectalis muscle thickness compared with that seen at 6 weeks indicated the extent of the injury. Younger white primiparous women had a better recovery at 6 months than older white women. Subjects experiencing more global injury, in particular to the iliococcygeous, tended not to recover muscle bulk.

Heilbrun and colleagues investigated the correlation between the presence of major LAM injuries on MRI with faecal incontinence (FI), POP, and urinary incontinence (UI) in primiparous women 6-12 months postpartum using a scoring system to characterise LAM injuries on MRI. Major LAM injuries were observed in 19.1% women who delivered vaginally with external anal sphincter (EAS) injuries, 3.5% who delivered vaginally without EAS injury, and 0% who delivered by cesarean section before labor (P = .0005). Among women with EAS injuries, those with major LAM injuries trended toward more FI, 35.3% vs. 16.7% (P = .10) and POP, 35.3% vs 15.5% (P = .09), but not UI (P = 1.0). These data confirm that both EAS and LAM are important for faecal continence and that multiple injuries contribute to pelvic floor dysfunction (75).

Handa and colleagues used MRI to measure bony and soft tissue pelvic dimensions in 246 primiparas, 6-12 months postpartum. A deeper sacral hollow was significantly associated with fecal incontinence (P = 0.005). Urinary incontinence was marginally associated with a wider intertuberous diameter (P = 0.017) and pelvic arch (P = 0.017). There were no significant differences in pelvimetry measures between women with and without prolapse in this study (76).
2.3.4.6 MRI and Biomechanical Investigation of the Pelvic Floor

MRI has allowed anatomically based biomechanical models to be constructed. Simulations have demonstrated important interactions between muscle and connective tissue in providing anterior vaginal wall support (77). MRI has enabled construction of finite element analysis (78)(79). It has also allowed for capture of 3D shape variation of the levator ani during straining where complete volumetric imaging is prohibited by the inherent temporal resolution of the scanning technique (80).

Chen recently developed and validated a 3D finite element computer model of the anterior vaginal wall and its supports based on spatial data from MR scans of normal women. They determined the combinations of muscle and connective tissue impairments that result in cystocele formation, as observed on dynamic MRI geometry from a healthy nulliparous woman. It included simplified representations of the anterior vaginal wall, levator muscle, cardinal and uterosacral ligaments, arcus tendineus fascia pelvis and levator ani, paravaginal attachments, and the posterior compartment. The authors found that development of a cystocele requires a levator muscle impairment, an increase in abdominal pressure, and weakening of apical and paravaginal support (81). These simulations provide a way to see what specific changes in structural components do to pelvic organ support in ways that would be impossible to study in living women.

Peng et al (82) assessed urethral support by developing a pelvic model from an asymptomatic female patient's MR images using the finite element method. Weakening the vaginal walls, puborectalis muscle, and pubococygeus muscle generated the top three largest urethral excursion angles. Weakening all three levator ani components together caused a larger weakening effect than the sum of each individually weakened component, indicating a nonlinearly additive pattern. The authors concluded that the vaginal walls, puborectalis, and pubococygeus are the most important individual structures in providing urethral support. The levator ani muscle group therefore provides urethral support in a well-coordinated way with a nonlinearly additive pattern according to the authors of this study.

2.3.4.7 Racial Differences in Pelvic Dimensions

There are differences in pelvic dimensions that exist in women from different racial backgrounds. Several groups have evaluated racial differences in the bony pelvis and the levator ani muscles (83)(84)(85). In a study by Handa et al (83), a wider transverse diameter (odds ratio 3.4) and a shorter obstetrical conjugate (odds ratio 0.2) were associated with pelvic floor dysfunction after controlling for age, race, and parity. Hoyte and colleagues found that levator ani volume was significantly greater in African-American (AA) asymptomatic nulliparous women without pelvic floor dysfunction compared to white American (WA) ones (mean = 26.8 vs. 19.8 cm3, P = .002). The levator-symphysis gap was smaller in the AA (left-18.2, right-18.8 mm) versus the WA group (22.4, 22.6 mm, P = .003, .048) on the left and right. Significant differences were also seen in bladder neck position, urethral angle, and the pubic arch angle (84). In another study with 3D MRI levator thickness was significantly greater bilaterally in black nulliparas compared to white ones, yet obturator internus muscle thicknesses were similar (85).

Handa found that the pelvic inlet was wider among white women than African-American women (10.7+/-.0.7 cm compared with 10.0+.0.7 cm, P<.001). The outlet was also wider (mean intertuberous diameter 12.3+/-1.0 cm compared with 11.8+/-0.9 cm, P<.001). There were no significant differences between racial groups in interpubic diameter, angle of the subpubic arch, anteroposterior conjugate, levator thickness, or levator hiatus (86).

A broader group of races was studied by Rizk et al with MR in asymptomatic multiethnic nulliparous young volunteers from 5 ethnic groups (Emirati, other Arab, Filipino, Indian/Pakistani, and European/white volunteers), with the white volunteers as the reference group (87). The white volunteers were taller (P<0.0001) than the other women. Their levator hiatus was longer than the Emirati women (P= 0.03) and wider than the Filipino women (P= 0.04). The bladder neck descent on straining was also greater than the other groups (P <.00001). The white women also had the longest transverse diameter of the pelvic inlet (P=.002). Their sagittal outlet diameter was longer than the Emirati and Arab women (P=.02), and their interspinous diameter was longer than the Arab women (P=.002).

2.3.5 Pelvic Organ Prolapse

MRI has proven to be a key assessment for understanding pelvic organ prolapse; a problem that arises from damage to connective tissue, muscles, and nerves that are invisible on standard radiography. With the advent of 3D ultrasound and MRI, the actual structures involved in the cause of prolapse can be seen and examined. This is possible not only in static scans that reveal morphological details of the pelvic structure, but also in dynamic scans where the movements of the various organs can be studied.

Evaluation of the degree of anterior compartment (bladder) and apical compartment (cervix) prolapse at maximal Valsalva using dynamic MRI showed a strong correlation between how far the bladder base and uterine cervix were below normal with $r^2 = 0.53$ indicating that slightly over half of the observed variation in anterior compartment support may be explained by apical support (88). Further analysis in the same patients showed that vaginal length was the strongest secondary factor determining 30% of the variation after apical descent was taken into account. This finding that a longer vaginal wall was associated
with increasing cystocele size was unexpected, but seems consistent with clinical observations (89).

Hsu et al found that vaginal thickness is similar in women with and those without pelvic organ prolapse. However, in prolapse patients the vaginal perimeter and cross-sectional areas are 11% and 20% larger respectively (90).

Broekhuis et al studied the relationship between patient symptoms using questionnaires’ domain scores and the perineal position on dynamic MR imaging of 69 women. They found that POP symptoms were associated with the degree of descent of the perineum but perineal descent was not related to anorectal and/or urinary incontinence symptoms (91).

In another study examining correlations of patients’ symptoms with findings on clinical examination and dynamic MR imaging of the pelvic floor, only the domain score genital prolapse was significantly correlated in the positive direction with the degree of POP as assessed by POP-Q and dynamic MR imaging (r(s) = 0.64 and 0.27, respectively), whereas the domain score urinary incontinence was inversely correlated (r(s) = -0.32 and -0.35, respectively). The sensation or visualisation of a bulge in the vagina was the only symptom which correlated positively with the degree of POP, with clinical examination and dynamic MR imaging showing similar correlation in this respect (92).

Broekhuis et al concluded that correlations for the POP staging with the use of POP-Q, dynamic MR imaging, and perineal ultrasonography are only observed in the anterior compartment (93).

**MRI for clinical evaluation of prolapse**

**2.3.5.1 Enterocoele**

In the past, enteroceles were usually only appreciated on radiographic examination after repeated straining after evacuation and usually required opacification of the vagina in order to demonstrate the insinuation of small bowel loops between the rectum and vagina (94). MRI has proven to be a much simpler and less invasive technique for the evaluation of enteroceles. In comparisons between physical examination, intraoperative findings and MR images in women with and without prolapse. MRI was significantly superior in detecting enterocoele when compared to physical examinations with a sensitivity of 87%, specificity of 80%, and positive predictive value of 91% (16). (Figure 30). Similarly, MRI had a much higher sensitivity for detection of enteroceles when compared to physical exam and dynamic cystoproctography (95). Whether or not this technique alters clinical outcome remains to be seen.

**2.3.5.2 Cystocele**

MRI has a sensitivity of 100%, specificity of 83%, and positive predictive value of 97% when evaluating for cystocele compared to intraoperative findings. In addition, urethral hypermobility and post-void urine residual can be documented, as well as evaluation of ureteric obstruction, hydroureteronephrosis and other pelvic abnormalities. Figures 31a, b

MRI can also be helpful in documenting the status of pelvic organ support as part of a program to assess operative efficacy (96)(97) and differentiating such problems as Müllerian remnant cysts from cystocele (98).

Larson et al showed that in women with anterior wall prolapse, Valsalva causes downward translation of the vagina along its length. A transition point separates a proximal region supported by levator muscles and a distal, unsupported region no longer in contact with the perineal body. In this latter region, sagittal and frontal plane “cupping” occurs. The distal vagina rotates inferiorly along an arc centered on the inferior pubis. Downward translation, cupping, and distal rotation are therefore novel characteristics of cystocele demonstrated by 3-D MR imaging (99). (figure 32,33)

In cystoceles, the distal anterior vaginal wall (AVW) may no longer be in contact with the posterior vaginal wall or perineal body as it bulges through the introitus. The exposed vaginal wall length has been quantified using dynamic MR imaging. The authors found a bilinear relationship between exposed vaginal wall length and most dependent bladder location as well as apical location. It is when the bladder descent is beyond the inflection point that exposed vaginal wall length increases significantly (100).
2.3.5.3 Rectocele

The reported sensitivity of pelvic examination for diagnosis of rectocele ranges from 31% to 80% (3)(4)(6)(101)(102). This is usually secondary to organ competition for space in the vagina with other significant prolapse (7). In addition, it is often difficult to reliably distinguish an enterocele from a high rectocele. **Figure 34** shows a rectocele diagnosed by dynamic MRI. A rectocele is easily seen when filled with gas, fluid, or gel. Although highly specific, when no rectal or vaginal opacification is used, MRI can miss up to 24% or rectoceles (16). When rectal opacification is used, a correct diagnosis of rectocele can be made in 100% of patients studied when compared to intraoperative findings (19). Rectal opacification by introducing sonographic transmission gel or gadolinium into the rectum is therefore necessary to increase MRI’s ability to diagnose rectocele. In complex situations such as rectal intussusception (103) MR can provide important information by distinguishing mucosal from full-thickness descent. MR defecography also shows movements of the whole pelvic floor. In this study, 30% of the patients studied were found to have associated abnormal anterior and/or middle pelvic organ descent that would not necessarily be seen in
traditional evacuation proctography (unless opacification of vaginal, bladder and intestine are carried out).

At maximal Valsalva on MRI, structures are more caudal and the hiatus longer in women with posterior prolapse. The posterior vaginal wall is longer; this length and point Bp strongly correlate with MRI prolapse size (r=0.5; P=.002; r=0.7; P<.001, respectively) (104).

What remains unclear is the relationship between anatomical findings and functional problems. The diagnosis of an anatomical abnormality does not mandate surgery. Simply identifying a rectocele on an imaging study based on the location of the intestinal lumen to a reference line does not mean that correction of the rectocele will cure defecation problems. Rectocele surgery is not without complications and the risk of dyspareunia after posterior colporrhaphy is real. Attention should be paid to make sure that symptoms are truly depending on stool trapping and the condition must be shown on imaging.

2.3.5.4 Uterine Prolapse

Although uterine prolapse is easily diagnosed on physical examination MRI is an excellent modality to record the structural relationships with the bladder and rectum in patients with uterine prolapse (Figure 35). In addition to depicting the position of the uterus and adjacent organs, it has the ancillary benefits of evaluating uterine size, position, orientation (retroversion) and pathology (fibroids, tumors, Nabothian cysts. etc.), but also ovarian pathology (cyst or mass) which may sometimes prove useful if these problems have not been picked up on physical examination. This is helpful information in determining the route of hysterectomy. Furthermore, MR imaging provides information on the presence or absence of cystocele, rectocele, urethral hypermobility and urethral diverticula, and evaluates for ureteral obstruction(10)(11)(14)(15)(16)(105). Gousse et al. report a sensitivity of 83%, a specificity of 100% and a positive predictive value of 100% when comparing dynamic MR imaging to intraoperative findings. These numbers were similar when compared to physical examination alone(16). More importantly, MRI was able to clearly define the other compartments of the pelvic floor and diagnose uterine and/or ovarian disorders in 30 of 100 patients evaluated(16).

2.3.5.5 Grading of pelvic floor relaxation

A number of studies have described reference values for grading POP(15)(16)(18). In order to evaluate pelvic organ descent, certain anatomic landmarks are used. The pubococcygeal line (PCL) marks the distance from the pubis to the coccyx and serves as a fixed anatomical reference. In the nomenclature used by Comiter et al. (15), Gousse et al. (16), and Barbaric (23), the width of the levator hiatus is measured as the distance from the pubis to the pubococcygeus muscle (H-line). The hiatus is formed by the puborectalis muscle and encompasses urethra, vagina, and rectum. The M-line depicts the relaxation of the muscular pelvic floor by measuring the descent of the levator plate from the PCL. Using these three simple measurements, an MRI classification for degree of POP has been described (15)(23). In the normal population, during straining, the hiatus (H-line) is less than 6 cm long and does not descend (M-line) more than 2 cm below the PCL. The upper urethra, urethrovesical junction, bladder, upper vagina, uterus, small bowel, sigmoid colon, mesenteric fat and rectum are all above the H-line. A combination of hiatal enlargment and pelvic floor descent constitutes relaxation. As the pelvic floor descends, so do the organs above it. The grading system for prolapse of any pelvic organ is based on 2 cm increments below the H-line. By determining the degree of visceral prolapse beyond the H-line, the degree of rectocele, enterocoele, cystocele, and uterine descent can be graded in a 0 to 3 scale as follows: 0=none, 1=minimal, 2=moderate, and 3=severe (Table 1). Other similar systems have been described (18) highlighting the need for standardization of nomenclature and grading of organ prolapse using MRI. In a small study, Ginath et al showed that MRI measurements of pelvic landmark angles can differentiate between women with and without uterine prolapse and correlate best with POPQ point C (106).

Novellas and colleagues evaluated two classification systems (using the PCL and the midpubic line, MPL) in 30 patients with symptoms of POP.

![Figure 34:Resting (a) and straining (b) midline sagittal section showing a rectocele that traps intestinal contents.](IMAGING IN URINARY INCONTINENCE AND PELVIC FLOOR DYSFUNCTION | 717)
For prolapse detection, the correlation between clinical examination and MRI ranged between 74 and 89%. For prolapse staging, the correlation was poor to moderate. Inter-observer agreement was good to very good (kappa between 0.67 and 0.95). It was slightly better at the mid stage, with both systems (kappa between 0.83 and 0.97). Comparison of the inter-observer agreement between both MRI classification systems showed better results for the system using the pubococygeal line (p<0.005). The classification system based on the pubococygeal line appeared more reliable and simple for the evaluation of pelvic prolapse on MRI (107). In another study, agreement between clinical and PCL staging was fair in the anterior (kappa = 0.29) and poor in the apical (kappa = 0.03) and posterior (kappa = 0.08) compartments. Agreement between clinical and MPL staging was fair in the anterior (kappa = 0.37), apical (kappa = 0.31), and posterior (kappa = 0.25) compartments. The MPL had higher agreement with clinical staging than the PCL in this study. However, neither reference line had good agreement with clinical staging (108).

The intra- and interobserver reliability of dynamic MR staging in POP patients has also been evaluated using various anatomical landmarks in relation to the PCL, H-line, and MPL. Clinical measurement points were assessed in relation to the mid-pubic line. Overall, the intra- and interobserver reliability of MR imaging measurements was excellent to good. The PCL showed superior reliability (intraclass correlation coefficients-ICC range 0.70-0.99). The reliability of clinical measurement points, however, were only moderate (ICC range 0.20-0.96). The intra- and interobserver reliability of quantitative prolapse staging on dynamic MR imaging were good to excellent. The PCL appeared the most reliable to use (109).

Singh et al (110) compared a new technique of grading POP by using dynamic MRI with the clinical staging proposed by the POP-Q system (111). A new reference line, the mid-pubic line, was drawn on the MR image to correspond to the hymenal ring marker used in the clinical staging. The proposed staging by MRI showed good correlation with the clinical staging (kappa = 0.61). Torricelli (112) also used MRI to evaluate functional disorders of female pelvic floor. In symptomatic women MRI confirmed the pelvic examination findings in all cases; MRI also detected additional alterations (4 cases of uterine prolapse and 3 of enterocele) that had been missed at clinical evaluation. Deval (113) compared dynamic MR imaging with physical examination as an alternative to dynamic cystoproctography for the evaluation of POP. PCL and puborectalis muscle were the reference points. The grading system is based on degree of organ prolapse through the hiatus and the degree of puborectalis descent and hiatal enlargement. They also used, the mid pubic line, which was drawn on the MR image to correspond to the hymenal ring marker used in clinical staging. Intra-operative findings were considered the gold standard against which physical examination, dynamic colpocystodefecography and MRI were compared. The sensitivity, specificity and positive predictive value of MRI were 70%, 100%, 100% for cystocele; 42%, 81%, 60% for vaginal vault or uterine prolapse; 100%, 83%, 75% for enterocele; 87%, 72% and 66% for rectocele. More recently Etlik (114) found physical examination and MR findings to be very concordant in the diagnosis of pelvic prolapse. Statistical correlations in the stages of prolapse between both of the methods were significant for anterior and middle compartment (P<0.01), as well as for posterior compartment (P<0.05).
Rosenkrantz et al evaluated the prevalence of pelvic organ prolapse as an incidental finding on dynamic magnetic resonance imaging (MRI) using the pubococcygeal line (PCL) and mid-pubic line (MPL) to diagnose and grade prolapse in all three pelvic compartments. Sixty women with symptoms unrelated to pelvic floor dysfunction who underwent dynamic MRI were included. In asymptomatic women, dynamic MRI identified the greatest degrees of prolapse in the posterior compartment. The MPL consistently yielded greater frequency of prolapse than the PCL. These findings however are of uncertain significance, requiring correlation with clinical examination (115).

Semiautomated pelvic floor measurement algorithmic models on dynamic MRI images have been developed and compared with manual pelvic floor measurements for pelvic organ prolapse (POP) evaluation. These models were shown to provide highly consistent and accurate locations for all reference points on MRI. The reference points can also be identified faster compared to manual-point identification. (116). A fully automated localization method for multiple pelvic bone structures on magnetic resonance images (MRI) has been developed by the same group. Identifying structures of interest such as the pubic bone, sacral promontory, and coccyx correctly, by a fully automated identification method may result in improved diagnosis of female pelvic organ prolapse according to the authors (117).

2.3.6 Assessing Treatment Outcome

2.3.6.1 Pelvic Organ Prolapse Operations

Several studies have evaluated the anatomic changes seen after surgical procedures using MRI to better understand how surgical therapies affect pelvic support and structures. Lienemann et al. (118) evaluated women after abdominal sacrocolpopexy and found that functional MRI identified the exact sacral fixation points after the procedure and easily identified the axis of the vagina and the exact position of the synthetic material used for the repairs. Sze (119) used MRI to study vaginal configuration on MR after abdominal sacrocolpopexy and sacrospinous ligament suspension. This study demonstrated the differences in the geometry of these two operations and should prove helpful in establishing outcome variables for different surgical procedures. Similarly Rane (120) used MRI to compare the vaginal configuration following transvaginal sacrospinosus fixation (SSF), posterior intravaginal slingplasty (PIVS), (infracoccygeal sacropexy) and sacrocolpopexy (SCP) and demonstrated improvements in the restoration of vaginal configuration and differences between the procedures in final anatomy. Boukerrou (121) compared outcomes of 1) abdominal sacral cervicopexy, 2) vaginal hysterectomy with paravaginal repair, sacrospinous suspension and posterior colporrhaphy and 3) sacrospinous suspension and posterior repair without paravaginal suspension with MRI. The correction provided by vaginal route was found to result in a return of the bladder and the vaginal apex to their normal positions. In addition, vaginal shortening and postoperative change in vaginal orientation were not present postoperatively.

Nicolau-Toulouse et al (122) evaluated the anatomic outcomes of bilateral sacrospinous vault fixation (BSSVF) with synthetic, polypropylene mesh arms using MRI in a small case series of women with symptomatic pelvic organ prolapse (POP) with and without uterus. They confirmed that BSSVF with synthetic mesh restores the anatomy between the vagina and the ischial spines.

Relationships between assessment of surgical correction studied with MR imaging and symptoms have been studied. Gufler (123) compared preoperative evaluations with those two to four months after surgery. Of the seven patients who had symptoms postoperatively, only two had abnormal findings on physical examination but MRI showed pathologic findings in five of the seven patients. Huebner et al assessed symptomatic changes after anterior levatorplasty with morphologic changes visualized by MR defecography (124). Anterior levatorplasty improved quality of life in patients with symptomatic rectocele and correction of rectocele is accurately documented by MRdefecography, however only moderate correlation between morphologic and clinical improvements was observed.

MRI has also been used for the evaluation of the effectiveness of POP surgical mesh procedures. Dynamic MRI may evaluate the support of anterior and posterior pelvic floor structures by anterior and posterior polypropylene implant respectively. But dynamic MRI evaluations in a small series by Siegmann and colleagues suggest that if one compartment of the pelvic floor is repaired another compartment frequently (73.3%) develops dysfunction. These results did not correspond to clinical symptoms on short-term follow-up (3 months) indicating the need for long-term follow-up studies to prove if dynamic MRI can reliably identify significant POP after surgery and before the onset of symptoms (125). In another small series of ten women by Kasturi et al (126) undergoing intervention for POP with Prolift, postoperative MRIs supported the inert nature of polypropylene mesh.

Larson et al examined structural relationships between anterior mesh kit suspension points and the upper vagina in women with normal support. Using MRI generated 3D models, they found that the anterior vagina extended above superior attachment points in 100% of women at rest and in 73% during Valsalva. It extended posterior to them in 82% and 100% (rest and Valsalva, respectively). The mean percentage of anterior vaginal length above superior anchoring sites was 40 +/- 14% at rest and 29 +/- 12%
during Valsalva. The upper vagina was therefore found to lie above and posterior to superior suspension points in the majority of women with normal support (127).

In an observational study, the 1-year outcomes after mesh repair in patients with POP were evaluated using clinical examination (CE), dynamic magnetic resonance imaging (dMRI), and the prolapse quality-of-life (P-QOL) questionnaire. Sixty-nine women were treated with Seratop(R) or Perigee mesh implants. Advanced cystoceles and enteroceles were underestimated by CE using the POP-Q system compared to dMRI (P = 0.003 and P < 0.001), vice versa dMRI overestimated POP compared to CE. (128).

### 2.3.6.2 Pelvic Muscle Exercises

Studies on the effects of pelvic muscle training on the pelvic floor (129) demonstrate reduced levator ani surface area and volume encircled by the levator ani muscle during contraction. When elite athletes are compared to normal women significant differences appear in the cross-sectional area and width of the pelvic floor muscles, (130). These types of studies are being facilitated by improved techniques of aligning contracted and non-contracted muscle (131).

### 2.3.6.3 Comparison of MRI with other Examinations and Assessment of Reliability

Dynamic contrast roentography and multiphasic fluoroscopic cystocolpoproctography (CCP) have previously been considered the best radiological studies for detecting POP. These studies rely on the opacification with contrast material of the bladder, vagina, small bowel, and rectum with all organs opacified together or in phases with each organ opacified individually prior to each straining phase(4)(120)(124)(129). These studies fail to detect opacified individually prior to each straining opacified together or in phases with each organ vagina, small bowel, and rectum with all organs opacification with contrast material of the bladder, previously been considered the best radiological fluoroscopic cystocolpoproctography (CCP) have dynamic contrast roentography and multiphasic fluoroscopic cystocolpoproctography have statistically similar frequency of POP as CCP (135).

Evacuation proctography has been used to diagnose enterocele, rectoceles, perineal descent and rectal intussusception. Dynamic contrast roentography or fluoroscopic cystocolpoproctography have also been used (4)(101)(102)(132)(136) to diagnose rectoceles. The disadvantages of these techniques are the inability to visualise the soft tissue planes comprising the pelvic floor, their invasiveness, and their use of significant levels of ionizing radiation. Without the use of rectal opacification, MRI appears to be a poor choice for the evaluation of rectoceles missing up to 25% of such defects. With rectal opacification a correct diagnosis of rectocele can be made in 100% of patients in comparison to intraoperative findings (19). Triphasic dynamic MRI and triphasic fluoroscopic cystocolpoproctography have similar detection rates for rectocele (132). Upright dynamic MR defecating proctography has been reported (137). Although these studies might prove to be more sensitive in detecting anorectal anomalies, their utility seems to be more pronounced in patients with disorders of defecation include anismus, intussusception, and others, and may be too invasive to justify their routine use in the evaluation of rectocele.

Kaufman (138) evaluated dynamic pelvic MRI and dynamic cystocolpoproctography in the surgical management of females with complex pelvic floor disorders. Physical examination, dynamic MRI, and dynamic cystocolpoproctography were concordant for rectocele, enterocele, cystocele, and perineal descent in only 41% of patients. Dynamic imaging lead to changes in the initial operative plan for 41% of patients. Dynamic MR was the only modality that identified levator ani hernias. Dynamic cystocolpoproctography identified sigmoidoceles and internal rectal prolapse more often than physical examination or dynamic MR. Whether this type of imaging creates measurably better outcomes remains to be seen. Singh et al (110) showed a reasonably good correlation between clinical staging and MRI staging (Kappa = 0.61) with the mid pubic line being used as a surrogate for the hymenal ring. In addition, specific features such as the levator-vaginal angle the area of the genital hiatus could be assessed quantitatively on MRI.

Torricelli (112) studied ten healthy volunteers and 30 patients with suspected pelvic floor deficiency with and without POP. They found good concordance between physical examination and MRI with four cases of uterine prolapse and three cases of enterocele seen on MRI that had not been suspected on pelvic examination. Whether these would have been detected at the time of surgery was not discussed. Deval (113) compared intraoperative findings as a gold standard for MRI based diagnosis. The sensitivity, specificity, and positive predictive value of MRI were 70%, 100%, 100% for cystoceles; 42%, 81%, 60% for vaginal vault or uterine prolapse;
100%, 83%, 75% for enteroceles; 87%, 72%, 66% for rectocele. Although all of these measurements are somewhat subjective, these figures show that it is possible to quantify the individual elements of pelvic floor dysfunction in reasonable parameters.

In a recent study, the value of dynamic pelvic floor MRI was assessed in comparison to standard clinical examination in treatment decisions made by an interdisciplinary team of specialists including a urologist, gynecologist, a proctological, and colorectal surgeon. The authors concluded that MRI has the advantage of allowing diagnosis of clinically occult enteroceles. In addition, in nearly half of cases, MRI changed management or the surgical approach relative to the clinical evaluation. (139).

### 2.3.7 Conclusions

Proof that MR imaging has value will eventually need to come from increased operative success rates. Better documentation of preoperative and postoperative anatomy could allow us to seek reasons of operative failure. Because MR provides a detailed picture of a woman’s pre-operative anatomy, once operative failures are discovered, it would be possible to look back at images from women with successful and unsuccessful operations to seek anatomical explanations for failure.

Advancements in MRI technology with the addition of 3D imaging as well as studies correlating imaging findings with clinical examination and symptom scores may establish further the clinical applications of these modalities.

### 2.3.8 Consensus Statement

MRI is not yet indicated in the routine evaluation of patients with (uncomplicated primary) pelvic organ prolapse. However data concerning the causes of prolapse are rapidly accumulating and this may change soon. It can provide useful information concerning complex prolapses and can be used in difficult cases. *(Level of evidence 3, Grade of Recommendation C)*

### 2.3.9 Future Research Areas

Studies that identify specific defects in the connective tissue and the muscles of the pelvic floor that correlate these findings with the clinical presentation in prolapse are needed.

Additional studies comparing MRI of healthy volunteers and patients with pelvic organ prolapse are needed to better evaluate the anatomical changes involved in pelvic floor prolapse.

Quality control in MRI, including: what manoeuvres are required to produce a maximal prolapse during MRI, bowel condition, bladder filling, pushing instructions, etc.)

### 2.3.10 Proof that MR imaging has value will eventually need to come from increased operative success rates. Better documentation of preoperative and postoperative anatomy could allow us to seek reasons of operative failure. Because MR provides a detailed picture of a woman’s pre-operative anatomy, once operative failures are discovered, it would be possible to look back at images from women with successful and unsuccessful operations to seek anatomical explanations for failure.

Advancements in MRI technology with the addition of 3D imaging as well as studies correlating imaging findings with clinical examination and symptom scores may establish further the clinical applications of these modalities.

### 2.3.11 MRI is not yet indicated in the routine evaluation of patients with (uncomplicated primary) pelvic organ prolapse. However data concerning the causes of prolapse are rapidly accumulating and this may change soon. It can provide useful information concerning complex prolapses and can be used in difficult cases. *(Level of evidence 3, Grade of Recommendation C)*

### 2.3.12 Studies that identify specific defects in the connective tissue and the muscles of the pelvic floor that correlate these findings with the clinical presentation in prolapse are needed.

### 2.3.13 Additional studies comparing MRI of healthy volunteers and patients with pelvic organ prolapse are needed to better evaluate the anatomical changes involved in pelvic floor prolapse.

### 3. SPECIAL ISSUES

#### 3.1. Post-Void Residual

Post-void residual urine (PVR) is defined as “the volume of urine left in the bladder at the end of micturition(1). Evaluation of PVR prevalence in women with symptomatic pelvic floor dysfunction suggests that 81% have a post-void residual of 30 ml or less (2). This is not significantly different from asymptomatic perimenopausal and postmenopausal women in whom 15% of subjects had a PVR greater than 50 ml (3). If symptoms cannot predict elevated PVR, a urogenital prolapse beyond the hymen seems to be associated with incomplete bladder emptying (4). Among patients older than 55 years with symptoms of overactive bladder, previous incontinence surgery, history of multiple sclerosis and vaginal prolapse stage 2 or greater, were found to be independent predictors of elevated PVR (5). Similar data were obtained by Fitzgerald in patients with urgency incontinence, the presence of pelvic organ prolapse ≥stage 2, symptoms of voiding difficulty and absence of stress incontinence symptoms predicted 82% of patients with elevated PVR (6). Higher prevalence of post-void residual was found in patients with stress urinary incontinence with 35.5% of women having a PVR >50 ml suggesting they have some degree of voiding dysfunction (7). Although elevated PVR and bacteriuria are common among elderly residents in nursing homes, no association between the two was observed in a Swedish study (8). Analysis of elderly patients with urinary incontinence failed to identify any significant association between PVR and any other clinical or urodynamic parameter (9). Sanders and co-workers addressed the issue of the real need for measuring flow rates and post-void residual urine in women with urinary incontinence. Analysis of 408 patients with elevated PVR (6) had their management modified because of the results of free uroflowmetry and PVR measurement. In their opinion, these data do not justify the inclusion of these tests in the “minimal care” programme for assessing primary, uncomplicated, urinary incontinence in female patients (10).

PVR is often considered a safety parameter, which needs to be monitored in the follow-up of medical or surgical management of urinary incontinence. A number of studies have addressed the effect of antimuscarinic treatment in men with symptoms of overactive bladder to rule out the old dogma that banned the use of these drugs in elderly men. Actually, all published data suggest that antimuscarinic treatment is safe for men with benign prostatic enlargement and no significant change in PVR values was found in active treatment groups compared to placebo (11, 12). In male patients with bladder outlet obstruction, antimuscarinic treatment may result in a significantly larger PVR.
(25 vs. 0 ml) that seems to be of no clinical relevance and with higher incidence of adverse events (13).

Measuring PVR is of importance in patients receiving intravesical injections of Botulinum toxin A for UUI. Significant increase of post void residual urine is observed following injection of onabolutinumtoxinA in patients with neurogenic urinary incontinence due to detrusor overactivity with 30 to 42% of patients needing to start clean intermittent catheterisation compared to 12 % in the placebo group (14). In patients with idiopathic UUI, increase of PVR was observed in those receiving onabolutinumtoxinA compared to placebo although only 8 of 70 patients required CIC and only 3 patients had a PVR >200 ml at day 8 and only one at 6 months (15).

Although the prevalence of incomplete bladder emptying among male and female patients with urinary incontinence and pelvic floor dysfunction is low, there is a general consensus that PVR should be measured in incontinent patients (16) although the evidence suggests that only patients with UI and symptoms of voiding dysfunction are at risk (17).

3.1.1 Measuring PVR

The measurement of PVR can be performed by invasive and noninvasive means. Invasive methods include: in-and-out catheterisation and endoscopy. Noninvasive means are transabdominal ultrasonography with real-time ultrasound or fully automated systems, and radioisotope studies. In-and-out catheterisation has been considered for some time, the goldstandard for the measurement of PVR. Nevertheless the method is subject to inaccuracies, if the person performing the catheterisation is not fully instructed as to the procedures and techniques to assure complete emptying (moving the catheter in and out slowly, twisting it, suctioning with syringe, suprapubic pressure), especially in cases of bladder diverticula and vesicoureteric reflux (18). The interval between voiding and PVR measurement should be as short as possible. It is advisable to ask the patients if the voiding was similar to a typical micturition in his/her daily life. Stoller and Millard showed inaccuracies in 26% of 515 male patients evaluated by full-time urology nurses with a mean difference between the initial and the actual residual volume of 76 ml in those measurements that were found to be inaccurate (19). After further education of the nurses, inaccurate assessments were reduced to 14% with a mean difference of 85 ml. PVR can be measured at the time of endoscopy, provided there is a blinded insertion of the instrument to avoid irrigation fluid inflow.

Both invasive means are usually performed with local anaesthesia and carry a small risk of urethral damage and urinary infection. Before the era of ultrasonography, PVR was measured non-invasively by the phenolsulfonphthaleine excretion test or with isotopes (20, 21).

In 1967, Holmes described the use of ultrasonography in the evaluation of bladder volume and this technique rapidly gained widespread acceptance as a satisfactory level of accuracy was demonstrated (22, 23). Using either three diameters (length, height, width) or the surface area in the transverse image and the length obtained in the longitudinal image, various volume formulae for a spherical or ellipsoid body are utilised to estimate the bladder volume (Table 3).

The intra-individual variability of PVR is high from day to day and even within a 24 hours period. This was reported in men with BPH by Birch et al. and by Bruskevitz et al. (34, 35). Griffiths et al. examined the variability of PVR among 14 geriatric patients (mean age 77 years), measured by ultrasound at three different times of day on each of two visits separated by 2-4 weeks (36). Within-patient variability was large (SD 128 ml) because of a large systematic variation with time of day, with greatest volumes in the early morning. The inherent random variability of the measurement was much smaller (SD 44 ml). Several factors can influence PVR variability: voiding in unfamiliar surroundings, voiding on command with a partially filled or overfilled bladder, the interval between voiding and the estimation of residual (it should be as short as possible), the presence of vesicoureteric reflux or bladder diverticula. Several studies reported the questionable value of PVR as an important outcome prognosticator in male patients with benign prostatic enlargement and benign prostatic obstruction (37-42). The cause of PVR is probably multifactorial, and no consensus exists on the relation of PVR, bladder outlet obstruction and detrusor contractility.

Table 3. Comparison of different formulae to assess PVR by transabdominal ultrasound in 30 men with BPH scanned three times (35).

3.1.4 Future Research Areas

1. Pathophysiology of PVR in male and female populations with UI;
2. Circadian variation of residual urine in patients with UI;
3. Determination of the cut-off value of significant residual urine in different patient populations with UI;
4. Residual urine as a prognostic indicator of outcome in the treatment of incontinence.

3.2 Open Bladder Neck and Proximal Urethra at Rest

The significance of open bladder neck and proximal urethra at rest observed during a voiding cystourethrogram or pelvic floor ultrasound scan remains doubtful (1) and the peer-reviewed literature is equally divided into papers associating such a condition with storage disorders and those suggesting this is a chance finding with no negative implications.

A 21% prevalence in nulliparous asymptomatic women has been reported (2). In the non-neurogenic population there is no pathophysiological correlation between this and urinary incontinence, Digesu and co-workers reported a prevalence of 1:3 amongst females suffering LUTS. An open bladder neck at rest is not pathognomonic of sphincter incompetence although it is associated with USI (3). In patients with stress incontinence, but also in asymptomatic women (4), funnelling of the internal urethral meatus may be observed on Valsalva (Fig. 5) and sometimes even at rest; funnelling is often associated with leakage. However, funnelling may also be observed in urgency incontinence and cannot be used to prove USI. Marked funnelling has been shown to be associated with poor urethral closure pressures (5, 6). Furthermore Shobeiri et al investigated the association between the levator ani muscle atrophy (levator ani deficiency) and the urethral sphincter muscle measurements using 3D endovaginal ultrasonography in female patients found no significant association. The authors concluded that although the rhabdomyosphincter deteriorated along with the levator ani muscle, this was not statistically significant. Themost valuable finding was that the smooth muscle was significantly smaller in patients with levator ani deficiency, and that patients with levator ani deficiency were more likely to have urodynamic stress urinary incontinence.

Reports in the peer reviewed literature suggest that an open bladder neck and proximal urethra at rest, during the storage phase, may be observed during cystography, videourodynamic or bladder ultrasound, both in patients with and without neurological disease and is interpreted as a sign of internal sphincter denervation as occurs in 53% of patients with multiple system atrophy (7). Distal spinal cord injury has been associated with an open smooth sphincter area, but whether this is due to sympathetic or parasympathetic decentralisation or defunctionalisation remains
uncertain (8). Relative incompetence of the smooth sphincter area may also result from interruption of the peripheral reflex arc very similar to the dysfunction observed in the distal spinal cord injury. Twenty-one out of 54 patients with spinal stenosis were found to have an open bladder neck at rest (9). In a review of 550 patients (10), 29 out of 33 patients with an open bladder neck had neurological disease. Although the association was more commonly seen in patients with thoracic, lumbar and sacral lesions, the difference when compared to cervical and supraspinal lesions was not significant. Damage to the sympathetic innervation to the bladder was also frequently observed in patients undergoing major pelvic surgery, such as, abdominal perineal resection of the rectum. Patients with myelodysplasia had an inordinately high incidence of open bladder neck (10 out of 18 patients versus 19 out of 290 having different neurological disorders).

Patients with sacral agenesis are included in the larger category of myelodysplastic patients and suffer from an open bladder neck with an underactive bladder. Shy-Drager syndrome is a Parkinson-like disorder with peripheral autonomic dysfunction. Neurogenic detrusor overactivity is usually found in association with an open bladder neck at rest and a denervated external sphincter (11). Peripheral sympathetic injury results in an open bladder neck and proximal urethra from a compromised alpha-adrenergic innervation to the smooth muscle fibres of the bladder neck and proximal urethra (12). Although it can occur as an isolated injury it is usually associated with partial detrusor denervation and preservation of sphincter EMG activity. The loss of bladder neck closure suggests an autonomic neural deficit. The site and nature of the requisite deficit is unclear.

Most authors agree on the importance of the sympathetic system in maintaining the integrity of the bladder neck (13-16) although the possible role of parasympathetic innervation has been proposed by others (17, 18). An open bladder neck at rest in children or in women without neurological disease can represent a different disorder, either related to a congenital anomaly or secondary to an anatomical pelvic floor defect. Stanton and Williams (19) described an abnormality in girls with both diurnal incontinence and bed-wetting, based primarily on voidingcystourethrogramy, in which the bladder neck was wide open at rest. Murray et al (20) reported the "wide bladder neck anomaly" in 24.5% of the girls (35) and 9.3% of the boys (10) out of 251 children (143 girls and 108 boys) undergoing videourodynamics for the assessment of non-neurogenic bladder dysfunction (mainly diurnal incontinence). The authors considered the anomaly congenital and made the hypothesis that wide bladder neck anomaly in girls may provide a basis for the development of USI in later life.

The presence of an open bladder neck has been proposed to explain the pathophysiology of urinary incontinence but such hypothesis did not stand the test of time. An open bladder neck was a key point in defining type III stress incontinence according to the classification of Blaivas and Olsson (21). This classification, no longer used in our daily practice, was based on history, imaging, and urodynamics, and distinguished five diagnostic categories of stress incontinence. Incontinence type III was diagnosed by the presence of an open bladder neck and proximal urethra at rest in the absence of any detrusor contraction suggesting an intrinsic sphincter deficiency.

In pelvic fracture with membranous urethral distraction defects, when cystography (and/or cystoscopy) reveals an open bladder neck before urethroplasty, the probability of postoperative urinary incontinence may be significant, although the necessity of a simultaneous (or sequential) bladder neck reconstruction is controversial (22-24). Skala and co-workers suggest that an open bladder neck at rest is associated with an increased risk of postoperative complications and failure after open colposuspension (25).

3.2.1 Conclusions

In conclusion, the diagnosis of open bladder neck at rest does not seem to be helpful to diagnose the underlying cause of urinary incontinence.

3.2.2 Consensus Statements

When observing an open bladder neck and proximal urethra at rest in male patients, during the storage phase, whatever imaging technique is used, it may be worthwhile to evaluate the possibility of an underlying autonomic neural deficit. (Level of Evidence 3, Grade of Recommendation C)

3.2.3 Future Research Areas

1. The relation of open bladder neck and proximal urethra at rest to the different neurogenic disorder
2. Longitudinal study of wide bladder neck and proximal urethra at rest in asymptomatic women
3. Evaluate the prognostic value of the open bladder neck and proximal urethra at rest

3.3. Female Urethral Diverticula

The prevalence of urethral diverticula ranges between 1 and 6% with rates up to 10% in among symptomatic women from tertiary referral centres (1, 2). The suspicion of a urethral diverticulum stems from LUTS or urethral masses on physical examination. Urethral masses include leiomyoma, vaginal cysts, malignancy, ectopic ureter, granuloma and urethral diverticula. The first case of female urethral diverticulum was reported in 1805 (3). Since the report from Davis and Cian in 1956 (4) using positive-pressure urography (PPU), the diagnosis has become much more common even though, despite increased clinical awareness, this pathology continues to be frequently overlooked. Urinary incontinence is often associated with a urethral diverticulum. Incontinence may be a sequel to urine loss from the diverticulum.
itself with stress manoeuvres, USI or UUI (5). Aldrige et al. (6) reported urethral diverticula in 1.4% of patients with SUI.

The presenting symptoms of a urethral diverticulum have classically been described as the three Ds (Dysuria, postvoid Dribbling, and Dyspareunia). Since most patients present with nonspecific lower urinary tract symptoms, and the pathognomonic presentation (postvoid dribbling, urethral pain, tender periurethral mass and expression of pus from the urethra) is very uncommon, these patients undergo extensive evaluation and treatment before a correct diagnosis is established (7, 8). The diagnosis of a urethral diverticulum may be achieved by physical examination, voiding cistouretryography, positive-pressure (double-balloon) urethrography, urethroscopy, endocavitary (transurethral or transvaginal) or pelvic floor ultrasonography, urethral pressure profile or MRI. Positive pressure urethrography is usually accomplished using a double balloon catheter according to the method described by Davis and Cian (4). Two different models exist: the Davis-TeLinde and the Tratner catheter. Positive-pressure urethrography (and voiding urethrography) may result in a false negative study when the inflammation of the diverticulum neck prevents contrast medium from flowing into the diverticulum cavity.

The accuracy of a diagnostic test may depend upon the characteristics of the study population and conflicting data are often reported in the peer-review literature. Blaivas et al reported a diagnostic accuracy of VCUG of 97% in a series of 66 patients and similar results (95%) were obtained by Ganabathi et al. (7, 9). Less favourable results have been reported by others. Comparison of VCUG versus PPU in the diagnosis of urethral diverticulum showed a clear superiority of the latter with good consistency among different studies (10, 11). In some patients, VCUG only delineated the lower part of the diverticulum (12). Ultrasound scanning and MRI should theoretically be free of such false negative imaging. Particularly, the emergence of high definition 3D endovaginal probes enables the operator to place the probe directly adjacent to the area of interest.

Chancellor et al. (13) described the use of intraoperative intraluminal echographic evaluation which may be of help in dissecting the diverticulum and achieving complete excision without damaging the bladder neck and urethra. A number of studies have shown that MRI is better than both voiding cistourethrography and positive-pressure urethrography and can be considered, if available, the imaging of choice when the diagnosis of urethral diverticulum is suspected (14-19) (Figure 36). MRI is superior to VCUG or double-balloon urethrography, particularly in diagnosing diverticula with narrow, noncommunicating necks (15, 16). MRI proved to be superior to radiological studies because diverticula can go undiagnosed on voiding cystourethrogram, furthermore size and complexity of the diverticulum is better defined on MRI (17). Endoluminal MRI is considered to be of particular importance in the diagnosis of a circumferential urethral diverticulum, a condition that is relatively rare but the diagnosis may increase with the increased use of this imaging technique.

Proper evaluation of the anatomy of the diverticulum is essential in planning reconstructive surgery (1, 20). MRI also proved to be useful in diagnosing inflammation or tumour in the diverticulum (21, 22). Endoluminal MRI with either a vaginal or rectal coil, may provide even better image quality than simple MRI (18).
A comparison of MRI versus urethrography and urethroscopy, in a group of 20 women with urethral diverticulum, reported a 69 and 77 per cent accuracy of the two latter imaging studies versus MRI (14). When surgical findings were compared to MRI, urethrography and urethroscopy, the diagnostic ability of the three methods was 70, 55 and 55 per cent, respectively. Diverticula ostia could not be identified by MRI not withstanding the use of contrast material. Neilitch et al. (15) reported in a series of 19 patients that MRI (using a fast spin echo T2-weighted pulse sequence and a dedicated pelvic multicoil) had a higher sensitivity for detecting urethral diverticula and a higher negative predictive rate in comparison to double balloon urethrography. Blander et al. (17), compared MRI and VGUG in 27 patients with urethral diverticula and found that endoluminal (endorectal or endovaginal) MRI was extremely accurate in determining the size and extent of urethral diverticula compared to VCGU; the related information can be critical when planning surgical approach, dissection and reconstruction. In conclusion, review of the peer reviewed literature suggests that positive pressure urethrography is still a valuable tool to diagnose female urethra diverticulum not withstanding both ultrasound sonography and particularly MRI represent better alternatives with a significantly higher diagnostic accuracy.

In males, both VCUG and ultrasonography can be successfully used to diagnose syringocele (cystic dilatation of the Cowper’s gland), congenital and acquired diverticula (23).

### 3.3.1 Conclusions

Proper imaging of female diverticula is essential to diagnose the condition and, in planning and conducting proper surgical repair. Ultrasonography may suffice to identify size and location of the diverticulum although MRI imaging in preferable whenever available.

### 3.3.2 Consensus Statements

In cases of female urinary incontinence if a urethral diverticulum is suspected, appropriate imaging (positive pressure urethrography, voiding cystourethrography, urethroscopy, ultrasound, MRI) is recommended. (The choice of the type of imaging depends on their availability. Data show a higher accuracy of MRI.) (Level of Evidence 3 – Grade of Recommendation C)

### 3.3.3 Future Research Areas

Properly conducted prospective studies are needed to compare the accuracy of ultrasonography and MRI in the diagnosis and staging of female and male diverticula

### 3.4. Imaging of the Nervous System

Lower urinary tract dysfunction often depends upon derangements of its neural control mechanism. Imaging of the spinal chord and central nervous system may help identifying occult neurological conditions or the site and extent of known neural damage. Functional imaging of the nervous system is a formidable research tool to better understand mechanisms of signal integration at the central level and its possible malfunctioning.

#### 3.4.1 Lumbosacral Spine X-Rays

In children with lower urinary tract dysfunction and urinary incontinence, the presence of a spinal dysraphism must be ruled out. Although in most of the cases abnormalities of the gluteosacral region and/or legs and foot are clearly visible, antero-posterior and lateral films of the lumbosacral spine have to be evaluated in order to identify vertebral anomalies. Sacral agenesis involves the congenital absence of part or all of two or more sacral vertebrae. In the absence of two or more sacral vertebrae a neurogenic bladder is usually found. Spina bifida occulta has a variable significance. Simple failure to fuse the laminae of the fourth and fifth lumbar vertebrae is unlikely to be important, but if the spinal canal is noticeably widened, there may be cord involvement (dysplasmyelia, tethered cord syndrome).

#### 3.4.2 CT, MRI, SPECT and PET

Numerous papers refer to rare neurological conditions presenting with different symptoms including urinary incontinence in which CT scan, MRI, SPECT, and PET imaging were carried out to identifying the underlying CNS disease. These references have little impact on daily practice although they can be helpful in occasional difficult cases.

With regards to the clinical diagnostic use of CT or MRI, a few papers evaluated the role of fetal MRI imaging. Fetal MRI has higher contrast resolution than prenatal sonography and allows better identification of normal and abnormal tissue. Moreover, MRI can diagnose some abnormalities such as cerebral malformations and destructive lesions which can be occult on prenatal sonography, where the more anterior cerebral hemisphere cannot be properly evaluated due to reverberations by the overlying structures (2). Common indications for fetal MRI include the evaluation of all the sonographically diagnosed abnormalities of ventriculi, corpus callosum, or posterior fossa, as well as all those fetuses at increased risk for brain abnormalities, such as in families with a history of a prior child or fetus with anomalies, genetic disorders, complications of monochorionic twinning, and maternal illness (such as maternal infection or major cardiac event). Moreover, with recent advances in fetal surgical techniques, fetal MRI is being increasingly used before surgical intervention (3). The results of fetal MRI, whether verifying absence of abnormality, confirming sonographically detected abnormalities, or discovering additional abnormalities that were not apparent by sonography, have been shown to affect clinical decision-making during pregnancy, both by physicians and parents, resulting in changes in pregnancy management in nearly half of cases (2). With regard to myelomeningocele, prenatal ultrasound can easily identify the absence of posterior elements of
the vertebral bodies at affected levels and extension of the subarachnoid space posteriorly through the bony spina bifida, as well as the frequently associated presence of small posterior fossa alteration and herniation of cerebellar tissue into the cervical subarachnoid, which define the Chiari II malformation. However, fetal MRI can be a helpful adjunct when sonography analysis is limited, such as in cases of large maternal body habitus, oligohydramnios, low position of the fetal head, or when the fetal spine is positioned posteriorly with respect to the mother. Moreover, fetal MRI can be very useful to detect additional associated anomalies, such as callosal agenesis or hypoplasia, periventricular nodular heterotopia, cerebellar dysplasia, syringohydromyelia, and diastematomyelia (3). If fetal surgery will show to improve long-term outcome, fetal MRI will surely become a routine examination for affected fetuses.

MRI is also recommended in children with anorectal abnormalities as abnormalities of the spine and of the spinal cord are diagnosed in 42 to 46% of cases and in about 50% of cases the spinal cord is involved (1). Wraige et Borzyskowski suggested that spinal cord imaging should be considered in children in whom day-time wetting is associated with impaired bladder sensation or poor bladder emptying even in the absence of clinical or radiological suspicion of lumbosacral spine abnormalities. Four out of 10 children with these symptoms had a spinal cord defect diagnosed on MRI(4).

MRI of the lumbar spine is now the gold standard for evaluating children with spina bifida and adults in which an occult form of spina bifida is suspected. A potential technical update might be the use of intrathecal contrast medium to perform cisternography and ventriculography contrast-enhanced MRI. Munoz et al., evaluated a series of 10 patients with complex cerebrospinal fluid diseases, where other imaging techniques had been unclear or inconclusive, performing MRI with intrathecal administration of gadopentate dimeglumine. In 8 out of the 10 patients, imaging findings influenced or changed the clinical decision-making program and the surgical planning (5).

Sharma et al. recently evaluated with MRI the surgical outcome in patients with spinal dysraphism. Specifically, MRI spectroscopy was used to evaluate the composition of cerebrospinal fluid before and after surgery. Before surgery, high levels of lactate, alanine, acetate, glycerophosphorylcholine, and choline were observed in the cerebrospinal fluid of patients with spinal dysraphism, while these levels normalised postoperatively to those observed in control subjects. However, in those patients where cord tethering occurred, increased concentrations of lactate and alanine were found, suggesting that MRI spectroscopy might be a promising tool in the assessment of surgical outcomes in patients with spinal dysraphism (6).

Several papers refer to the use of CNS imaging in clinical research of voiding dysfunction and pathophysiology. Positron emission tomography (PET) and functional MRI studies provided information on specific brain structures involved in micturition in humans. During micturition an increase in regional blood flow was shown in the dorsomedial part of the pons close to the fourth ventricle, in the pontine micturition centre (PMC), in the mesencephalic periacqueductual grey (PAG) area, as well as in the hypothalamus including the preoptical area (1). A good review on CNS imaging and lower urinary tract function was recently published by Drake and co-workers (7).

A couple of significant original studies have been published recently on the role of functional MRI in stress and urgency urinary incontinence. Specifically, previous brain imaging studies showed that during pelvic floor muscle contraction there was activity in the superior medprecentral gyrus, anterior cingulate cortex (ACC), cerebellum, supplementary motor cortex (SMA) and the thalamus (8, 9). Similarly, during anal sphincter contractions multifocal cerebral activity was shown in the primary and secondary sensory/motor cortices, the insula as well as the cingulate gyrus, prefrontal cortex, and the parietooccipital region (10). Di Giangi Herms et al. evaluated the neuroplastic changes of cortical representation of pelvic floor motor function induced with pelvic floor muscle training (PFMT) by biofeedback in patients with SUI (11). Specifically, the authors used functional MRI to evaluate 10 patients with SUI before and after a 12-week PFMT with EMG-biofeedback program. In the MRI performed before the beginning of PFMT, the authors identified significant brain activation in superior lateral and medial precentral gyrus and the superior lateral postcentral gyrus, in the SMA, the left premotor area, and in the left and middle cerebellum, as well as in the insula and in the ACC. In the MRI film after PFMT, less brain areas were activated, mainly the superior lateral and medial precentral gyrus, superior lateral postcentral gyrus and the insula. In other words, after PFMT there was more focused activation in the primary motor (superior lateral and superior medial precentral gyrus) and somatosensory areas, which is consistent with automation of the relearned skillful behavior (11). PFMT with biofeedback may improve muscular strength therefore enhancing support of the urethra and also optimise central muscular control of the pelvic floor, modulate bladder sensation, and reflect the emotional neutralisation related to symptom reduction.

With regard to UUI, Tadic et al. reported a small study, which used functional MRI to investigate 11 patients with UUI and 10 healthy controls. Specifically, the connections of the right insula (RI) and anterior cingulate gyrus (ACG) to other cortical area were evaluated, based on the assumption that the two areas were among the most important regions of the supraspinal neuronal network controlling the bladder. In normal subjects, there were significant positive effective connections with many of the regions involved in supraspinal bladder control, including left insula and frontotemporal and parietal regions, thalamus, putamen and caudate, posterior cortex, cerebellum,
pontine micturition centre and mesencephalic periacqueductal grey. Vice versa, in the patients with urgency incontinence, significant negative connections to left parieto-temporal lobes, hippocampus, parahippocampal gyrus and cerebellum were found, with few positive connections (12). In subjects with normal bladder function, RI and/or ACG have been reconfirmed to have effective connections with many of the brain regions involved in bladder control such as the frontotemporal and sensorimotor regions, thalamus, putamen, cerebellum and midbrain, as well as to the posterior cortex, a region which may have a role in the control of bladder function. Vice versa, in the patients with urgency incontinence, the connections were shifted to an alternative complex of brain regions, such as left parieto-temporal lobes, parahippocampal gyrus and parts of cerebellum, which might represent expression of the recruitment of accessory pathways in order to control urgency and the voiding reflex as well as the emotional charge due to the abnormal sensation of urgency (12). On the whole the data from these recently published studies have improved our knowledge of nervous functional anatomy related to vesicourethral function and dysfunction but, to date, have no clear clinical relevance.

In conclusion, central nervous system imaging is rarely indicated in urinary incontinence. Spinal cord imaging is recommended in cases of children with anorectal malformation and whenever spina bifida occulta is suspected. In the case of clinical neurological signs and/or symptoms suggestive of central nervous lesions, imaging may be indicated along with more specific neurophysiological tests (e.g., signal latency, testing, evoked potential, etc.). Further improvements in the knowledge of the correlation between morphological and functional evaluation of the CNS is foreseeable using present CNS functional imaging technology.

3.4.3 Consensus Statements

In patients with suspected congenital neurogenic incontinence, with or without abnormalities of neurourological physical examination, lumbo-sacral spine anteroposterior and lateral radiological evaluation (or MRI) is indicated. (Level Evidence 3, Grade of Recommendation C)

Neuroimaging should be considered when a nervous system disorder is suspected on the basis of clinical and/or neurophysiologic test findings (Level of Evidence 3 - Grade of Recommendation C)

3.4.4 Future Research Areas

To investigate the effect of antimuscarinics and neuromodulation on brain activity;

To standardise bladder filling parameters to investigate brain activity during different types and levels of bladder sensations;

To investigate the effect of environmental and behavioural factors on brain activity in patients with UUI.

3.5. Endoscopy of the Lower Urinary Tract

Since the introduction of the cystoscope by Bozinni in 1805, endoscopy has played a critical role in the evaluation of lower urinary tract disorders (1). Many investigators have proposed the routine use of urethrocystoscopy in the evaluation of urinary incontinence. These recommendations have rarely been based on evidence. There are five specific areas pertaining to urinary incontinence in which urethrocystoscopy has been advocated.

1. Observation of the female urethral sphincter to assess its ability to close and coapt. Urethrocystoscopy has been advocated in the static state to assess intrinsic sphincter deficiency (ISD) as well as in the dynamic state, when the patient is straining, to evaluate hypermobility and urethral closure while the patient is straining. It has been reported that sluggish closure of the bladder neck during periods of a rise in intra-abdominal pressure is associated with anatomical stress urinary incontinence. Intrinsic sphincter deficiency has classically been described as a fibrotic or pipe-stem urethra. It has been suggested that endoscopy can even help to differentiate between the hypermobile urethra and the intrinsically damaged urethra.

2. Assessment of the bladder, to rule out concomitant bladder conditions which may be the cause of DO and UI or may simply require treatment.

3. Search of extraurethral causes of urinary incontinence, such as vesico-vaginal fistula and ectopic ureter.

4. Intraoperative cystourethroscopy during correction of USI to assess for bladder damage and ureteral patency.

5. Evaluation of the membranous and prostatic urethra in male patients with post-prostatectomy stress incontinence to evaluate possible iatrogenic damage of the external sphincter region. Assessment of bladder outlet in males with urgency incontinence considered to be secondary to bladder outlet obstruction to appraise prostate morphology.

3.5.1 Evaluation of the Female Bladder Outlet

Robertson described the procedure of dynamic urethrocystoscopy to evaluate the bladder neck (2). In this procedure a gas urethroscope is used to observe the urethra, bladder neck, and portions of the bladder. During visualisation manometric recording can be performed. Robertson described the appearance of SUI as a sluggish closure of the bladder neck and the appearance of the overactive bladder as a bladder neck that closes and then opens like the shutter of a camera. This procedure was reported to be extremely
useful in patients with urinary incontinence as the bladder neck can then be observed at rest, with straining, and Valsalva manoeuvres. Unfortunately, in Robertson’s original description of this procedure, it was never compared to other standard methods of measuring outlet resistance. Others who advocate the technique of Robertson reported that only 43% of patients with SUI actually had loss of bladder neck support on urethroscopy (3). Scotti, et al performed a retrospective review of 204 patients who underwent dynamic urethroscopy for the evaluation of USI (4). Of the 204 patients, 99 had USI. Urethroscopy was found to be an imprecise predictor of USI with a 62% sensitivity, a 74.6% positive predictive value and a specificity of 79.1%. Moreover, there were many equivocal studies. The authors concluded that urodynamically evaluated rather than urethroscopy was a more accurate predictor of stress incontinence. Sand, and associates compared supine urethrocystoscopy cystometry (dynamic urethroscopy) to the gold standard of multichannel urethrocystometry (5). They found a sensitivity of only 24.6% and a positive predictive value of only 65.2% in predicting detrusor overactivity.

Horbach and Ostergard tried to predict urethral sphincter insufficiency in women with SUI using urethroscopy (6). They retrospectively reviewed the records of 263 women who had a diagnosis of USI. They defined ISD as a maximal urethra closure pressure of 20 cm H2O or less with the patient upright with a symptomatically full bladder. They then divided patients into two groups, those with ISD and those with maximal urethral closure pressures of more than 20 cm H2O. Based on this classification, 132 women, or 50.2%, had evidence of ISD. However, when urethral function was assessed by endoscopy, only six of 132 patients with ISD were found to have an open or partially open proximal urethra and urethrovesical junction at rest during urethroscopy. Clinically, these patients had very low urethral pressures and reported difficulty with continuous leakage of urine. Endoscopy appeared to have little predictive value for ISD as defined by urethral pressure profilometry. Govier et al compared cystoscopic appearance of the female urethral sphincter mechanism to videourodynamic studies in 100 consecutive women with complex types of UI (7). Sphincter dysfunction was classified as minimal, moderate, and severe based on the radiographic appearance of the bladder neck with straining. Urethroscopy underestimated the degree of sphincter deficiency 74% of the time in patients with moderate sphincter dysfunction and 44% of the time in patients with severe sphincter dysfunction. The authors concluded that cystoscopy is inadequate to judge the functional integrity of the bladder outlet. Furthermore, cystoscopy alone will underestimate intrinsic sphincter deficiency in a large number of patients.

3.5.2 Evaluation of the Bladder

Is cystoscopy necessary to rule out concomitant bladder pathology in patients with urinary incontinence? Langmade and Oliver reported on 253 patients who were operated on for SUI (8). They used a simple evaluation that consisted of history, stress tests, and urinalysis alone. They did, however, recommend cystoscopic evaluation if the patient also complained of symptoms of urgency. Although this dogmatic approach was recommended, it was never clearly stated if it made a difference to the treatment or outcome in these patients. Fischer-Rasmussen, et al performed extensive evaluation of women with urinary incontinence (9). This included cystoscopy in 190 patients. They found cystoscopy to be abnormal in only 12 patients, 8 who had SUI and 4 who had other types of UI. Abnormal findings were trabeculated bladder in five patients, benign bladder papillomas in four, and metaplasia of the trigone in two. None of these was considered to be a significant finding. The authors concluded that cystoscopic examination did not contribute to the classification of incontinence in any case. Cardozo and Stanton evaluated 200 patients with SUI and detrusor overactivity (10). Cystoscopy revealed no abnormalities amongst the 100 patients with USI. Fourteen of the 100 patients with detrusor overactivity had cystoscopic abnormalities, eg trabeculation-11, injected mucosa-1, sacculation D1, a bladder capacity of less than 100 cc-1. However, in none of these patients was the treatment affected by the results of cystoscopy. In support of these findings, Mundy has stated that there is no direct diagnostic value of endoscopy in a patient with an overactive bladder. It may sometimes be helpful to look for and exclude a cause of hypersensitivity when this is in the differential diagnosis (11). Duldualo and colleagues found this necessary only in patients with haematuria (12). They performed urinalysis, urine cytology, and cystoscopy on 128 women who presented with urgency incontinence and/or storage voiding symptoms. Of these, 68 patients had UUI, 35 of whom also had microscopic haematuria. One patient with UUI and haematuria was found to have a transitional cell carcinoma of the bladder. None of the patients with urgency incontinence (or storage symptoms only) and no haematuria were found to have significant cystoscopic findings. This would support the routine use of cystoscopy for patients with urgency incontinence only if haematuria is present.

3.5.3 Extra-Urethral Urinary Incontinence

Endoscopy can be an invaluable tool in the diagnosis and treatment of extrourethral incontinence due to vesico-vaginal fistula and ectopic ureter. With respect to vesico-vaginal fistula, cystoscopy can precisely localise the fistula site in the bladder and help plan surgical correction. Occasionally, a small fistula that is not seen on physical examination or radiographic studies, can only be diagnosed by cystoscopy. Incontinence due to ectopic ureter in the female is usually diagnosed by radiographic studies. However, the exact location of the ureteral orifice in urethra or vagina can be identified by cystourethroscopy and/or vaginoscopy. This can be extremely helpful in the planning corrective surgery.
3.5.4 Intraoperative Lower Urinary Tract Evaluation

Several authors have studied the value of routine cystoscopy during operative procedures for incontinence and prolapse. The approach may be transurethral (13) or transvesical(14). The American College of OB/GYN has published a Bulletin on Operative Lower Urinary Tract Injuries (15) in which is stated “at the conclusion of the procedure, when hemostasis has been ensured, both ureters and the bladder should be inspected to confirm their integrity.” Harris and co-workers (13) reported 9 unsuspected ureteral or bladder injuries during urogynaecological surgery, which included 6 ureteral ligations, with four of these occurring after Burch cystourethropexy. Burch sutures were also found in the bladder as well as fascia lata from a sling procedure.

3.5.5 Evaluation of the Male Bladder Outlet

Urgency incontinence is one of the lower urinary tract symptoms associated with benign prostatic hyperplasia, bladder outlet obstruction, and aging in the male population. Based on the available evidence and world literature, The World Health Organisation Fifth International Consultation on BPH made the following recommendation: “Diagnostic endoscopy of the lower urinary tract is an optional test in the standard patient with LUTS (lower urinary tract symptoms) because: 1) the outcomes of intervention are unknown, 2) the benefits do not outweigh the harms of the invasive study, 3) the patients’ preferences are expected to be divided However, endoscopy is recommended as a guideline at the time of surgical treatment to rule out other pathology and to assess the shape and size of the prostate, which may have an impact on the treatment modality chosen” (16). Several contemporary series have described the value of urodynamics in the diagnosis of post-prostatectomy UI (17-21). However, only one describes the routine use of urethroscopy. In that series 67% of patients had urethral fibrosis confirmed by endoscopy (18). However, how this finding affected treatment was not discussed. In the study by Leach and Yun treatment of incontinence was based solely on urodynamic findings and was successful in 87% of patients (22). Anastomotic strictures may be suspected based on uroflow and urodynamic (pressure-flow) studies and can be confirmed by voiding cystourethrogram or videourodynamics as well as by endoscopy. However, if intervention for the stricture is deemed necessary, endoscopy would be a more critical part of the evaluation. Furthermore if surgical treatment of incontinence, such as, an artificial urinary sphincter, is planned it would seem to make good clinical sense to evaluate the urethro-vesical anastomosis with endoscopy prior to surgery.

3.5.6 Evaluation of Urethral Sphincter in Post-Prostatectomy Incontinence

Iatrogenic UI in males usually occurs after prostate surgery for benign and malignant conditions. The pathophysiology of UI following transurethral surgery for BPH includes sphincter damage from extending the resection too distal, particularly in the ventral aspect of the sphincter where muscle fibres are more abundant. Endoscopy in post-TURP incontinence reveals insufficient closure at rest with tissue loss in the ventral aspect of the sphincter area, voluntary muscle recruitment is often good. The pathophysiology of UI in post-radical prostatectomy patients is unclear. Numerous studies have investigated the relationship between parameters of urethral pressure profile, morphology of the prostate apex and length of the external sphincter area to post-prostatectomy incontinence. Although the results of these studies suggest a relationship between sphincter competence and UI, no consensus has been reached regarding the gold standard test to be performed prior to surgery to assess the individual patient risk of incontinence. Recently, Gozzi and Rehder suggested that post-radical prostatectomy incontinence may be related to prolapso of the sphincter complex and that repositioning of it by a transobturator sling may be successful. Preoperative selection of surgical candidates for such intervention include endoscopy of membranous urethra testing whether manual push-up of the centrus tendineus perinei results in recruitment of the sphincter fibres comparable to a voluntary contraction. Contraction of the sphincter muscle upon repositioning in a more cranial position is used as an indication for a transobturator sling with the Gozzi and Rehder technique (23-25). Further research is required to confirm such an interesting pathophysiological explanation of post-radical prostatectomy UI and to support the role of endoscopy in the evaluation of these patients.

3.5.7 Consensus Statements

- Routine urethro-cystoscopy is NOT indicated in primary female UI, when other pathologies are not suspected (Level of Evidence 3, Grade of Recommendation C)
- Endoscopy can be considered (Level of Evidence 3, Grade of Recommendation C):
  - in urgency incontinence to rule out other pathologies, especially in case of microscopic haematuria (e.g., bladder tumour, interstitial cystitis, etc)
  - in the evaluation of recurrent or iatrogenic cases when surgery is indicated and planned
- Endoscopy is indicated in the evaluation of vesico vaginal fistula and extra-urethral urinary incontinence (Level of Evidence 3, Grade of Recommendation C).
- Endoscopy is indicated intraoperatively in incontinence surgery to look for ureteral or vesical injury (Level of Evidence 3, Grade of Recommendation C).

B.3.e.8 FUTURE RESEARCH AREAS
III. IMAGING IN ANAL INCONTINENCE

Anal incontinence may result from anatomical and/or neurological disruption of the anal sphincter complex. Prior to the development of anorectal imagining techniques, anal sphincter disruption was detected by digital palpation supported by EMG needle mapping and ano-rectal manometry. Use of endoanal ultrasonography (EAUS) for anal sphincter imaging was first described by Wild in 1956 (1) but remained neglected for many decades because of the limitation of technology then available (2). In 1989 Law and Bartum defined the technique of EAUS and endosonographic anatomy of the anal sphincter complex (3). Since then EAUS has become the gold standard of imaging the anal sphincter complex.

Development of 3-D rendering technique over the last decade has enabled better quality imaging of the anal sphincter complex using the EAUS. Recently other imaging modalities such as transvaginal, transperineal and translabial ultrasonography, MRI, Defaecography and Sonoelastography have been described to assess the anal sphincter complex in patients with anal incontinence.

1. INDICATIONS

Anal sphincter imaging has become an integral part of the assessment of anal incontinence. Following detailed history and examination, the patient should be offered anal sphincter imaging (either 2D or 3D EAUS) depending on the availability of imaging modalities and the expertise. Even though ano-rectal physiological studies indicate dysfunction of the anal sphincter complex, they do not identify the anatomical site and the degree of anal sphincter disruption. EAUS has been the gold standard for detecting anal sphincter disruption or atrophy. EAUS is also used in the follow up of women after obstetric anal sphincter injuries to assess the success of the primary repair and to advise on subsequent delivery. EAUS has been used intra-operatively to identify the damaged EAS prior to secondary repair and also to identify the IAS defects prior to injecting bulking agents.

2. IMAGING MODALITIES

2.1. Ultrasonography

The increased availability of ultrasound scanners to urologists and urogynaecologists and its high resolution in the near field makes this the perfect tool to investigate patients with anal incontinence as a part of their physical examination.

2.1.1 Endoanal Ultrasound (EAUS)

EAUS is performed using a 360° rotating rectal probe with a 7 - 10 MHz transducer (focal range 2-4.5cm) with minimum beam width of 1.1mm. Several systems are currently available, and recently integrated 3D systems are also available (B&K Medical, Sandofen 9, 2820 Gentofte, Denmark). Women should be examined prone with an endoanal system to minimise anatomical distortion. Figure 37 shows a schematic diagram of the anal sphincter complex in relation to the endoanal probe (4).

![Figure 37: A schematic diagram of the anal sphincter complex in relation to endoanal probe.](image-url)

The standard EAUS image of the anal canal is of 4 layers (Figure 38):

1. The subepithelial layer is moderately reflective.
2. The internal sphincter is the most obvious landmark and is a well-defined low reflective ring. The internal sphincter varies in thickness with age, being <1mm in neonate, 1-2mm in young adults, 2-3 in middle age and >3mm in the elderly.
3. The longitudinal layer is a complex structure with a large fibroelastic and muscle component, the latter formed from the puboanalis as well as the longitudinal muscle of the rectum (Figure 38).
4. The external sphincter is better defined in men than women, where it tends to be less hypoechoic. It is distinguished mainly by interface reflections between muscle/fat planes either side (Figure 38). In women the external sphincter is shorter anteriorly than posteriorly, which must not be misinterpreted as a tear. The transverse
perinei muscles fuse anterior with the sphincter, whereas in men they remain separate.

With experience the examination can be performed in about 5 minutes and provides an ideal method for a rapid assessment of sphincter integrity and thickness.

2.1.2 3-Dimensional Endoanal Ultrasonography (3-D EAUS)

With 3D-EAUS, the anal canal is scanned in a conventional manner, and dedicated software provides a final 3D appearance (3D rendering). The data obtained from a series of closely spaced EUS images (0.25 mm) are combined to create a 3D volume displayed as a cube. The image can then be freely rotated and it is possible to visualise defects at different angles and to obtain the most information from the data (5). The advent of 3D ultrasonographic multiplanar reconstruction of the anal canal has further improved the detection of anal sphincter injuries with nearly 95-100% sensitivity and specificity (6). With 3D-EAUS, the aspect, localisation (circumference involved, height), size (in degrees or percentage of circumference) and number of sphincter defects can be described in detail, together with a calculation of the volume of such defects (7). Defects of the puborectalis fibres of the levator ani are less common and these can be seen as heterogeneous remodelling or shortening of the two bands is visible after episiotomy or pelvic floor injury during vaginal delivery.

Figure 38: Axial endosonography in the mid canal in a normal 38yr old female. Subepith: subepithelial layer; IAS: internal anal sphincter; LL: longitudinal layer; EAS: external anal sphincter. The outer border of the external sphincter is defined by an interface reflection at the fat/muscle boundary (arrow).

Figure 39: Three-dimensional endoanal ultrasound showing no (a), partial (b) or complete EAS defect (c). Arrows indicate an EAS defect in the sagittal view (10).
Its role in the development of AI is probably underestimated and characterisation, particularly in terms of volume, would be of interest to assess the functional impact (6). Two scoring systems has been introduced to objectively evaluate the anal sphincter defects detected in 3D EAUS (8, 9) and both these scoring systems have shown acceptable intraobserver and interobserver agreement (9).

Although EAUS has been accepted as the gold standard of imaging anal sphincter complex, the equipment and the expertise may not be readily available in some centres. Some patients may find EAUS technique embarrassing and unacceptable. Hard endoanal cone of EAUS may cause the disruption of normal anal canal anatomy. Because of these drawbacks, other imaging modalities such as endovaginal, transperineal and translabial ultrasonography have been evaluated to assess the anal sphincter complex.

Sultan et al first described the vaginal use of 360° rotating probe used for the EAUS and obtained clear images of anal sphincter complex (11). Since then different types of probes including side-fire transrectal probe, a standard transvaginal probe and modified vaginal probe has been used to evaluate the anal sphincter complex with variable sensitivity and specificity for detecting anal sphincter injury (12).

2.1.3 Transperineal Ultrasonography

Transperineal ultrasonography (TPU) to image the anal sphincter complex was first described by Peschers et al. (13) and found to have a good interobserver reliability in detecting IAS and EAS defects compared with EAUS (14). A recent study by Roos et al. (12) comparing endovaginal and transperineal ultrasonography to detect obstetric anal sphincter have concluded that neither of these modalities is sensitive enough to detect anal sphincter defects.

2.1.4 Translabial Ultrasonography

Translabial ultrasound (TLU) offers an alternative imaging modality of the anal sphincter complex and has proven to be well-tolerated by patients. It has been used to describe anal sphincter complex integrity (13, 15). Hall et al evaluated 60 women with TLU and reported that mean sphincter measurements are given for symptomatic and asymptomatic intact women and are comparable to previously reported endoanal MRI and endoanal ultrasound measurements (16). The advantages of TLU are that the equipment needed is readily available to all gynaecology and radiology imaging laboratories.

2.1.5 Integrated Multicompartmental Pelvic Floor Ultrasonography

Pelvic organ dysfunction includes multiple conditions such as pelvic organ prolapse, urinary incontinence, anal incontinence, defaecatory disorders and sexual dysfunction. Based on this concept integrated multicompartmental Pelvic Floor imaging including two-dimensional (2D), three-dimensional (3D) and 4D pelvic floor ultrasonography as well as transvaginal, endoanal and transperineal techniques, has been described from a global and multicompartmental perspective (17). The value of this approach in routine assessment of pelvic floor dysfunction is yet to be evaluated.
2.1.6 Dynamic Anorectal Endosonography (DAE).

DAE uses a rigid biplane transrectal probe with a frequency of 7 MHz with the tip of the probe covered with a water-filled balloon to maintain the acoustic window for the ultrasound waves. By slowly and manually rotating the linear probe through 360°, various layers constituting the anal wall (mucosa, internal anal sphincter, and external anal sphincter), the layer forming the rectal wall, and the perirectal tissues (puborectalis muscle, bladder, and vagina, or prostate) has been demonstrated. After the initial examination, the patient simulates defaecation with the probe left in the same position (18). In a study of 56 women using DAE and Dynamic MRI Defaecography significantly more internal anal sphincter defects were found with DAE than with dynamic MRI defaecography, but there was no significant difference for the diagnosis of external anal sphincter defects (18).

2.1.7 Sonoelastography

Sonoelastography is a new imaging technique based on differences in radiofrequency signals following endogenous/exogenous compression due to different elastic properties of the targeted tissues or organs (19). This technique has been evaluated in pathological conditions of breast, thyroid, pancreas and prostate. The elastographic pictures registered simultaneously with conventional grayscale B-mode images during sonography or endosonography are assumed to distinguish malignant from inflamed areas and thus facilitate diagnosis. Based on this concept it is assumed that Sonoelastography is able to diagnose different conditions causing anal incontinence. However there is only one published study comparing the conventional endoanal ultrasonography and elastography (20). This prospective study included 50 patients with faecal incontinence following ano-rectal surgery and Crohn’s disease. Elastogram colour distribution within the sphincter representing elastic properties was quantified using a visual analogue scale and an off-line computerised area calculation program. The IAS, a smooth muscle, and the EAS, a striated muscle, have different elastogram colour distributions, probably reflecting their different elastic properties. The absence of significant correlations with the major clinical and functional parameters suggests that in routine clinical practice ultrasound real-time elastography may not yield additional information in patients with faecal incontinence except in patients who have had radiation.

2.2 MRI

Anatomy of the anal sphincter complex has been redefined over the past 20 years by the use of body coil, endoanal coil and phased-array coil magnetic resonance imaging (MRI). However these different MRI techniques have led to conflicting anatomical descriptions of the anal sphincter complex (21). Endoanal coil MRI studies by Rociu et al. (22, 23) have suggested that the levator ani muscle has only a transverse portion and that the EAS muscle is composed of only a subcutaneous and a superficial portion describing five image layers. (Fig 41)

However, body coil MRI studies by Guo and Li (24) suggested that the levator ani muscle also has a vertical portion (vertical levator), and separate body coil MRI studies by Hsu et al. (25) suggested that the EAS muscle has 3 separate components which has been identified in EAUS as well.

FIGURE 42:T2-weighted turbo spin-echo endoanal coil MRI studies by Rociu et al.
A: “5-layer” anal region and blind zone of the endoanal coil MRI.
B: Drawing of anal midcoronal section.
C: Inner intersphincteric space with high signal intensity is mislabeled as the internal sphincter.
Es - external sphincter; Is - internal sphincter; Lam - levator ani muscle; Lm -longitudinal rectal muscle; Pr - puborectalis; Sm –submucosa
More recent study by Guo et al. (26) using multiplanar body-coil MRI studies demonstrated that the anal region actually has 7 image layers: the mucosa, submucosa, anal smooth muscle, inner space, vertical levator, outer space, and the EAS muscle (Figure 42). The authors reported that endoanal MRI does not reliably outline the superficial layers of the anal region because a blind zone is created in the anal canal near the coil. This blind zone led investigators to effectively ignore the mucosa, submucosa, anal smooth muscle, intersphincteric groove, and subcutaneous sphincter and this accounts for the early endoanal MRI description of the anal region as comprising only 5 image layers. Images of the anal sphincter complex obtained using endoanal MRI are thought to be superior to MRI performed with a body coil because of increased signal to noise ratio resulting in high spatial resolution images. Although the endoanal MRI allows comprehensive assessment of atrophy and focal defects of the external canal, the internal sphincter has been less well defined (27). A meta analysis of nine studies, comparing endoanal MRI with endoanal ultrasound or surgical diagnosis in 157 patients by Tan et al. (28) has shown that endoanal MRI was sensitive and specific for the detection of external sphincter injury and especially sphincter atrophy. It may be useful as an alternative to endoanal ultrasound in patients presenting with faecal incontinence. However, the limited availability of dedicated endoanal coils outside specialist units has resulted in less widespread familiarity with this technique and further clinical studies are needed to identify its best application in clinical practice.

In addition to the damage to the anal sphincter complex, levator ani muscle (LAM) injury has also been postulated as a cause for anal incontinence especially after childbirth. A recent MRI study by Helliburn et al. (29) reported major LAM injuries in 19% of women who delivered vaginally with external anal sphincter (EAS) injuries compared to 3% delivered vaginally without EAS injury, and 0% delivered by caesarean section before labour. Among women with EAS injuries, those with major LAM injuries tend to have more anal incontinence symptoms than those who did not have EAS injury. These data suggest that both EAS and LAM are important to maintain faecal continence.

2.3. Evacuation Defaecography (Proctography)

Evacuation defaecography is indicated in patients with constipation, and in those with obstructive defaecation associated with anal incontinence caused by overflow incontinence or post defaecation leakage. In these patients, defaecography is useful to visualise outlet obstruction due to an anatomical (e.g. enterocele, rectocele, intussusception) or a functional (e.g. anismus) cause. Evacuation defaecography is also useful to demonstrate bladder and uterovaginal prolapse as well as pelvic floor descent (Figure 43 a-b) but gives limited information as to rectal function. Evacuation defaecography has shown good reproducibility in the diagnoses of enterocele, anterior rectocele and their grading in patients with faecal incontinence (30).

The rectum is opacified with 120 mls of a barium paste and the small bowel with a dilute barium suspension given orally about 30mins before defaecography starts. The patient is seated sideways within the fluoroscopic unit on a radiolucent commode. Evacuation of the barium paste is recorded either on video or on cut film at 1 frame/sec using a low dose protocol. At rest the anorectal junction is at the level of the ischial tuberosities and the anal canal closed. Evacuation is rapid (<30sec) and the rectum below the main fold should be emptied completely. During
evacuation the anorectal angle widens as the anorectal junction descends and the anal canal opens. At the end of evacuation pelvic floor tone returns and the puborectalis pulls the anorectal junction upwards and forwards back to the resting position. Intra-anal intussusception creates a thick double fold of rectum, which impacts into the anal canal on straining at the end of rectal evacuation. Rectal prolapse represents an extension of this process, with passage of the intussusception through the anal canal and inversion of the rectum (Figure 44 a-c).

Compared to conventional evacuation defaecography, dynamic MR defaecography at a vertical open magnet unit has become popular recently as it produces multiplanar images with increased soft tissue contrast and avoids radiation exposure. However the comparative results between conventional defaecography and dynamic MR defaecography in patients with prolapse and anal incontinence are variable (31, 32). Some of these variations have been attributed to the difference in technique. The main drawback of MR defaecography is the supine position required which causes suboptimal assessment of prolapse and evacuation (31). Since vertical open-magnet MR imaging units are not widely available, the role of MR defaecography in the diagnostic work-up of faecal incontinence is still limited.

**Figure 44: Sagittal views from a dynamic MRI examination.**

The dotted line indicates the position of the pubococcygeal line. At rest (a) there is some descent as the anorectal junction (ARJ) is more than 1 cm below this. During pelvic stress (b) there is marked pelvic floor descent, with descent of the cervix (Cx) and bladder base (Bl).

**Figure 45: Evacuation proctogram showing the development of rectal prolapse.** Intussusception starts at the end of rectal emptying (a) and rapidly passes through the anal canal (b) to form the external prolapse(c).
Figure 46: Endosonography with an axial image in the mid canal of an elderly patient, aged 73yrs with passive faecal incontinence. The internal sphincter measures only 1.1mm (markers) indicative of internal sphincter degeneration.

3. SPHINCTERIC DISORDERS

3.1. The Internal Anal Sphincter (IAS)

IAS is responsible for the maintenance of resting anal pressure and plays a vital role in maintaining anal continence. Isolated IAS defects are associated with surgery for ano-rectal malignancies, anal fissure and undetected obstetric anal sphincter injuries. These patients may present with passive faecal soiling and seepage rather than frank faecal incontinence.

Abnormalities of thickness are usually related to the patient’s age. A sphincter less than 2mm thick in a patient more than 50 years of age is indicative of internal sphincter degeneration (Figure 45) and is associated with passive faecal incontinence.

Obstetric trauma to the internal sphincter parallels that of the external sphincter in extent, but should always be in the anterior half, so that any defect between 3 and 9 is due to some other cause.

Sphincterotomy may be more extensive than was planned, particularly in women, and 3D studies are especially helpful to assess the longitudinal extent of the defect. The length of the sphincter divided relates directly to the risk of incontinence (33). Dilatation procedures are hazardous and may completely fragment (Fig 46) the internal sphincter.

3.2. The External Anal Sphincter

When striated muscle is stretched beyond the limits of its elasticity fibres rupture and heal with granulation tissue and eventually fibrosis. Most chronic tears are seen with scar formation, and present as a uniform area of low reflectivity distorting and obliterating normal anatomical planes (Figure 44). A key to the diagnosis is lack of symmetry with the anterior part of the
external sphincter not fusing at 12 o’clock as the probe is moved slowly down the canal. This may also be seen on 3D studies in the coronal plane (Figure 45). Other perineal structures, such as the puboanalis and transverse perineii are frequently torn and distinguishing these tears from external sphincter trauma requires experience, and again may be helped by 3D multiplanar imaging. The distinction is important as tears of the puboanalis or transverse perineii are not associated with a significant fall in squeeze pressure (34), and it is only damage to the external sphincter that results in a significant change. Childbirth damage to the puborectalis part of the levator ani muscle with intact EAS and IAS has been reported as a distinct cause of anal incontinence. 3-D EAUS is reported to be superior in detecting this type of injury (35).

In healthy young adults a good correlation has been found between measurements of layers thicknesses on endosonography and endocoil MRI, with an Ri of 0.96 for the external sphincter (36). The outer border of the external sphincter is easier to see on MRI, but fibrosis is not so markedly different in signal from normal muscle, so that the conspicuity of tears may not be as obvious as with endosonography.

Atrophy of EAS is a more difficult problem. Determining the thickness of the external sphincter on EAUS depends on visualising its borders from interface reflections between the longitudinal layer on the inside and subadventitial fat on the outer border. As atrophy involves a reduction of muscle fibres and an increase in fat, the outer interface reflection is lost and the thickness of the external sphincter cannot be measured. Such loss of definition of the outer border of the external sphincter on endosonography has a positive predictive value of 71% for atrophy (37). Using 3D EAUS and a grading system based on definition (Figure 47) and echogenicity of the external sphincter showed a comparable accuracy to endocoil MRI in detecting atrophy (38).

4. CONCLUSIONS

Claims for superiority of one or other modality for the detection of sphincter tears probably depend largely on individual experience, but the relative low cost and speed of EAUS makes this an ideal screening procedure to assess sphincter integrity. A leading issue is the significance of occult sphincter tears (diagnosed on endosonography but not apparent clinically) following vaginal delivery. Although these may be detected by careful examination immediately post partum (39), retrospective detection will still require EAUS. A meta-analysis of 717 vaginal deliveries revealed a 26.9% incidence of anal sphincter tears in primiparous, with 8.5% new tears in multiparous women. Overall 29.7% of women with tears were symptomatic, compared to only 3.4% without tears. The probability of faecal incontinence being due to a sphincter tear was 76.8-82.8% (40). Recent studies confirm the strong relationship between obstetric sphincter damage and faecal incontinence (41), and its late onset (42,43). Subsequent deliveries increase the risk of incontinence particularly if there has been a tear at the first delivery (44). Tears that involve the internal sphincter increase the severity of incontinence (45). A sphincter tear at EAUS is therefore an important finding, but how this is used to decide management is a little more controversial. Secondary anal sphincter repair has fallen out of fashion following the finding that results deteriorate over a few years (46), although a more recent study (47) suggests a better response.

Fluoroscopic studies have little role in faecal incontinence, unless there is an underlying rectal abnormality such as obstructive defaecatory symptoms and prolapse. Dynamic MRI studies have the added value of demonstrating prolapse in the rest of the pelvis, but apart from the lack of ionising radiation, has no real advantage for studying rectal function.

EAUS therefore remains the first line imaging investigation for anal incontinence, giving accurate information regarding the external and/or internal sphincter tears and the likelihood of atrophy. Dynamic studies of rectal evacuation are required only if there is some other problem suspected, such as prolapse. The advantages of using MRI are the lack of ionising radiation and a global view of the pelvic floor. Although imaging gives hard evidence of sphincter damage, this is really only part of a much more complex functional problem, and colorectal abnormalities may be just as important (48) with tears accounting for perhaps only 45% of incontinence (49).

Figure 47: 3D EAUS of a small tear to the external sphincter (arrow).
5. CONSENSUS STATEMENTS

- EAUS is the first line imaging investigation for faecal incontinence providing accurate information regarding external and/or internal sphincter tears and the likelihood of atrophy. (Level of Evidence 3, Grade of Recommendation C).
- 3-D EAUS offer better quality images and diagnosis of the depth of anal sphincter injury. (Level of Evidence 3, Grade of Recommendation C).
- Routine use of 3-D EAUS is not recommended because of the cost. (Level of Evidence 3, Grade of Recommendation C).
- Routine use of transperineal, transvaginal and translabial ultrasonography to image the anal sphincter complex are not recommended. (Level of Evidence 3, Grade of Recommendation C).
- Dynamic imaging of rectal function is required when rectal abnormalities such as prolapse are suspected (Level of Evidence 3, Grade of Recommendation C).
- MRI offers no advantage over other imaging modalities except for the lack of ionising radiation and global view of the pelvis (Level of Evidence 3, Grade of Recommendation C).

6. FUTURE RESEARCH AREAS

Better image quality with 3D EAUS and MRI have improved our understanding of pelvic floor anatomy, and this in turn has enabled sonographic anatomy to be re-evaluated, however, conflicting views of anal sphincter anatomy remain.

- Are clinical symptoms related to the size and the site of anal sphincter defect (50) or not (51)?
- Significance of imaging in detecting anal sphincter injury especially immediately after childbirth in preventing future anal incontinence (39,52).
- The value of ano-rectal physiological studies combined with imaging in assessing the success of surgical repair of the anal sphincter complex (53).
- Identify (and modify) the risk factors leading to anal sphincter injury especially during childbirth and develop preventive strategies (54).

The most valuable aspect of 3-D ultrasonography and MRI imaging is that they give a global view of the pelvis, capable of investigating urological, gynaecological and coloproctological problems at the same time (17). Many patients do not have faecal incontinence as an isolated symptom, but also have urinary, prolapse or defaecatory problems. The overview provided by imaging sets the way for a combined approach to the pelvic floor and should be the prime area of future investigation (17).

IV. PAD TESTING

The use of a perineal electronic nappy using electrical conductivity to estimate the amount of urine leakage was first proposed by James et al. (1, 2). Accuracy of this technique was, however, questioned by others and the technique was improved (3-8). Walsh & Mills and Sutherst et al. introduced a more simple approach by estimating leakage by perineal pad weight gain (9, 10). These tests were not standardised until Bates et al. described a "structured" one hour pad test which was endorsed by the International Continence Society in 1988 (11). This test, however, was shown to have poor interdepartmental correlation and to be highly dependent on bladder volume (12, 13). In an attempt to make pad tests more reliable 24 hour and 48 hour pad tests were developed. A more precise estimation of urine loss was shown, but they were more cumbersome. The Pyridium pad test was also proposed for diagnosing urinary incontinence (14).

1. DEFINITION

The pad test is a diagnostic method to detect and quantify urine loss based on weight gain of absorbent pads during a test period under standardised conditions.

2. INDICATION AND METHODOLOGY

A pad test allows the detection and quantification of urine loss, but it is not diagnostic of the cause of the incontinence. Several different standards have been developed. Tests can be divided into four groups according to the length of the test: <1h, 1h, 24h and 48 h. (Table 4)

*Maximum Cystometric Capacity

3. OFFICE-BASED PAD TESTING

Pad tests up to 2 hours were developed to be performed in outpatient clinics or hospital wards under supervised conditions. Bladder volume is predefined to reduce variability and a structured set of exercises is usually implemented to elicit the occurrence of urine loss.

3.1. Short Pad Test

**Quantification:**

These tests are based on a fixed bladder volume and a standard set of activities to facilitate the occurrence of urine loss, if any, over a short period of time. Jakobseny et al. found that the 40 minute test with a bladder volume of 75% maximum cystometric capacity and similar activities as a 1-hour ward test produced consistently larger amounts of urine loss than a standard 1-hour ward test (17). The difference was attributed to significantly larger bladder volumes during performance of physical activity in a 40 minute pad test.

Kinn & Larsson reported no correlation between a short 10 minute test with fixed bladder volume and the degree of incontinence as judged from the symptoms (18).

Hahn & Fall in a 20 minute test with half cystometric capacity showed no false negative results in 50 women with stress urinary incontinence although there was a discrepancy in 12% of patients between the perception of incontinence severity and pad test results (15).

These data suggest that short pad tests are more provocative than activities of daily living.

**Reproducibility:**

The correlation factor (Pitman’s nonparametric permutation test) between two separate 20 minute tests was 0.94 (p=0.001) (15). Kinn and Kinn & Larsson showed that the 10 minute test with a fixed pre-test bladder volume of 75% of maximal capacity was moderately reproducible (r=0.74) (18). Using a 1 hour pad test, a standardised bladder volume of 300ml and standardised physical activity mean differences of leakage was 8.5 ml and coefficient of repeatability was 33.6 ml (19).

3.2. One-Hour Pad Test

The use of a one-hour pad test has been investigated thoroughly for validity, reproducibility and sensitivity to change.

**Quantification**

Jakobseny et al. reported that a one hour test detected less leakage at 3 g compared to a 40 minute (7 g) and a 48 hour pad test (37 g) (17). In the elderly, a one-hour ward test did not demonstrate incontinence in 66% of those complaining of incontinence compared to 90% with a 24 in-patient monitoring of urine leakage (20). A one hour pad test was found to reflect everyday incontinence in only 48% of patients in comparison to 81% with a 48 hour test and 77% with a 40 minute test. Jorgensen et al. noted that 90% completed the test and 69% had test results which correlated with daily leakage (16). Lose et al. found a poor to moderate correlation of the modified one-hour test (200-300 ml in the bladder) with a history of stress urinary incontinence (n=31) (21). Mouritsen et al. showed that a 1-hour ward pad test did not detect grade I stress incontinence in 46%, grade II in 27% and grade III in 66% (22). Thind & Gerstenberg compared a 1-hour ward pad test to a 24-hour home pad test and found that a 1-hour pad test had a 36% false-negative rate as compared to a 24-hour home pad test (23).

**Reproducibility**

Klarskov & Hald demonstrated in 3 consecutive 1-hour pad tests, a correlation coefficient of 0.75 and 0.97 depending on the activity regimen (24). The test, however, was quite demanding and a lot of patients did not complete the full testing. Christensen et al. compared a one-hour pad test in two different urological and one obstetrics & gynaecological departments (20 women) (13). The test results in two urological departments did not differ with an average pad gain of 24g and 21 g (p>0.1). However, pad test results
between the departments of urology and gynaecology differed significantly, with average pad weight gain 9 g and 24 g respectively (p<0.05).

Lose and co-workers showed a significant variation between 1-hour ward test and retest in 18 patients (correlation coefficient 0.68) (12). In 50% of patients the leakage volume was variable due to differing bladder volume. When the results of the 1-hour pad test were corrected for urine volume, the correlation coefficient value increased to 0.96. Simons et al found the reproducibility of the standard 1 hour pad test to be poor (25).

Validity

Walsh & Mills in the elderly and Holm-Bentzen et al. in patients with an AMS artificial sphincter showed that the one hour pad test did not correlate with subjective patient satisfaction but this may due to other lower urinary tract symptoms (9, 26).

Bladder volume

Jorgensen et al showed test-retest correlation was improved when the bladder volume was taken into account and the correlation value (r) raised from 0.68 to 0.93 (16). Fantl et al used a one hour test with the bladder filled to capacity and had a test-retest correlation of 0.97 which was improved if the fluid loss was expressed as a percentage of bladder volume (27). Lose et al. using a 1-hour pad test with standardised bladder volume of 50% of maximal cystometric capacity (MCC) showed in 25 women a test retest correlation of 0.97 but the intertest variation was up to 24g (28). Jakobsen et al. compared a 1-hour pad test with a bladder filled to 50% and 75% of maximal cystometric capacity and found that the final bladder volume was equal in both groups showing the importance of diuresis even with equal starting bladder capacities (29). The amount of leakage in both groups was the same. Simons et al. found the volume in the bladder after a standard 1 hour pad test varies by -44 to +66g in a test-retest situation (25). The fluid volume in the bladder appears to be critical in making the pad test reproducible and increasing the sensitivity of the test for detecting leakage.

Aslan et al compared a 1 hour pad test loss with the symptom impact index (SII) and the symptom severity index (SSI) (30). Only the SSI showed a relationship between the severity of the score and the pad test loss. The 1 hour pad test has also been used in assessing the validity of the Incontinence Impact Questionnaire and the Urogenital Distress Inventory unfortunately both had poor correlations with the pad test (31). This is to be expected as the questionnaires assess other urinary symptoms rather than just leakage.

Diagnosis

Fluid loss was significantly greater in patients with detrusor overactivity in comparison to urodynamic stress incontinence (27, 32). The reverse finding was reported by Matharu and co-workers (33). There is high variability in patients with detrusor overactivity making the test impractical as a diagnostic tool.

Sensitivity to change

The 1 hour pad test has been shown to be useful in detecting significant improvements after pelvic floor exercises for men suffering urinary incontinence after radical prostatectomy (34). Ward et al. found the standard 1 hour pad test to show significant reductions in loss after tension free vaginal tape procedures from 18g (IQR 6-37) and Burch colposuspension from 16g (IQR 6-38) both decreasing to 0g (IQR 0) (35). The 1 hour pad test has also been tested for the reduction in loss after conservative and surgical therapy (36). The changes were significant but there was moderate correlation (r = 0.53) with the changes in the St. George Urinary Incontinence Score.

3.3. Two-Hour Pad Test

A test period of 60-120 minutes after a 1 litre fluid load was proposed as the optimal duration for the pad test because of a consistently high bladder volume (37). Han et al showed, however, that a 1-hour pad test is more practical (38). In children a 2-hour ward pad test yielded 70% positive results for incontinence (39). Richmond et al. compared two exercise regimens with a 2-hour pad test and showed no significant differences regarding which order the exercises were performed (40). Walters et al. performed a 2-hour pad test with standard exercise in 40 women with SUI showing 78% positive tests (>1g pad gain) after 1 hour and 98% after the second hour (41). Overall, the two-hour pad test was found to be superior to the one-hour one. There was no correlation between pad test results and the severity of a symptoms score.

4. HOME BASED PAD TESTING

These tests were developed to diagnose and measure urine loss in a situation as close as possible to standard daily life of the patient. The longer observation period usually requires a less structured procedure.

4.1. 12-Hour Pad Test

Quantification:

Hellstrom et al. demonstrated in 30 children with incontinence a positive 12-hour home pad test in 68%. When a standard fluid load (13 ml/kg) was instituted in 20 children, the frequency of the positive test increased to 80% (39).

4.2. 24-Hour Pad Test

Quantification:

Lose et al. found a 90% correlation of a 24-hour pad test with a history of stress incontinence in 31 women (21). This was better than the results of a 1-hour test. Thirteen of 31 patients were found to be continent after a 1-hour ward test in comparison to only 3 with a 24-hour home pad test. Mouritsen et al. showed that
the 24-h home test was well tolerated and as good at detecting incontinence as a 48-h test (22). Griffiths et al. found only a 10% false negative rate of a 24-hour pad test in an elderly population (20). Using non-parametric coefficient of correlation, they found a significant difference between the 1-hour test and the 24 hour test. Loss et al. found that a 24h home test performed during daily activities was more sensitive that a 1-hour ward test with standardised bladder volume of 200-300 ml (21). High fluid intake did not change the results of a 24-h home test, but a low fluid intake reduced a positive test by 56% (42). Ryhammer et al. showed that 24-h test is superior to subjective self-reported assessment of urinary incontinence (43).

Reproducibility

Loss et al showed poor correlation in a test-retest study with a variation of more than 100% (21) although Groutz et al. using Lin’s concordance correlation coefficient (CCC), found the 24-h test to be very reliable instrument (44). Increasing test duration to 48 and 72 hours slightly improved reliability but decreased patient compliance.

The values for the pad test increase in asymptomatic men and women were reported by Karantanis et al with the median value 0.3g (IQR 0.2 – 0.6; 95th centile 1.3g). It is surprising that the loss is so low and the same for men and women (45).

Diagnosis

Matharu et al found women with urodynamic stress incontinence leaked more than women with detrusor overactivity but the amounts were not diagnostic for the individual abnormalities (33). Pad test loss is unaffected by the degree of hypermobility however there is increased loss associated with urethral sphincter incompetence diagnosed by a vesical leak point pressure less than 60 cmH2O (46).

Validity

Karantanis et al found the 24-hour pad test was poorly correlated in women with urodynamic stress incontinence with incontinence episodes on a 3 day urinary diary (Kendall’s corr coeff b = 0.4) and the ICIQ-SF (r = 0.4) (47). Singh et al. reported that fewer (52%) women after surgery were willing to complete a 24 hour pad test at follow up (48).

4.3. 48-Hour Pad Test

Quantification:

Jakobseny et al. showed that 48-hour pad test reflects everyday incontinence in 81% of patients (17). No statistical analysis data were given. Ekelund et al., found patients own weighing correlate well to control weighing at the clinic in 48-h pad test (r=0.99) (49).

Nygaard and Zmolek in 14 continent women showed a mean pad weight, attributed to sweat for all exercise sessions of 3.19 ± 3.16 g (the Kendall coefficient of concordance of the test-retest reliability was 0.96) but there was a lot of variation between patients (53). Pyridium staining was not helpful in increasing specificity. Similar results with Pyridium were reported by Wall et al. in a 1-hour ward test (14). In his study (n=18) the Pyridium test was 100% positive in patients with SUI but had false positive results in normal women (52%).

Mean pad weight loss due to evaporation or leakage (was calculated to be 1.003 g, and ranged from -6.5 to +3.85 g (SD 1.85 g) (9). Lose et al. showed no evidence of evaporation over 7 days if the pad was stored in a plastic bag (21). Versi et al. showed pads wetted with saline showed no difference in weight after 1 week and less than 10% weight loss after 8 weeks (51). Twelve pads were weighed by the patient and a healthcare worker with a coefficient of variance =1.55% with a mean deviation of 49%.

Comments

Pad tests can either be used as a qualitative diagnostic tool to diagnose urinary incontinence and as a quantitative test to grade its severity. Pad test is unable to distinguish among different types of incontinence such as stress, urgency or mixed urinary incontinence. The ICS definition of urinary incontinence (the complaint of any involuntary leakage of urine) does not describe how the diagnosis is made but clearly refers to a patient’s complaint that excludes urodynamics and rather points at the patient perception of the condition. Following this line of thought, research in this area has moved away from the evaluation of diagnostic accuracy of pad test versus a urodynamic diagnosis of UI and entered the more interesting field of the relationship between the patient perception of UI and pad test. Franco and co-workers in London, UK tested the correlation between different questionnaires for UI and 1-hour pad test showing that only the ICIQ-SF reached statistical significance with a Kendall’s τb of 0.177 and a P value of 0.037 while no significant correlation was found for a 0 to 10 Vas score, a patient-based 3-point symptom severity scale, Stamey grade, Urogenital Distress Inventory and the Incontinence Impact Questionnaire (IIQ-7) (56). In another study from Wijma and co-workers, the diagnostic accuracy of pad test for self-reported symptoms of UI was evaluated during pregnancy and after childbirth and the authors conclude that the diagnostic value of pad testing has no clinical relevance in this setting (57). A similar analysis, performed in a male population undergoing sling surgery for post-radical prostatectomy incontinence suggested a good correlation between ICIQ-SF and the Patient Global

Perception of Improvement (PGPI) with a 24-hour pad test (58).

Studies from the Urinary Incontinence Treatment Network in US investigated the relation between different measures of incontinence severity and showed how pad weight from a 24-hour test had a good correlation with the incontinence episode frequency derived from a 3-day bladder diary (Spearman correlation coefficient 0.61) but a much lower degree of correlation was found with questionnaires such as the Medical, Epidemiological, and Social Aspect of Aging (r=0.33), the Urogenital Distress Inventory (r=0.17) and the Incontinence Impact Questionnaire (r=0.34) (59). In the same study, the use of pad testing as a prognostic parameter for treatment outcome was investigated but 24-hour pad testing showed no prognostic value for treatment failure in a study of Burch colposuspension versus autologous rectus fascia sling (60). An interesting result was obtained in a predominantly female population of patients receiving neuromodulation for refractory urgency incontinence in which a 24-hour pad test performed after the initial test stimulation was able to predict long term satisfaction in this difficult patient population (61). In this, as in other studies, the number of pads used per day proved to be an unreliable measure of urinary incontinence (62).

A couple of important methodological issues have been raised concerning the use of pad testing. Khan & Chien eloquently pointed out that test-retest comparison should include methods of blinding and use of an appropriate index of degree of agreement which is the intra-class correlation coefficient. In most of the literature this was not implemented (63). Kromann-Andersen et al. argued that with considerable inter- and intra-individual variation of urine loss, the correlation of test/retest results may be overestimated and suggested different trials for small, modest and large leakage in large numbers of patients (64). This trial has not been carried out.

A recent Health Technology Assessment of pad testing concluded that although high sensitivity and specificity for the diagnosis of UI was reported in some studies, it was difficult to draw any conclusions about the diagnostic accuracy for SUI because of the differences existing in pad test methodology. The number of studies comparing the same pad tests with adequate reporting is insufficient and no formal pooling of published data could be performed (65).

Role of the investigation

The test has been standardised by ICS in 1988 for quantification of urine loss and suggested uses for assessment and comparison of treatment results for different types of urinary incontinence in different centres. Also, the AUA report on Surgical Management of Female Stress Urinary Incontinence includes a pad test (pretreatment evaluation) as a standard of efficiency for clinical trials (66). The Urodynamic Society included a pad test in a Standards of Efficacy for Evaluation of Treatment Outcomes in Urinary Incontinence (67). No suggestion was made in the last two reports of which test to use.

### 5. CONCLUSIONS

- The 1-hour pad test is not very accurate unless a fixed bladder volume is applied
- Set exercises during the test improve test-retest reliability
- The sequence of exercises has little effect on test results
- A pad weight gain ≥1 g suggests a positive 1h test
- A 24 hour test correlates well with symptoms of incontinence
- A 24-hour test has good reproducibility but poorer compliance
- A pad weight gain ≥1.3g = positive 24 h test
- A test lasting longer than 24 h has little advantage
- A pad test cannot distinguish between USI and DO

### 6. CONSENSUS STATEMENTS

- The pad test is an optional investigatory tool in the routine evaluation of UI (Level of Evidence 3, Grade of Recommendation C)
- Pad test is a useful outcome measure in clinical trials and research studies. (Level of Evidence 3, Grade of Recommendation C)

The following standards are suggested:

- 20 min-1 h ward/office test with fixed bladder volume (pad weight gain ≥ 1g = positive test) (Level of Evidence 3, Grade of Recommendation C)
- 24 h home pad test during daily activity (pad weight gain ≥ 1.3g/24h = positive test) (Level of Evidence 3, Grade of Recommendation C)

### 7. FUTURE RESEARCH AREAS

Proper validation analysis using the coefficient of variability
Evaluation of the ability to detect all the spectrum of urinary incontinence (from mild to severe)
Sensitivity to change in time of incontinence status for 24 hour pad tests
Validity of pad tests with other measures of incontinence such as urinary diaries and symptom questionnaires.
1. INTRODUCTION

Neurophysiological investigations of muscles and nerves in the perineum and pelvis originated in the 1930-ties, and have evolved with the developments in general clinical neurophysiology. The data from these investigations can assist clinicians in diagnosing neurological disease or injury; the tests can be used intraoperatively for identification of nerves and muscles.

This text details the investigations, their applications and limitations, enabling investigators and clinicians to make a well informed decision about using these tests.

The present text is based on the previous chapter on clinical neurophysiology prepared for the International Consultations on Incontinence (1), which has been updated by a literature search in Medline using key words incontinence, clinical neurophysiology, electromyography, reflex, evoked potentials, autonomic nervous system tests.

1.1. Classification of Clinical Neurophysiological Tests

Although different types of tests may be included under the term "neurophysiological", it is particularly the electrophysiological tests that shall be discussed in the present text.

Electrophysiological tests are an extension of the clinical examination, and a functional anatomic approach to classification makes most sense. For the purpose of this categorisation, the nervous system is divided into the somatic and the autonomic nervous systems. The somatic nervous system provides motor innervation to the skeletal muscles and joints, and sensory innervation from skin and muscle spindles. The autonomic nervous system provides motor innervation to the viscera and other end-organs not under voluntary control (e.g., sweat glands). Its sensory fibres are referred to as visceral afferents. Both systems have central pathways (neurons participating in spinal cord and supraspinal control) and peripheral nerves (those going to and from end-organs).

Thus, electrophysiological tests can be divided into: a) somatic motor system tests (EMG, terminal motor latency measurements/motor nerve conduction studies, and motor evoked potentials (MEP)); b) somatosensory system tests (sensory neurography, somatosensory evoked potentials (SEP)); c) reflexes; and d) the autonomic nervous system tests (for sympathetic or parasympathetic fibres).

Electrophysiological tests may also be categorised "technically" into those limited to simple recording some bioelectrical activity (for instance: electromyography), and those which record particular biological responses to anatomically localised stimulation (these may be subsumed under the term "conduction tests").

1.2. Biological Correlates Of Electrophysiological Tests

1.2.1 Conduction Tests: Nerve Conduction, Evoked Potential and Reflex Studies

The electrophysiological responses obtained on stimulation are compound action potentials and relate to populations of biological units (neurons, axons, motor units, muscle fibres, etc.). Latency and amplitude are commonly measured parameters of responses during neurophysiological testing. If the onset of the potential is measured, the latency of a compound potential represents the fastest conduction through a particular neural channel. As a general rule, latency measurements are not markedly affected by technical factors, but provide little information about the loss of biological units (e.g., motor neurons or axons). The amplitude of the compound potential correlates with the number of activated biological units. In theory, the amplitudes are the more relevant physiological parameter, as they reflect the functional or structural loss of biological units. Unfortunately, amplitudes are also strongly influenced by many poorly controllable technical factors. Measurements of latencies and amplitudes of evoked potentials and reflex responses, including sympathetic skin responses, relate not only to conduction in peripheral and central neural pathways, but also to trans-synaptic transmission.

1.2.2 Electromyography (EMG)

Knowledge of the structure and function of the motor unit (Figure 47) is fundamental to understanding the application of EMG. Motor neurons, which innervate striated muscle, lie in the anterior horn of the spinal cord and are called "lower motor neurons". (Neurons that innervate the sphincters lie in Onuf’s nucleus in the sacral spinal cord; they are somewhat smaller than those innervating skeletal limb and trunk muscles). Within the muscle, the motor axon branches to innervate a certain number of muscle fibres, which are scattered throughout the muscle. All muscle fibres innervated by one lower motor neuron are activated simultaneously; all these constituents together are called "motor unit". The innervation of muscle fibres is such that it is unlikely that muscle fibres that are part of the same motor unit will be adjacent to one another.
It is difficult to estimate the number of muscle fibres innervated by a single axon (i.e., the “innervation ratio”) or the number of motor units supplying a muscle, by clinically available neurophysiological techniques.

1.3. General Methodological Considerations

To date, there are no universally accepted standards for conducting individual uro-genital-anal neurophysiological tests, but the variations of testing in different laboratories are minor.

There are technical standards on equipment safety.

1.3.1 Equipment

Clinical neurophysiological tests are conducted with complex electronic instruments and various devices that come into contact with the patient. Though this equipment is mostly standard, some specially constructed electrodes or stimulating devices have been devised to conform to uro-genito-anal anatomy. As long as the standards of electrical safety are adhered to, the risk to patients is negligible.

Surface electrodes, which are applied to skin or mucosal surfaces, or needle electrodes are used for electrical stimulation and to record bioelectrical activity. The important neurophysiological difference between surface and needle electrodes is their selectivity, and the practical difference is their invasiveness. The choice and application of electrodes is guided by the need for selective recording or stimulation. Less commonly, special devices are used for magnetic and mechanical stimulation.

The electrical stimulation should be specified and characterised both in technical (e.g., rectangular electrical pulse, 0.2 ms, 15 mA) and physiological terms (e.g., 3-times sensory threshold). A stimulus with defined technical parameters may have variable biological effects because of the variable influences of electrode condition, contact, tissue conductivity etc. Supramaximal stimulation is preferred to elicit a compound muscle action potential (CMAP) or sensory nerve action potential. Supramaximal stimuli yield responses with the largest amplitude and shortest latency, and are the least variable and most reproducible. The sites at which stimulation electrodes are applied should be described using anatomical terms.

1.3.2 Recording

1.3.2.1 Apparatus settings

For recording, the apparatus settings (gain, sweep speed) have to be adapted to the known range of amplitudes, latencies, and duration of the response and it has to be appropriately displayed for analysis. Particularly important is the frequency setting of filters: for surface electrode recordings it is typically 2 Hz – 1 kHz; for concentric needle EMG recordings, it is 5 Hz – 10 kHz.

Placement of electrodes on the scalp for evoked potential recordings is defined according to the 10-20 International EEG System

1.3.2.2 Reproducibility and Reliability

Any potential recorded should be reproducible; therefore, as a rule, at least two to three consecutive recording procedures need to be performed. To improve the signal-to-noise ratio some small amplitude responses need to be averaged. Therefore, many repetitions of stimulation/recording need to be done (typically 100-200). Even such an averaged recording needs to be repeated at least twice. Responses whose nervous pathways include synapses may show marked fatiguability with stimulus repetition (e.g., SSR); others are facilitated (the bulbocavernous reflex).

1.3.2.3 Waveform Analysis

For a particular recorded potential, its shape, latency, and amplitude are analysed. Morphologically, a particular response (or part of it) needs to be recognised as present or absent. The shape of potentials is important to accurately determine the latency and duration (if applicable) and amplitude of the response. The onset of the response obtained on stimulation (for M-waves, MEP and sacral reflex testing) or the individual peaks of the potentials (for SEP) are used to determine the latency. The amplitudes are analysed relative to the baseline or “peak to peak”.

2. CLINICAL NEUROPHYSIOLOGICAL TESTS

2.1. Somatic Motor System Tests

2.1.1 Electromyography (EMG)

The term “EMG” is used for several different procedures, the common denominator of which is the recording of bioelectrical activity from muscle. In practice, EMG is used a) to record the activity of a particular striated muscle as a functional unit (as for instance in combined urethral sphincter EMG and a pressure-flow study - see kinesiological EMG); b) to indicate that a particular muscle has been activated, either by stimulation applied to its motor innervation (M-wave, MEP) or to sensory pathways (reflex response); c) to differentiate between normal, denervated, reinnervated, and myopathic striated muscle; and d) to measure neuromuscular transmission (the later is not relevant for clinical diagnostics in pelvic floor muscles).

EMG recordings from smooth muscles are as yet only experimental.
2.1.1.1 General Technique for Needle EMG in Pelvic Floor Striated Muscles

All tests requiring needle electrodes are invasive and some pain is inevitable, even with use of local anaesthetics. Local anaesthesia is infrequently used for needle EMG examination. Intramuscular electrodes need to be appropriately placed in the target muscle.

The pelvic floor and perineal muscles can be examined, including the levator ani, the bulbocavernous muscle and the striated anal and urethral sphincter muscle. Facility with needle examination requires some practice. As a rule, several sites from one or more skin penetrations are sampled, which is difficult in small muscles.

The audio output from the loudspeaker of the EMG apparatus helps in assessment of the quality of recording as well as in recognition of the electrophysiological phenomena.

2.1.1.2 Concentric needle EMG (CNEMG)

The examination is conducted with a single use, disposable electrode, and all different “types of EMG" mentioned above can be performed with this electrode. It consists of a central insulated platinum wire inserted through a steel cannula and the tip ground to give an elliptical area which can record spike or near activity from about 20 muscle fibres.2 what’s this? The number of motor units recorded therefore depends both upon the local arrangement of motor units within the muscle fascicle and the level of contraction of the muscle.

In principle, CNEMG can provide information on a) muscle insertion activity, b) abnormal spontaneous activity within the muscle (FIGURE 48), c) MUPs, d) interference pattern (IP), neuromuscular jitter.

In normal striated muscle, needle movement elicits a short burst of “insertion activity," which is due to mechanical stimulation of excitable muscle cell membranes. This is recorded at a gain setting of 50 µV per division (sweep speed 5 – 10 ms/division), which is also used to record spontaneous activity. Absence of insertion activity with appropriately placed needle electrode usually means a complete denervation atrophy of the examined muscle.

The amount of recruitable motor units during voluntary and reflex activation can also be estimated. Normally, MUPs should intermingle to produce an “interference" pattern on the oscilloscope during muscle contraction, and during a strong cough. In addition, the number of continuously active MUPs during relaxation,3 MUP variability (neuromuscular jitter) as well as MUP recruitment on reflex and voluntary activation (kinesiological parameters) can be observed.4

MUPs (and occasionally encountered end-plate activity) are recordable in normal resting sphincter muscles in a relaxed subject. This is in contrast to limb muscles where relaxation is associated with “electrical silence" by EMG. In addition to continuously firing motor units, new MUPs are recruited voluntarily and reflexly in the sphincters. It has been shown that the two MUP populations differ in their characteristics: reflexly or voluntarily activated “high-threshold MUPs” being larger than continuously active “low-threshold MUPs”. As a consequence, standardised level of activity at which a template based multi-MUP analysis obtains 3-5 MUPs on a single muscle site was suggested.5

Although EMG abnormalities of striated muscle are detected as a result of a host of different lesions and diseases, there are in principle only two standard manifestations which can occur: a) disease of the muscle fibres themselves (“myogenic" changes), and b) changes in their innervation (“neuropathic changes).

Myogenic changes may result from muscle disease, probably also from direct trauma (e.g., the anal sphincter tear during vaginal delivery). Neurogenic changes may be attributable to injury at any level along the lower motor neuron supplying the particular muscle, extending from the motor neuron body, sacral nerve roots to the small branches within the muscle. (In the pelvic floor muscles, only neurogenic changes are well recognised and routinely evaluated).
In partially denervated sphincter muscle there is – by definition – a loss of motor units (MUs).

This can be estimated during relaxation by counting the number of continuously firing low-threshold MUPs. In patients with cauda equina or conus medullaris lesions, fewer MUPs fire continuously during relaxation,6 probably due to partial axonal loss. The main obstacle to qualified assessment of reduced number of activated MUs and activation of MUs at increased firing rates (as occurs in limb muscles) is a lack of concomitant measurement of level of contraction of the examined muscle (this can be readily assessed when studying limb muscles).

There are two approaches to analysing the bioelectrical activity of motor units: either analysis of individual motor unit potentials (MUPs), or analysis of the overall activity of intermingled MUPs. (This is the so called “interference pattern” – IP. Exploring different sites of the activated muscle with a needle electrode provides “samples” of intermingled motor unit potentials (IP epochs), which can be analysed).

Generally three different techniques of MUP analysis (manual-MUP, single-MUP and multi-MUP) and 1 technique of IP analysis (turn/amplitude – T/A) are available on advanced EMG systems.6

It is easy to grasp the “motor unit potential analysis”, as it is simply a measurement (by different methods) of the “parameters” of single individual MUPs (i.e. its amplitude, duration, number of phases…). The changes in MUP parameters furthermore are “direct” results of understandable physiological changes, and are thus “meaningful” to the interpreter.

The changes in IP parameters are, however, less readily grasped. These are: numbers of turns per second (any peak or trough of the signal where the activity changes by more than 100 μV); amplitude/turn (change in volts between two turns); number of short segments (parts of signal that has “sharp” activity); percent activity (percent of epoch with sharp activity); envelope (peak to trough amplitude exceeded by 1% of peaks/troughs). These parameters relate both to MUP parameters and to the activation level of the muscle. Recorded data are log transformed and linear regression lines are created. Amplitude/turn, and number of turns/second data from normal subjects can be used to create upper and lower boundaries (95% confidence intervals) for assembly of future data from individual patients. Individual data create a scatter plot (“cloud”) which compares to the normative boundaries. (See Figure 49). It has been asserted that this approach does not require a standardised muscle contraction, but the shape of the “cloud” is dependent on the strength of muscle contraction. Therefore it has been suggested to standardise the method by measuring pressure exerted by the contracting sphincter.7

Both the template based multi-MUP analysis of MUP and T/A analysis of IP are fast (5-10 and 2-3 minutes per muscle, respectively), easy to apply, and, technically, represent clinically useful techniques.

2.1.1.2.1 CNEMG Findings Due to Denervation and Reinnervation

After complete denervation, all motor unit activity ceases. In a denervated muscle, complete “electrical silence” is noted in the first days after such an event. The diagnosis of complete denervation is confirmed by the absence of muscle response during electrical stimulation. Because motor axons take days to degenerate after injury, this proof is not available for up to 5-7 days after a denervation injury. However, it is rarely necessary to demonstrate complete denervation in the acute stage because the clinical condition is usually obvious. Denervated muscle fibres become hyperexcitable and start to fire spontaneously giving rise to abnormal spontaneous activity, but these may take up to three weeks to appear. The “insertion activity” becomes prolonged and short biphasic spikes (fibrillation potentials) and biphasic potentials with prominent positive deflections (positive sharp waves) appear (Fig 48). Thus, concentric needle EMG (CNEMG) correlates of denervation are pathologically prolonged insertion activity and pathological spontaneous activity. Completely denervated muscle may be reinnervated by axonal regrowth from the proximal nerve stump with few muscle fibres constituting “nascent” motor units. These are short, bi- and triphasic, soon becoming polyphasic, serrated and with prolonged duration. In partially denervated muscle, collateral reinnervation takes place. Surviving motor axons will sprout and grow out to reinnervate those muscle fibres that have lost their nerve supply. This results in a change in the arrangement of muscle fibres within the unit. Whereas in healthy muscle, it is unusual for two adjacent muscle fibres to be part of the same motor unit, following reinnervation, several muscle fibres belonging to the same motor unit come to be adjacent to one another. CNEMG correlates are changes in MUPs (duration, amplitude, number of phases, turns, etc). Early in the process of reinnervation, the newly outgrown motor sprouts are thin. Therefore, they conduct slowly such that the time taken for excitatory impulses to spread through the axonal tree is abnormally prolonged. Moreover, the neuromuscular transmission is unstable due to immaturity of the motor end-plates. The CNEMG correlate is instability of long-duration complex potentials.

In partially denervated muscle, some MUPs remain and mingle eventually with abnormal spontaneous activity. Changes due to collateral reinnervation are reflected by: prolongation of the wave form of the MUP (Fig 49) which may have small, late components (“satellite potentials”). MUPs show “instability” due to insecure transmission in newly formed axon sprouts and end-plates. This “instability of potentials” (meaning both “jitter” and “blocking” of individual components in a complex potential) is not routinely assessed during sphincter EMG.8 In striated muscle, the diameter of reinnervating axonal sprouts and conduction velocity increase with time, thereby improving
synchrony of activation in the reinnervated motor unit. Thus MUP amplitude increases while MUP duration reverts towards normal. However, in degenerative neurological diseases (such as multiple system atrophy), long duration motor units are a prominent feature of anal sphincter reinnervation.9 It is important to note that in patients with more severe neurogenic lesions, reinnervation may be inefficient resulting in MUP with parameters below confidence limits describing size (area, duration).10

The changes in MUP parameters (along with changed number of MUPs and changes in activation frequency of MUPs) will be reflected also in IP parameters.

Abnormalities of parameters evaluated by needle EMG are in principle non-specific, i.e. most abnormalities can occur both in neuropathic or myopathic conditions. It is the overall clinical picture that dictates interpretation of results. It has been suggested that the combination of MUP thickness and number of turns might be even more accurate11 than previously suggested combination of MUP area, duration, and number of turns.12

**Figure 49:** Comparison of normal (above) and pathological (below) motor unit potentials (MUPs) sampled by multi-MUP analysis from the right halves of the subcutaneous parts of the external anal sphincter (EAS) muscles. To the right logarithm (amplitude) vs. duration plots of the MUPs are shown; the inner rectangle presents normative range for mean

**2.1.1.2.2 CNEMG of the External Anal Sphincter**

The external anal sphincter (EAS) is the most practical indicator muscle for sacral myotomes because it is easy to access, has enough muscle bulk for exact EMG analysis, and its examination is not too uncomfortable.

The needle electrode is inserted into the subcutaneous EAS muscle about 1 cm from the anal orifice, to
a depth of a 3-6 mm under the non-keratinised epithelium. For the deeper part of the EAS muscle 1-3 cm deep insertions are made at the anal orifice, at an angle of about 30° to the anal canal axis. In most patients only examination of the subcutaneous EAS muscle is necessary. Separate examinations of the left and right EAS muscles are recommended. The needle is inserted into the middle of the anterior and posterior halves of each side (“quadrants”) of the EAS muscle. After insertion in two positions on each side the electrode is turned backwards and forwards in a systematic manner. At least 4 sites in each of the subcutaneous and/or the deeper EAS muscle are thus analysed.

Use of quantitative MUP and IP analyses of the EAS is further facilitated by the availability of normative values that can be introduced into the EMG systems’ software. It has been shown that normative data are not significantly affected by age, gender, number of uncomplicated vaginal deliveries, mild chronic constipation, and the part of EAS muscle (i.e. subcutaneous or deeper) examined.

Intramuscular electrode insertion into other perineal muscles and pelvic floor muscles is not standardized and is described in textbooks and primary literature.

2.1.1.3 Single fibre EMG (SFEMG)

SFEMG is nowadays used practically only in diagnostics of neuromuscular transmission disorders, and not anymore in the pelvic floor muscles.

The SFEMG electrode has similar external proportions to a concentric needle electrode, but with a smaller recording surface. It will pick up activity from within a hemispherical muscle volume 300 µm in diameter, much smaller than the volume of 2-3 mm diameter from which a concentric needle electrode records. Apart from the neuromuscular jitter it can also record data which reflect motor unit morphology (muscle fiber density) but for this purpose it has several disadvantages in comparison to the concentric needle EMG.

2.1.1.4 Kinesiological EMG

Kinesiological EMG is the term for the type of EMG recording aimed only to assess the pattern of an individual muscle’s activity/inactivity during defined manoeuvres (Fig 50), typically during urodynamics. Any type of electrode can be used to make kinesiological recordings. The electrical activity of a muscle is described as present or absent (and can also be quantified). Technical issues will be dealt here; the relevance for diagnostics will be discussed in the Chapter on dynamic testing.

Although either standard EMG equipment or EMG facilities contained within urodynamic systems can be used, the better visual and audio control provided by standard EMG equipment facilitate optimal electrode placement and improve recordings. When using surface electrodes there are problems related to validity of signal (e.g., artefacts, contamination from other muscles). The quality of the EMG recorded from the external urethral sphincter (EUS) muscle is improved by a catheter-mounted surface electrode device that applies mild suction. With intramuscular electrodes, the procedure is more invasive, and there are questions as to whether the whole muscle in large pelvic floor muscles is properly represented by the sampled muscle portions. Intramuscular electrodes should ideally be fine wire electrodes, as they do not dislodge, and no pain is induced with muscle contraction.

The kinesiological sphincter EMG recordings in health show continuous activity of MUPs at rest. It can be recorded in many but not all detection sites of the levator ani muscle. The urethral and anal sphincter as well as the other pelvic floor musculature (e.g. pubococcygei) can be voluntarily activated typically for less than 1 minute. Timely activation of the levator ani muscle has been demonstrated to be an important aspect of stable bladder neck support; its activation precedes activity of other muscles in the cough re-

Figure 50: Kinesiological EMG recording from the urethral sphincter muscle of a healthy 53 years old continent female. Recruitment of motor units on reflex manoeuvres and on a command to contract is shown; regular continuous activity of motor units represents “tonic activity”. (Recorded with concentric needle electrode).

The kinesiological sphincter EMG recordings in health show continuous activity of MUPs at rest. It can be recorded in many but not all detection sites of the levator ani muscle. The urethral and anal sphincter as well as the other pelvic floor musculature (e.g. pubococcygei) can be voluntarily activated typically for less than 1 minute.20 Timely activation of the levator ani muscle has been demonstrated to be an important aspect of stable bladder neck support; its activation precedes activity of other muscles in the cough re-

750 | COMMITTEE 7. IMAGING, NEUROPHYSIOLOGICAL TESTING AND OTHER TESTS
2.1.1.5.1 Neurogenic Conditions

In children with spinal dysraphism,31 after mainly on lumbar discs,30 electrodiagnostic tests intraspinal tumours; or a result of spinal surgery, herniation, spinal fractures, epidural hematomas, and lesions within the spinal canal caused by intervertebral disc mainly been a consequence of neural compression commonly cause pelvic floor dysfunction. These have findings could not be established at time of electrodiagnostic testing.29

In an-plexus lesion in 1 patient. Furthermore, neuropathic cle in 6, a pudendal nerve lesion in 2, and a sacral dursalis lesion in 36 patients, a lesion of the EAS muscles and pelvic organs. In a series of 194 consecutive patients with neurogenic detrusor overactivity, EMG of the EUS muscle can be used to demonstrate the onset of detrusor contractions.20

Apart from polygraph urodynamic recordings to assess detrusor-sphincter coordination, thediagnostic usefulness of kinesiologic EMG has not been established.

2.1.1.4.1 Surface Electromyography Using Noninvasive Electrode Arrays

Surface EMG recording using noninvasive electrode arrays and multichannel EMG amplifiers can localize muscle innervation zones and asymmetry in muscle innervation,25 and analyze discharge patterns of MUPs, and propagation velocities along the muscle fibers.26 While it is expected that the new sophisticated computer assisted analysis techniques will help diagnosing sphincter function (for instance the “circular” for patients with neurogenic detrusor overactivity, EMG of the EUS muscle can be used to demonstrate the onset of detrusor contractions.20

Sphincter activity during voiding is characterised by the cessation of all EMG activity prior to detrusor contraction. Needle electrodes are more useful than perineal patch electrodes to demonstrate MU quiescence during voiding.23,24

Pathologic incoordination of the detrusor and sphincter is called detrusor sphincter dyssynergia. In selected patients with neurogenic detrusor overactivity, EMG of the EUS muscle has been used to demonstrate the onset of detrusor contractions.20

2.1.1.5 Clinical application of EMG

2.1.1.5.1 Neurogenic Conditions

Trauma, surgery (for instance: radical prostatectomy, and neurological disease have all been implicated in denervation of pelvic floor and perineal muscles and pelvic organs. In a series of 194 consecutive patients referred for electrodagnostic evaluation, quantitative needle EMG of the EAS muscles supported a diagnosis of a cauda equina or conus medullaris lesion in 36 patients, a lesion of the EAS muscle in 6, a pudendal nerve lesion in 2, and a sacral plexus lesion in 1 patient. Furthermore, neuropa-thic findings in the EAS were compatible with a diagnosis of multisystem atrophy in 11, and were most probably caused by severe polyneuropathy in 2 patients. In another 11 patients, the aetiology of the pathological findings could not be established at time of electrodagnostic testing.29

Lesions of the cauda equina or conus medullaris commonly cause pelvic floor dysfunction. These have mainly been a consequence of neural compression within the spinal canal caused by intervertebral disc herniation, spinal fractures, epidural hematomas, and intraspinal tumours; or a result of spinal surgery, mainly on lumbar discs.30 Electrodiagnostic tests are also useful in the assessment of neurogenic lesions in children with spinal dysraphism.31 After detailed clinical examination of the lumbosacral segments (with particular emphasis on perianal sensation), neurophysiological testing assesses the severity of the lesion and may clarify the diagnosis. In the authors’ series, 10 percent of patients with cauda equina lesions reported normal perianal sensation.32 Electrodiagnostic tests that need to be considered are bilateral needle EMG of the EAS muscle and the bulbocavernosus muscle in subacute situations; and electrophysiological evaluation of the bulbocavernosus reflex. Detection of spontaneous denervation activity by needle EMG (in the bulbocavernosus muscle!) is common from approximately 3 weeks to several months after injury. Later, MUP analysis becomes more important for demonstrating reinnervation. Most of these lesions cause partial denervation; a traumatic lesion to the lumbosacral spine or pelvis is probably the only acquired condition in which complete denervation of the perineal muscles can be observed.35, 36, 37

Following a cauda equina or a conus medullaris lesion, the MUP of pelvic floor and perineal muscles are prolonged and polyphasic, of increased amplitude, area, number of turns.6 Surgical dissections can also affect the innervation of the sphincter and lead to loss of motor units and reinnervation of those surviving.38 After pelvic trauma, gross changes of denervation and reinnervation may be detected in pelvic floor muscles. Abnormalities in polyneuropathy, as for instance diabetic, are usually minor.39

Neuropathic changes can be recorded in sphincter muscles of patients with multiple system atrophy (MSA), a progressive neurodegenerative disease, which can be mistaken for Parkinson’s disease (PD). Among 30 patients with a pathological diagnosis of multisystem atrophy, 24 had abnormal, 5 had a borderline, and only 1 had a normal sphincter EMG.41 Sphincter EMG has been proposed to distinguishing MSA from Parkinson’s disease, but is probably not specific in the latter stages of parkinsonism, and may not be sensitive enough in the early phase of the disease,42 43 44 Some studies have failed to demonstrate the effectiveness of MUP analysis in sphincter muscles,45, 46 probably because of the exclusion of late components from MUP duration.9 Extensive discussion on the subject can be found elsewhere.47 The changes of chronic reinnervation may also be found in progressive supranuclear palsy,48, 49 and in Machado–Joseph disease,50 in which neuronal loss in Onuf’s nucleus has also been demonstrated histologically.51

In patients with acute idiopathic autonomic neuropathy and lower urinary tract (LUT) dysfunction the EMG of external sphincter muscles was reported as normal.52

NEUROPHYSIOLOGY
2.1.1.5.2 Changes in Primary Muscle Disease

In skeletal muscle, the “typical” features of a myopathy are small, low amplitude polyphasic units recruited at mild effort. There are few reports of pelvic floor muscle EMG in generalised myopathy. In a nulliparous woman with limb-girdle muscular dystrophy, histology revealed involvement of pelvic floor muscles, but concentric needle EMG of the urethral sphincter was normal. Myopathic EMG changes were observed in the pubococcygeus and the EAS in patients with myotonic dystrophy, but not in another group of patients with myopathy.

2.1.1.5.3 Stress Incontinence

Pelvic floor muscle denervation has been implicated in the pathophysiology of UI. SUI (GSI). EMG techniques have been used to identify sphincter injury after childbirth and to evaluate women with USI. SUI and POP were associated with partial denervation of the pelvic floor. The changes were most marked in women who were incontinent after delivery, who had a prolonged second stage of labour, and had given birth to heavier babies. In a recent study, nearly all EMG parameters showed significant differences between continent and SUI women consistent with better motor unit recruitment in continent women. Continent women had larger-amplitude, longer-duration MUPs with increased turns and better MUP recruitment during bladder filling (P < 0.05).

Myogenic histological changes in pelvic floor muscles after vaginal delivery were also reported, with some EMG support by another group. "Myopathic EMG changes" (i.e. short, small MUPs) may, however, be a consequence of deficient reinnervation.

There were claims urethral sphincter EMG can assist in selecting the type of surgery for patients with intrinsic sphincter deficiency.

Although CNEMG of the urethral sphincter seems the logical choice in patients with urinary incontinence of possibly neurogenic origin, only a small amount of pathological muscle tissue remains in many incontinent parous women, which makes EMG of the muscle impractical. CNEMG findings generally will not affect therapeutic considerations.

2.1.1.5.4 Idiopathic Faecal Incontinence

"Idiopathic" faecal incontinence refers to patients in whom this symptom is not attributable to an underlying disorder, but it has been often implied that it is a neurogenic condition. Vaginal delivery is proven to cause structural sphincter defects: it may cause out-right sphincter denervation in rare cases, but its more widespread implication in causing “idiopathic” incontinence is controversial.

CNEMG may be helpful in selected patients with faecal incontinence if a specific neurogenic condition (e.g., trauma or disease affecting the conus, sacral roots, sacral plexus or pudendal nerves) is suspected on clinical grounds.

External anal sphincter muscle innervation pattern evaluation by multichannel surface EMG has been claimed to offer information to the obstetrician to prevent damaging episiotomies.

2.1.1.5.5 Idiopathic Urinary Retention in Women

In the external urethral sphincter of young women with urinary retention (or obstructed voiding) complex repetitive discharges (and decelerating bursts) in profuse amounts have been described. The abnormality was reported to be a predictor of the long-term success of therapeutic sacral neuromodulation. In a group of such women an occult generalised dysautonomia was found.

It has been known before that repetitive discharges develop in chronically partially denervated sphincters, and that they are present even in a proportion of asymptomatic women. Recently, it has been shown that this activity changes during the menstrual cycle (more commonly found in the luteal phase of the menstrual cycle in symptomatic women). The importance of this »abnormal« EMG activity in the aetiology of urinary retention in young women remains uncertain.

Currently, the diagnosis of Fowler syndrome remains a clinical one, based on a multimodal assessment of the patient.

2.1.1.5.6 EMG in Urodynamic and Functional Anorectal Studies

In health, voiding is characterised by cessation of motor unit firing in the urethral sphincter prior to detrusor contraction, as can be demonstrated by recording of kinesiological EMG. Bladder-sphincter coordination is impaired with lesions between the lower sacral segments and the upper pons. Consequently, sphincter activity is not inhibited, and often increases before detrusor contraction (i.e., “detrusor-sphincter dyssynergia”). On the basis of the temporal relationship between urethral sphincter and detrusor contractions, three types of dyssynergia have been described.

There are other clinical situations that mimic detrusor sphincter dyssynergia. Sphincter contraction or at least failure of relaxation during involuntary detrusor contractions can be seen in patients with Parkinson’s disease. The pelvic floor muscle contractions of the so-called nonneurogenic voiding dyssynergia may be a learned abnormal behaviour, and are a feature of dysfunctional voiding. There is insufficient data to determine the nature of the non-relaxation of sphincter activity as demonstrated by EMG signals during micturition (often seen in children and females) by EMG as such. The EMG recording has to be interpreted in the light of the overall clinical picture of the examinee.

The pubococcygeus in the healthy female reveals similar activity patterns to the urethral and anal sphincters at most detection sites: continuous activity at rest, often some increase of activity during bladder...
filling, and reflex increases in activity during any acti-
vation manoeuvre performed by the subject such as
talking, deep breathing, coughing. The pubococ-
cocygeus relaxes during voiding; the muscles on either
side act in unison. In stress-incontinent patients, the
patterns of activation and the co-ordination between
the two sides can be lost. A delay in muscle activa-
tion on coughing has also been demonstrated, as
compared to continent women.

Little is known about the complex activity patterns of
different pelvic floor muscles (the urethral sphincter,
urethrovaginal sphincter, anal sphincter muscle, dif-
ferent parts of the levator ani) during different ma-
noeuvers. It is generally assumed that they all act in
a co-ordinated fashion functionally as one muscle.
However there are demonstrable differences be-
tween the intra- and peri-urethral sphincter in healthy
females and in activation of the levator ani and the
urethral sphincter. Co-ordinated behaviour is fre-
quently lost in abnormal conditions.

Kinesiological needle EMG analysis of the urethra
with the patient at rest and coughing may predict the
outcome after certain types of incontinence sur-
gery. However, other studies found that preoperative
EMG did not predict patients at risk for postoperative
voiding dysfunction. (Kirby AC, Nager, CW, Litman, HJ et al. Perineal Surface Elec-

tromyography Does Not Typically Demonstrate

Expected Relaxation During Normal Voiding Neurology and Urodynamics 30:1591–1596
(2011)

Indeed, while kinesiological EMG (particularly when
combined with other urodynamic tests) promises the-
oretically relevant data, technical standards are lack-
ing, and findings have been reported in single center
studies. Further basic research is necessary to delin-
eate the correlation of EMG signals and their interpre-
tation in terms of clinical significance (the significance
of EMG data for defining overall LUT function).

Current concepts suggest that defecation requires in-
creased rectal pressure co-ordinated with relaxation
of the anal sphincters and pelvic floor muscles. Pelvic
floor relaxation allows opening of the anorectal angle
and perineal descent, facilitating faecal expulsion.
During defecation puborectalis activity is as a rule in-
hibited, but was unchanged in 9% and increased in
25% of healthy subjects. Thus, while “paradoxical”
puborectalis contraction during defecation is used to
diagnose pelvic floor dyssynergia in patients with typ-
ical symptoms, this finding may be a variation of the
ormal.

Same considerations regarding the lack of controlled
studies, technical standards, etc. apply as stated above for kinesiological EMG in studies of LUT func-
tion.

2.1.2 Pudendal Nerve Conduction Tests

Measurement of motor conduction velocity is rou-
tinely used to evaluate limb nerves, distinguishing be-
tween a demyelinating and axonal neuropathy. To
make the measurement requires access to the nerve
at two well-separated points and measurement of the
distance between them, a requirement that cannot be
met in the pelvis. Another way to evaluate peripheral
motor nerve function is the measurement of the la-
tency of a muscle response, requiring only a single
stimulation site. The muscle response is the com-
pound muscle action potential (CMAP) or M-wave.

Because in limb nerves the site of stimulation to ob-
tain only the motor latency (without measuring the ac-
tual conduction velocity) is as a rule placed distally on
the nerve, it is also called the distal (or terminal) la-
tency. For the pudendal nerve the site of stimulation
may be more or less “distally”, but the term distal or
terminal has — in accordance to general clinical neu-
rophysiology — become generally used. Distal motor
latency can be measured by recording with a concen-
tric needle electrode from the bulbocavernousus, the
EAS and the EUS muscles in response to bipolar sur-
face stimulation placed in the perianal/perineal re-

gion, or with needle electrode stimulation of the pu-
dendal nerve in the perineum. The most widely em-
ployed technique to obtain pudendal nerve terminal
motor latency (PNTML) relies on stimulation with a
special surface electrode assembly fixed on a gloved
index finger, known as the St Mark’s stimulator. It
consists of a bipolar stimulating electrode on the tip
of the gloved finger with the recording electrode pair
placed proximally on the base of the finger. The finger
is inserted into the rectum or vagina and stimulation
is applied close to the ischial spine. It is assumed that,
using this approach, the pudendal nerve is stimulated
close to the ischial spine, and that the response rec-
orded is of the EAS muscle. In women, intravaginal
stimulation and recording from the bulbocavernous mus-
cles has also been undertaken, with similar distal
latencies. However, the latency of such a response is
typically only around 2 msec, which seems unusu-
ally short compared with the perineal technique and
with conduction in the much thicker motor fibers of
peripheral nerves in the limbs. It seems unlikely that
the PNTML using the St. Mark’s electrode really eval-
uates conduction along the last 8 cm of the pudendal
nerve. Stimulation of the terminal pudendal branches
or pelvic floor muscles near their motor points seems
more likely, and this is supported by the much longer
PNTML (3.7 ± 0.9 msec) obtained with a monopolop
intrarectal stimulation electrode. If a catheter-
mounted electrode is used for recording, EMG re-
sponses from the striated muscle of the urethral
sphincter can be obtained. Experts differ in their esti-
imation of validity of this test. A prospective evalua-
tion of anorectal physiologic tests in 90 patients with fae-
cal incontinence did not find that PNTML results
changed treatment decisions. Indeed, the Ameri-
can Gastroenterological Association statement indi-
cated that “PNTML

2.1.3 Anterior Sacral Root (Cauda Equina)
Stimulation

Anterior root stimulation has been used to study con-
duction of the sacral nerve roots. Electrical stimula-
tion with needle electrodes at vertebral laminae Th12-
LI elicits M-waves in the bulbocavernous and EAS muscle.80

Transcutaneous stimulation of deeply situated nervous tissue became possible with development of special electrical and magnetic stimulators. When applied over the spine, these stimulators activate the roots as they exit the vertebral canal. Needle EMG rather than non-selective surface electrodes should be used to record pelvic floor and particularly sphincter responses to electrical or magnetic stimulation of the cauda equina. These stimuli non-selectively depolarise underlying neural structures, thereby activating several muscles innervated by lumbosacral segments.81 Lumbosacral stimulation often evokes a large stimulus artifact that can be decreased by positioning the ground electrode between the stimulating and recording electrodes.82 Invasive percutaneous stimulation of individual roots in sacral foramina is used to identify patients with lower urinary and anorectal dysfunction who are likely to benefit from long-term stimulation, e.g., with the Interstim (Medtronic, Inc., Minneapolis, USA). Electrical stimulation of nerve roots at the level of the appropriate sacral foramina results in observable muscle contraction in the foot and perineum. These responses can be identified as MEP or reflex responses on the basis of their latency. Selective stimulation of individual sacral roots is possible by appropriate positioning of surface stimulating electrodes.83

In conclusion, demonstrating the presence of a perineal MEP on stimulation over lumbosacral spine may occasionally be helpful in patients without voluntarily activated muscles. It also identifies the particular nerve root before introducing therapeutic electrical stimulation. However, the clinical value of the test has yet to be established and there are no sensitivity and specificity data on test results in individual patients.

2.1.4 Motor Evoked Potentials

Using magnetic or electric stimulation, it is possible to depolarise the motor cortex and record a response from the pelvic floor. Magnetic cortical stimulation is better tolerated than electrical stimulation, which has been abandoned in awake subjects, but may be useful for intraoperative monitoring.

By performing the stimulation at two different sites (brain and spinal roots), it is possible to record three different conduction times: a total conduction time, a peripheral conduction time, and a central conduction time (Fig 51). The total conduction time corresponds to the transit time from brain to target muscle. The peripheral conduction time is the transit time from sacral roots to the muscle. The central conduction time is obtained by subtracting the peripheral conduction time from the total conduction time. The total conduction time can be measured both at rest and during a facilitation procedure. MEPs from the EAS, the urethral sphincter, the bulbocavernosus muscle, and the levator ani muscle have been reported, but normative values have only been obtained (for transcranial magnetic stimulation) for the urethral sphincter and the puborectal muscle in adult women.84 A central conduction time of 15 to 16 msec without and 13 to 14 msec with facilitation is obtained for pelvic floor and sphincter muscles.85, 86, 87 The necessity to use concentric needle EMG for recording has been reconfirmed.88

Substantially longer central conduction times have been found in patients with multiple sclerosis and spinal cord lesions as compared to healthy controls.87, 88, 89 However all patients in this study had clinically recognisable cord disease. Nevertheless, MEPs may be useful in patients with unclear localization of spinal lesions.87

Conceptually, MEP may help to differentiate between involvement of motor and sensory pathways. However, the clinical utility of these measurements is not established. MEP have opened an avenue of research on excitability of motor cortex. It has been demonstrated that in comparison to the motor area for hand muscles the anal sphincter motor cortex has less intracortical inhibition.90
2.2. Sensory System Tests

There are several methods of sensory testing for the perineum, the genitourinary and anorectal tract. Clinical testing includes perineal and external genital skin sensation for light touch and pinprick, and sensation of bladder filling during cystometry. Anorectal sensory testing can be clinically assessed through rating of applied stimuli. More objective sensory testing can be performed with quantitative sensory testing (QST), which assesses sensory perception. For evaluation of the integrity of sensory pathways sensory neurography, and somatosensory evoked potentials (SEP) can be used.

2.2.1 Sensory Measurements During Cystometry

During routine cystometry bladder sensation is assessed by recording first sensation of bladder filling, first desire to void and strong desire to void.

Although not strictly a neurophysiologic test, measurement of electrical thresholds adds clinically non-obtainable information on sensory function of the lower urinary tract.91 Bladder and urethral sensory thresholds have also been measured using electrical stimulation,91 and mechanical traction on the bladder trigone.92 Electrical currents are applied to the bladder, urethra or genital skin using catheter-mounted or surface electrodes. High-frequency stimulation (> 20 Hz), with a stimulus duration of 0.5 or 1 msec is used because it is more easily perceived in the lower urinary tract. Measurement of sensory thresholds with such stimulation is reproducible, and normative data have been published.91 To date it has been used in only a few conditions (e.g., painful bladder syndrome93). There is no established clinical use for any of these tests other than simple reporting of sensation during cystometry.

In addition, palmar SSR and perineal surface EMG recordings can be used for more objectively demonstrating sensations during cystometry. The activity of both appears and increases in parallel with the first sensation of bladder filling, and with the first desire to void, respectively.94 Further studies using these methods are needed to establish their clinical utility.

2.2.2 Assessment of Anorectal Sensation

Rectal sensation is assessed by progressively distending a balloon manually or by a barostat while measuring thresholds for first perception, desire to defaecate, and severe discomfort. The intensity of perception during rectal distension can be recorded by a visual analogue scale during phasic distensions of graded intensity.95 The rate and pattern of distension affect rectal perception and internal sphincter relaxation.96

Anal sensation can be assessed by determining the perception threshold to an electrical stimulus or temperature change in the anal canal. Electrical testing does not activate mucosal receptors. Anal sensitivity to temperature change has been reported reduced in faecal incontinence.97

2.2.3 Quantitative Sensory Testing

Quantitative sensory testing (QST) of the urogenital-anal system should provide more objective and reproducible data than routine clinical testing. QST sensory modalities applied to the evaluation of urogenital function include vibration,98 temperature,99 and electrical current.100 (See also Sensory Measurements During Cystometry). There is no commonly accepted, detailed, standardised test, and the specificity and sensitivity of the tests are not known. The relationship of cutaneous quantitative sensory tests to bladder and urethral sensation and function is unknown. The physiological, psychophysiological and methodological issues and controversies will not be addressed in this chapter.

2.2.4 Sensory Neurography

Nerve conduction velocities of the dorsal nerve of the penis can be calculated by placing a pair of stimulating electrodes across the glans and a pair of recording electrodes across the base of penis. A nerve action potential can be recorded with an amplitude of about 10 µV. It can also be recorded by stimulating the nerve trans-rectally or transperineally. There is no known association between penile sensory neuropathy and bladder/sphincter dysfunction.

A few studies have recorded activity in sacral roots during electrical stimulation. Intraoperatively, when the sacral roots are exposed, compound sensory action potentials on stimulation of dorsal penile and clitoral nerve may be recorded directly.101 This helps to preserve roots mediating perineal sensation in spastic children undergoing dorsal rhizotomy, and reduce the incidence of postoperative voiding dysfunction.102 These tests are limited to their very specific intraoperative indications.

2.2.5 Somatosensory Evoked Potentials (SEP)

Somatosensory evoked potentials are electric waveforms of biological origin elicited by stimulation of a sensory nerve (or a sensory innervated skin area dermatome). The most commonly performed tests in the urogenital-anal region are pudendal somatosensory evoked potentials (SEP), which assesses conduction in large fibre pathways between the site of nerve stimulation and the parietal sensory cortex. Potentials can also be measured at the spinal level (spinal SEP).

Visceral (thin) fibre pathways are assessed by recording SEPs while stimulating the proximal urethra and bladder, although this is technically not depolarisation of nerves, but a mesh of afferents.
2.2.5.1 Pudendal Somatosensory Evoked Potentials

2.2.5.1.1 Cerebral Pudendal SEP

On electrical stimulation of the dorsal penile/clitoral or perineal nerve, a cerebral SEP can be recorded. (Fig 52) This SEP is as a rule of highest amplitude at the central recording site (Cz - 2 cm : Fz of the International 10-20 EEG System) and is highly reproducible. The first positive peak at about 40 ms (called P40) is usually clearly defined in healthy subjects using a stimulus 2-4 times stronger than the sensory threshold.103 The presence and amplitude of subsequent negative and positive waves are quite variable between subjects. Classically described pudendal SEP techniques stimulate both dorsal penile/clitoral nerves, thus reducing the sensitivity of the test. However, techniques of pudendal SEP that isolate each dorsal penile/clitoral nerve may be more sensitive for identifying pathology.104

Pudendal SEPs have been advocated in patients with neurogenic bladder dysfunction, e.g. in multiple sclerosis.105 However, even in patients with multiple sclerosis and bladder symptoms, the tibial cerebral SEP was more often abnormal than the pudendal SEP. The combination of an abnormal pudendal SEP with a normal tibial SEP suggests isolated conus involvement.106 The pudendal SEP was less useful than neurological examination for identifying neurological disease in patients with uro-genital symptoms.107 Following spinal cord injury, tibial and pudendal SEPs may be of some value for predicting recovery in bladder control.108 Cerebral SEP during penile/clitoral stimulation may be useful for intraoperative monitoring. Pudendal SEP were used to study the mechanism of sacral neuromodulation.109

2.2.5.1.2 Spinal Pudendal SEP

Stimulating the dorsal penile nerve and recording with surface electrodes at the level of the Th12-L2 vertebræ (and the S1, Th6 or iliac spine as reference) reveals the postsynaptic segmental spinal cord activity (the spinal SEP). Unfortunately, this spinal SEP may be difficult to record even in normal (particularly obese) subjects.

2.3. Sacral Reflexes

Clinically, two reflexes are commonly elicited in the lower sacral segments: (1) the penilo- or clitoro-cavernosus (i.e. bulbocavernosus) reflex; and (2) the anal reflex.110

To elicit sacral reflexes, electrical,111, 112, 113, 114, 115, 116, 117, 118 mechanical,115,116, 119 or magnetic120 stimulation can be used. Whereas the latter two modalities have only been applied to the penis,117, 118, 119 clitoris, electrical stimuli can be applied to various sites: to the dorsal penile or clitoral nerve; perianally; and, using a catheter-mounted ring electrode, to the bladder neck/proximal urethra.121

2.3.1 Sacral Reflex on Electrical Stimulation

Electrical stimulation of the dorsal penile or clitoral nerve elicits (somato-somatic) sacral reflexes in perineal muscles with a typical latency approx. 33 ms (29.9 ± 5.7 msec in one study in men117), traditionally called the bulbocavernosus reflex (Fig 52). In addition to single-pulse electrical stimulation, two identical electrical pulses separated by a 3-msec interval
can be used (i.e., double-pulse electrical stimulation).117, 118 Double-pulse electrical stimulation is more efficient in eliciting sacral reflexes.117 Stimulation of the perianal skin, bladder neck or proximal urethra elicits sacral reflexes with latencies above 50 ms. This latency is longer compared to responses conveyed by the pudendal nerve, suggesting that the afferent limb for these responses involves visceral afferent fibres accompanying the pelvic nerves, which are thinly myelinated and have a slower conduction velocity than the thicker pudendal afferents. With visceral denervation (e.g. following radical hysterectomy) the viscero-somatic reflexes (from both bladder and urethral stimulation) may be lost while the bulbocavernousus (penilo-/clitoro-cavernosus) reflex is preserved. Loss of bladder-urethral reflex with preservation of bladder-anal reflex has been described with urethral afferent injury after recurrent urethral surgeries.122

The longer latency anal reflex (the contraction of the EAS on stimulation of the perianal region) is quite variable thus limiting its usefulness as a diagnostic tool. On perianal stimulation, a short latency response can also be recorded, as a result of depolarisation of motor branches to the EAS, possibly involving antidromic travelling of the depolarisation, with “returning” of the depolarisation orthodromically to the sphincter at a branching point of the motor axon. EMG recording of the sacral reflex has been shown to be more reliable than the clinically assessed response (e.g. observing and palpating the contraction) in males and particularly in females.123 In men, value of 40, 36 and 36 msec have been suggested as the upper limit of normal for the shortest latency obtained on eliciting a series of reflex responses using single, double and mechanical stimulation, respectively.117

In men with cauda equina lesions penilo-cavernosus reflex could not be elicited in 64%, 47% and 47% of patients on single electrical, double electrical, and mechanical stimulation, respectively. Measurement of the reflex latency increased the sensitivity to record abnormalities for 17%, 36%, and 34%, respectively. Furthermore, it has been shown that sacral reflex measurement increase sensitivity of quantitative EMG of the EAS muscles from 73% to 81-83% using the different stimulation techniques mentioned.118

Sacral reflex testing has been studied extensively and is used in many laboratories in everyday practice to demonstrate objectively the integrity of the S2-S4 reflex arc. The sacral reflex evoked on dorsal penile or clitoral nerve stimulation (the bulbocavernosus or penilo-/clitoro-cavernosus reflex) was shown to be a complex response, often forming two components. The first component with a typical latency of about 33 ms, is the response that has been most often called the bulbocavernosus reflex. It is stable, does not habituate, and has other attributes of an oligosynaptic reflex response.112 The second component has latency similar to the sacral reflexes evoked by stimulation perianally or from the proximal urethra, and is not always demonstrable as a discreet response. In those subjects in whom the first reflex component is difficult to elicit, stimulation strength should be increased, but preferably double electrical stimuli should be used. A complete reflex arc lesion should not be inferred by absence of a response if only single pulse is used for stimulation.

During voiding sacral reflexes are un-elicitable but in presence of spinal cord lesions such as myelodysplasia this normal suppression is lost.

Sacral reflex responses recorded with needle or wire electrodes can be analysed separately for each side from the EAS or bulbocavernosus muscle. Using unilateral dorsal penile nerve blocks, the existence of two unilateral BCR arcs has been demonstrated. Thus by detection from the left and right bulbocavernosus (and also the EAS) muscles separate testing of right and left reflex arcs can be performed. Some authors reported that sensitivity of the test can be increased by use of the inter-side latency difference (normative limits: < 3 ms), but finding could not be confirmed by others (normative limits: < 7.2 ms).117 In cases of unilateral (sacral plexopathy, pudendal neuropathy) or asymmetrical lesions (cauda equina), a healthy reflex arc may obscure a pathological one on clinical elicitation, but not on neurophysiologic measurements of the sacral reflexes.

As described above, penilo-cavernosus reflexes were absent in 47-64%, and delayed in additional 17-19% of patients with conus/cauda lesions. Of these patients 47% were incontinent for urine and 47% for faeces. However, a reflex with a normal latency does not exclude the possibility of an axonal lesion in its reflex arc, as demonstrated by pathologic quantitative EMG of the EAS in 79-86% of patients with conus/cauda lesions.118 Furthermore, much delayed sacral reflex responses are compatible with normal bladder and sexual function as found in patients with hereditary motor and sensory demyelinating neuropathy. In a proportion of women with non-neurogenic sacral dysfunction clitoro-cavernosus reflex latencies were found to be much longer compared to those obtained in women with intact sacral function.124

Sacral reflex recording is suggested as a complementary test to CNEMG examination of pelvic floor muscles in patients with suspected peripheral nervous lesions.4

In addition to latency, a number of other parameters can also be measured using electrical, but not mechanical stimulation. These are the sensory threshold (i.e., the stimulus strength (mA) at which subjects feels stimulation), and reflex threshold (i.e., the stimulus strength (mA) at which the reproducible penilo/clitoro-cavernosus reflex appears on the screen). They evaluate lower sacral sensory pathways, and excitation level of the sacral reflex pathway, respectively. Although for men normative data for these parameters is available,117 their utility in clinical situation remains unclear.

NEUROPHYSIOLOGY  |  757
Continuous intraoperative recording of sacral reflex responses on penis/clitoris stimulation is feasible if double pulses or a train of stimuli are used.125

2.3.2 Sacral Reflex on Mechanical Stimulation

Mechanical stimulation has been used to elicit BCR in both sexes and found to be a robust technique. Either a standard reflex hammer or a customised electromechanical hammer can be used. Using a reflex hammer, the stimulus is applied to a wooden spatula placed on the glans penis or clitoris.117, 118 Such stimulation is painless and can be used in children.119 The latency of the BCR elicited mechanically is comparable to the electrically elicited reflex in the same patients, but depends on the electromechanical device used.117, 119

2.4. Autonomical Function Tests

Most uro-neurophysiological methods discussed so far assess myelinated fibres, but not the autonomic nervous system, especially the parasympathetic component, which is most relevant for pelvic organ functions. Methods for evaluating the autonomic nerves innervating the pelvic viscera are not available. Cystometry indirectly evaluates the parasympathetic innervation to the bladder. However, from a clinical neurophysiological point of view direct electrophysiological testing would be desirable.

2.4.1 Tests in Generalised Autonomic Neuropathy

Cardiovascular autonomic function tests are useful for identifying generalised autonomc dysfunction in patients with bladder or gastrointestinal motility disturbances.

In cases when a general involvement of thin fibres is expected, an indirect way to examine autonomic fibres is to assess thin sensory fibre function. Thin visceral sensory fibres are tested by stimulating the proximal urethra or bladder, and by recording sacral reflex responses or cerebral SEP.

2.4.2 Dartos reflex

In men, another approach to test lumbosacral sympathetic function is by neurophysiologic measurement of the dartos reflex obtained by electrical cutaneous stimulation of the thigh. The dartos muscle is a sympathetically innervated dermal layer within the scrotum, distinct from the somatically innervated cremasteric muscle. A reliable and reproducible dartos reflex (i.e., scrotal skin contraction) with a latency of about 5 seconds has been demonstrated in healthy men.126

Technical problems have so far limited smooth muscle electromyography of the detrusor muscle, and of genital smooth muscle. Recently, successful intrinsic (smooth muscle) anal sphincter muscle EMG recordings on electric autonomc nerve stimulations were reported to spare the autonomc nerve supply during surgery in pigs.127

2.4.3 Sympathetic Skin Response (SSR)

The sympathetic nervous system mediates sweat gland activity in the skin. Changes in sweat gland activity lead to changes in skin resistance. On noxious stimulation (such as a sudden noise, electrical pulse, etc.) a potential shift can be recorded with surface electrodes from the skin of the palms and the soles, and has been reported to be a useful parameter in assessment of neuropathy involving non-myelinated nerve fibres. The response, known as the SSR, can also be recorded from perineal skin and the penis. Similarly, the SSR can be recorded from the genital region in women. The SSR is a reflex, which consists of myelinated sensory fibres, a complex central integrative mechanism and a sympathetic efferent limb with postganglionic nonmyelinated C fibres. SSR is the only electrophysiological method directly testing sympathetic fibres; recording from the perineal region assesses sympathetic nerve function of thoracolumbar segments. Limited literature exists regarding the relationship between SSR results and bladder dysfunction. A correlation has been shown between the absence of the SSR response in the foot and bladder neck dyssynergia following spinal cord injury.128

Only complete absence of response can be regarded as abnormal. Its utility in evaluating bladder and urethral dysfunction is not established.

3. EVIDENCE BASED USE OF CLINICAL NEUROPHYSIOLOGICAL TESTS

Evidence-based medicine is founded on the assessment of evidence for and against the efficacy of particular types of therapeutic intervention. Clinical neurophysiology testing should thus demonstrate evidence that testing improves outcome (through treatment choice and patient selection). However, testing and therapeutic intervention are different concepts, and neurophysiological testing has another important objective. It is to generate knowledge about the situation to be treated in a given patient, so that the practitioner can formulate rational treatment options based on knowledge rather than do so blindfold; that is, he or she can practice “knowledge-based medicine”.

To judge the importance of this second objective different criteria are needed. Particularly in the referral setting, the physician is confronted with complicated cases in which the underlying pathophysiology is quite uncertain, and what is required is to identify all the factors that may be contributing. Neurophysiology is helpful in assessment of neurogenic dysfunction because it contributes to “knowledge-based medicine”, whether or not there is narrowly-defined “evidence” that it improves outcomes.
Of course, it remains true that we should seek evidence of the conventional kind for and against testing. Any test should be subjected to three questions:

1. Does the test have good technical performance?
2. Does the test have good diagnostic performance, ideally against a “gold standard” measure?
3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

Clinical diagnosis requires that measures obtained in individual patients be compared to population norms with the intent of determining whether they are “normal” or “abnormal”. Data can be classified as “abnormal” only with the understanding that they are compared to a sample from the normal population. Predictive statements are made possible by the use of tolerance limits. For most clinical neurophysiological tests, one-tailed tolerance limits are recommended. For any given limit of normality, there is a certain probability of falsely interpreting values (obtaining false-positives or false-negatives). Further confounding these issues is the practice of applying multiple criteria of abnormality. But ultimately, the adequacy of any given normal limit in discriminating between normal and abnormal must be supported by appropriate clinical or clinico-pathological correlations; for uroneurophysiological techniques, such data are scarce.

3.1. Usefulness of Clinical Neurophysiological Tests in Evaluation of Individual Patients

Whenever pathophysiology is uncertain or unpredictable, and especially if irreversible treatment is necessary or contemplated, it seems logical to gather quantitative knowledge of the dysfunction in order to make a rational treatment choice.

In most patient groups with neurogenic incontinence, the pathophysiology is unpredictable and comprehensive urodynamic evaluation is essential in order to practice knowledge-based medicine. In selected patients from these groups, clinical neurophysiological testing will clarify issues related to the neural control of lower urinary tract, relevant for understanding pathophysiology.129

As is generally true for electrophysiological tests, uro-neurophysiological examinations are particularly useful for substantiating the clinical diagnosis of a peripheral nerve lesion. The potential usefulness of testing in an individual patient needs to be analysed in the overall clinical setting. The indications for testing are guided primarily by expert opinion, not on definitely established criteria derived from controlled studies.

In the incontinent patient without other signs or symptoms of a neurological condition, as in most patients with stress/urgency, or mixed urinary incontinence electrophysiological testing is as a rule non-contributory.61

Neurophysiological methods may have other uses, as for instance using the EMG signal for correct needle positioning for infiltration of sphincter muscle with botulinum toxin,130 or using tests for intraoperative identification and monitoring of nerves and muscles.126

3.2. Usefulness of Clinical Neurophysiological Tests in Research

As understanding pathophysiology of neural control of lower urinary tract is essential in the application of more sophisticated therapeutic methods, such as electrical stimulation techniques,131,132 there is a continuing place for clinical neurophysiology in research on neurogenic urinary and anorectal dysfunction and their therapy.

There is ongoing research on already described techniques to validate their usefulness in diagnostics133, and in intraoperative monitoring.134

4. CONSENSUS STATEMENT

4.1. Recommendation for Clinical Neurophysiological Testing

The information gained by clinical examination and urodynamic testing may be enhanced by uro-neurophysiological tests in selected patient groups with suspected neurogenic urinary incontinence with lesions within the nervous reflex arcs of sacral segments 2 – 5. Concentric needle EMG to diagnose denervation and reinervation of pelvic floor and perineal muscles, and sacral reflex testing to assess the continuity of the sacral reflex arc, are the recommended tests.

Level of evidence: 2b
Level of recommendation: B

Clinical neurophysiological testing should be performed in accredited laboratories, by trained and certified staff, with formal control of the quality of the results. Ideally, the uro-neurophysiologist should be in liaison with general clinical neurophysiologists.

It seems optimal to create interdisciplinary teams between urology, urogynecology, proctology, and neurology departments.

4.2. Recommendation for Technical Standards

Even in the more widely used “general” clinical neurophysiology there is no universal standardisation of tests. This is mainly due to different historical backgrounds of testing developed in different countries. The need to standardise methods is, however, recognised.

Proposals for standardisation for external anal sphincter CNEMG4 and the bulbocavernosus
(penilo/clitoro-cavernosus) reflex have been made, and seem to be widely adopted.

Level of evidence: 2b
Level of recommendation: B

4.3. Future Research Areas

Clinical neurophysiological methods should be further explored and used to better define the neural control in lower urinary tract function, demonstrating both the nervous system’s “hardware” (integrity of anatomy) as well as “software” (level of activity, excitation thresholds) for co-ordinated urinary storage and voiding, in physiological and in pathological conditions.

There is as yet no standardisation of the technical aspects of (kinesiological) EMG within urodynamic (and ano-rectal) function testing. Furthermore, more research is needed to shed light on the relationship between the EMG signals, pelvic floor muscle function, and overall LUT (ano-rectal) function (Anding et al. When Should Video and EMG Be Added to Urodynamics in Children With Lower Urinary Tract Dysfunction and Is This Justified by the Evidence? ICI-RS 2014. Neurourology and Urodynamics 35:331–335 (2016) References at end and ano-rectal function).

There are also challenges to validate the use of the described techniques for intraoperative identification of structures and monitoring nervous function, to define neurophysiological changes induced by therapeutic electrostimulation, and to develop tests to assess directly the sacral parasympathetic system.

VI. OTHER INVESTIGATIONS

1. URINALYSIS

“Urinalysis is a fundamental test that should be performed in all urological patients” (1). In patients with urinary incontinence, urinalysis is not a diagnostic test for the condition, but it is rather used to screen for haematuria, glucosuria, pyuria and bacteriuria. Even in the absence of controlled studies, there is general expert consensus that the benefits of urinalysis clearly outweigh the costs involved (2). A positive urinalysis will prompt infection treatment and/or the use of additional tests such as endoscopy and urinary tract imaging. In the evaluation of urinary incontinence in the female, urinalysis is recommended since 60% of women develop urgency symptoms at the time of urinary tract infection (UTI). Pyuria was found to be common among incontinent but otherwise asymptomatic, female patients. Pyuria was not necessarily associated with UTI, the significance of sterile pyuria in the elderly population is still unclear (3).

A Norwegian survey of general practitioners’ management of female urinary incontinence suggested that urinalysis is the most frequently performed test (73%) and is far more frequent than gynaecological examination (54%) (4). Another survey suggested that urinalysis is one of the three-part assessment of UI together with patient history and physical examination (5). The same apply, according to Stricker, for patient selection for collagen implant (6). A minority of the reviewed papers suggested that urine culture should be carried out together with urinalysis (3, 7). Urinalysis is also considered of importance in the evaluation of nursing home residents who are incontinent (8), in peri- and postmenopausal women (9), in older women reporting urinary incontinence (10). Belmin et al. suggested that significant urine samples can even be obtained from disposable pads in elderly incontinent women (11, 12). It is recommended that geriatric incontinent patients undergo history, physical examination, tests of lower urinary tract function and urinalysis. The latter test is proposed to rule out the presence of UTI (12). The clinical relevance of asymptomatic bacteriuria in the elderly is controversial. Although DuBeau and Resnick suggest the use of urinalysis in the diagnostic algorithm to identify asymptomatic bacteriuria in incontinent residents of nursing homes (13), others consider that the condition does not require any treatment (11). Urinalysis is less sensitive and specific for urinary tract infection in women who have had radiotherapy but the combination of leucocyte esterase and nitrites still has a positive predictive value of 95% (14). Urinalysis in patients with stents and patients on haemodialysis has not been found to be an effective screening test and routine culture is recommended (15, 16).

1.1. Consensus Statement

• It is considered standard practice to perform a urinalysis either by using a dipstick test or examining the spun sediment. (Level of Evidence 3, Grade of Recommendation C)

• If a dipstick test is used, it is recommended choosing of a “multiproperty” strip that includes testing for haematuria, proteinuria, glucose and ketones, leukocytes esterase (indicating the presence of leukocytes in the urine) and nitrite tests (suggesting bacteriuria). (Level of Evidence 3, Grade of Recommendation C)

1.2. Future Research Areas

• Needed to screen analysis of urinalysis in the diagnosis and treatment of UI, MUI and SUI

2. BLOOD TESTS

The prevalence of renal damage or of biochemical abnormalities in the general population of patients with urinary incontinence is very low, but there are subgroups of patients where the prevalence can be higher (e.g., neurogenic incontinence, overflow incontinence). The routine use of a battery of common chemical and/or haematological tests in patients with
UI appears to be a prudent rule of good clinical practice in the following situations:

- chronic retention with incontinence
- neurogenic LUT dysfunction
- when surgery is contemplated
- when there is a clinical suspicion
- sodium plasma concentration may be reduced in patients on desmopressin.

Special tests such as measurement of anti diuretic hormone (ADH) and atrial natriuretic polypeptide have proven useful in research of enuresis in childhood and nocturia in the elderly (1, 2). Changes in the circadian rhythm of these, and probably also other hormones regulating the renal excretion of water, will in the future contribute to a better understanding of pathophysiology. Synthetic ADH analogues have already come into clinical use for the treatment of nocturnal enuresis. However, the clinical value of these specific tests remains to be established.

### 3. TISSUE ANALYSIS

Since the last report of the International Consultation on Incontinence in 2012, several papers have been published based on the analysis of sample of tissues coming from patients with SUI and/or pelvic organ prolapse aiming at evaluating the molecular bases of these conditions. The main targets of both preclinical and clinical research have been the pelvic floor-supporting tissues and the role of steroid hormones, with some intriguing linkages between the two lines of research.

Pelvic floor-supporting tissues are composed mainly of connective tissue in which fibrous elements such as collagen and elastic fibres and visco-elastic matrix based on proteoglycans are the predominant components of the so called extracellular matrix. Extracellular matrix is a complex network of numerous macromolecules that fulfill a large number of mechanical, chemical and biological functions (1). While collagens and elastin fibres confer strength and elasticity to tissues, respectively, structural proteoglycans allow tissue cohesiveness. Specifically, collagen is the most prevalent component, with type I fibres usually well organised and associated with ligamentous tissue, while type III collagen is more common in the loose areolar tissue, which makes up the vaginal wall adventitia and surrounds the pelvic organs (2). According to the molecular weight, indeed, proteoglycans are distinguished into large molecules (aggrecan, versican and perlecan) and small molecules, such as decorin, fibromodulin, biglycan, lumican and chondroadherin (3).

The organised structure of the matrix is due to a clear balance between the production of the different constituents and their breakdown. There are many proteolytic enzymes capable of degrading the elements of the extracellular matrix, falling into into three groups: the serine proteases, the cysteine proteases, and matrix metalloproteinases (MMPs) (4).

Several authors evaluated the expression of the different proteins as well as of their precursors and fragments of degradation. With regards to the metabolism of collagen, some studies seem to indicate that women with SUI have a reduced total collagen content in the skin and urogenital tissue (5-7), while other studies reported higher total collagen concentration and higher levels of mRNAs for type I and type III collagen in paraurethral connective tissue (8). Chen et al., evaluating cultures of fibroblasts taken from endopelvic fascia and skin biopsies in 14 patients with stress urinary incontinence and 12 controls, showed that the overall collagen synthesis and the ratio of type III and type I fibres were not significantly different between fibroblasts obtained from women with or without SUI (4), indicating that alteration in the collagen synthesis might not be involved in SUI.

On the other hand, a few studies reported change in the relative percentages of the different fibres, with a decrease in type I and increase in type III ones (9, 10). In women with SUI, Skorupski et al. evaluated the transcription factor Sp1-binding site in the gene encoding α1 chain of type I collagen, and suggests that the observed G-T polymorphism is a risk factor for incontinence (11). Again at molecular level, some studies evaluated the cycle regulatory proteins in patients with pelvic organ prolapse, showing controversial results. Some papers reported reduced expression of proteins such as p53 and p21 which normally cause cycle G1 arrest suggesting an increase in proliferation capacities for fibroblasts derived from human cardinal ligaments of patients with prolapse (2).

Other authors evaluated markers of collagen degradation. Specifically, Edwall et al. evaluated markers of collagen synthesis and breakdown such as the carboxy-terminal propeptide of type I procollagen (PICP), the carboxy-terminal telopeptide of type I collagen (ICTP), and the amino-terminal propeptide of procollagen III (PIIINP) in urogenital tissue homogenates and peripheral serum from 71 patients with SUI and 31 healthy control women (12). After adjusting for age, BMI, parity, and hormonal status, the patients with SUI had significantly lower serum concentrations of PICP and significantly lower tissue concentrations of PIIINP and ICTP than the controls, suggesting reducing breakdown in the presence of unchanged synthesis of type I collagen and, regarding type III collagen, a potential reduction in either synthesis or breakdown, the second being considered more probable (12). These data may lead to the hypothesis that SUI might be associated with impaired degradation of collagen, leading to reduced turnover and accumulation of aging collagen, negatively affecting the strength and elasticity of urogenital tissue. Further studies on transforming growth factor-β (TGF-β) identified the molecular basis of such mechanism, suggesting that overexpression of TGF-β might trigger the accumula-
tion of aging collagen, inhibiting the expression of collagenases and increasing the production of the tissue inhibitor metalloproteinase (13-15). Moreover, some genes, such as those of the Homebox A (HOXA) family, encoding transcription factors that regulate mammalian embryonic growth and development of the urogenital tract, have been shown to be underexpressed in patients with pelvic organ prolapse, suggesting a further molecular basis for the alterations in collagens (16).

Some other studies investigated the role of proteinases that may degrade elements of the extracellular matrix. Chen et al., evaluating full-thickness peri-urethral vaginal wall tissues from patients with SUI or prolapsed and matched control women, found significant decrease in mRNA and protein expressions of alpha-1 antitrypsin (ATT), a neutrophil elastase inhibitor in tissues from affected women, while no difference was found in neutrophil elastase and cathepsin K expressions (17). Similarly, Gabriel et al. studied the expression of different MMPs in 17 women with prolapse and 18 control, identifying higher expression of MMP2 in patients with prolapse (18). These studies allowed to hypothesize that altered catabolism of some components of the extracellular matrix might contribute to the connective tissue alterations observed in pelvic floor dysfunction.

Other studies were focused on the expression of small proteoglycans. Wen et al. studied mRNA and protein levels of biglycan, decorin, and fibromodulin in vaginal wall tissue from women with SUI and menstrual-cycle matched continent women (1). Specifically, the authors demonstrated that the mRNA expression of fibromodulin was significantly lower in patients in the proliferative phase compared to controls, while decorin mRNA expression was higher both in the proliferative and secretory phases in the patients with SUI, supporting the hypothesis that the expression of such small proteoglycans was hormonally modulated and may contribute to the altered pelvic floor connective tissues of women with SUI (1).

Oestrogens interact with specific receptors which, when activated by the ligand, have conformational change, dimerisation and recruitment of co-factors, once translocated into the nucleus, these promote the expression of region of oestrogen-responsive genes, called the oestrogen response elements, leading to the synthesis of proteins (19). More recently, selective modulators of oestrogens receptors have been identified, that act modulating the activity of the receptors, working as agonists, partial agonists, or antagonists in a tissue-dependent manner (20). Studies on these molecules supported a new role of oestrogens in SUI and pelvic organ prolapse. Specifically, the expression of metalloproteinase 7 and 14, reduced the expression of their inhibitors such as TIMP-3, while selective modulators of oestrogens receptors such as raloxifene had minimal effects on metalloproteinase 7, and maintained or restored expression of the mRNA for tissue inhibitor of metalloproteinases-3 (TIMP-3) and other components of the extracellular matrix, such as glypicans, and biglycan (19). Although the role of selective oestrogen-receptor modulators (SERMs) in the expression of the component of extracellular matrix has to be further clarified, these findings support the hypothesis that the increased occurrence of urinary incontinence and pelvic organ prolapse observed with oestrogen therapy and SERMs such as levormeloxifene may be related to changes in expression of genes regulating collagen turnover that ultimately weaken the normal structural integrity and support for the genitourinary system (19).

3.1. Consensus Statement

To date, all these tissue analyses are not part of the everyday clinical practice.

3.2. Future Research Areas

The relationship between tissue composition and risk of UI and POP

The relationship between tissue composition and treatment outcome in patients with UI and POP

VII. CONCLUSIONS

Clinical research involving diagnostic accuracy and clinical benefit of imaging studies and other diagnostic tests is particularly difficult. Recommendation of a diagnostic test is based upon the evidence that the outcome of it provides valuable information for patient management and this often involves evaluating the outcome of surgery. Implementation of good clinical research in this area remains difficult and sometimes lacks adequate founding. We acknowledge that only a few of the imaging techniques and other investigations we reviewed in the current chapter have been properly evaluated with respect to reproducibility, specificity, sensitivity and predictive value in connection with the diagnosis and management of urinary incontinence. Nevertheless, we acknowledge the great amount of work performed in the last four years and the continuous advancement in this field. The use of imaging and other investigations, described in this chapter, remains mostly based on expert opinion, common sense, availability and local expertise, rather than on evidence based clinical research. The diagnostic tests we considered can be subdivided into safety tests, tests with specific and selected indications, investigational tests.

Safety tests - Intended to protect patients’ health, they are indicated in all patients complaining of urinary incontinence. They include urinalysis and measurement of post-void residual urine. While a consensus is easily achieved for urinalysis, the clinical benefit
and cost-effectiveness of PVR measurement in the primary evaluation of urinary incontinence needs to be confirmed in prospective studies.

**Tests with specific and selected indications.** Upper urinary tract imaging (as well as renal function assessment) may be indicated in cases of neurogenic urinary incontinence with risk of renal damage, chronic retention with incontinence, incontinence associated with severe genitourinary prolapse and suspicion of extravesical incontinence. No other imaging technique is recommended in the primary evaluation of uncomplicated urinary incontinence and/or pelvic organ prolapse. Cystourethrography remains a reasonable option only in the preoperative evaluation of complicated and/or recurrent cases. Video urodynamic testing is the gold standard in the evaluation of neurogenic incontinence, particularly in the paediatric population, although the clinical benefit of it remains unclear. In female urinary incontinence videourodynamic testing is not recommended except under specific complex circumstances. MRI remains the gold standard for the diagnosis of urethral diverticula although ultrasonography is a good alternative option. Lumbosacral spine X-rays have specific indications in children with suspect neurogenic incontinence without gluteo-sacral stigmata. Imaging of the CNS should be considered when a neurological disorder is suspected on the basis of clinical, imaging and neurophysiological findings. Urethrocystoscopy is indicated in cases of incontinence with microscopic haematuria, in the evaluation of recurrent or iatrogenic cases, in the evaluation of vesico-vaginal fistula and extra-urethral urinary incontinence.

Endoanal ultrasound and endocoil MRI are the gold standard for the evaluation of anal sphincter disorders, dynamic X-ray imaging remains the standard for evaluating rectal prolapse.

**Investigational tests** Pelvic floor ultrasound is widely used as an adjunct to physical examination in patients with urinary incontinence and/or pelvic organ prolapse. Although the technique is rapidly evolving and much progress has been made in clinical research in this field, ultrasonography remains optional as evidence of its clinical benefit is not there yet.

MRI of the pelvic floor is rapidly gaining popularity in the evaluation of enterocoeles and in the morphological analysis of pelvic floor muscles although evidence of its clinical benefit is still lacking. Both ultrasonography and MRI are the most rapidly evolving techniques and hold promises for potential future clinical applications.

Research in this area is also performed to improve our understanding of the pathophysiology of continence disorders and POP. Functional neuroimaging continues to provide new insight regarding functional anatomy of CNS related to vesicourethral function and dysfunction. The content of the draft reflects the composition of the Committee is made up of clinicians with a particular interest in a specific area of imaging and neurophysiology. The chapter certainly reveals the enthusiasm the authors poured in clinical research into this area but we believe that the methodology implemented by the Consultation is the best guarantee of a balanced opinion and evidence based recommendations. We hope that this chapter will stimulate clinical research in this field and will inspire those involved in the management of continence disorders and POP.

Neurophysiological testing should be part of the armamentarium available in the management of neurogenic incontinence and the establishment of good collaboration with neurophysiologists is recommended.

INTRODUCTION

The function of the lower urinary tract (LUT) is to store and periodically release urine, and is dependent on the activity of smooth and striated muscles in the bladder, urethra, and pelvic floor. These structures form a functional unit, which is controlled by a complex interplay between the central and peripheral nervous systems and local regulatory factors [Andersson, 1993; de Groat and Yoshimura, 2001; 2015; Andersson and Wein, 2004; see, Andersson and Michel, 2011].

Malfunction at various levels may result in bladder control disorders, which roughly can be classified as disturbances of filling/storage or disturbances of voiding/emptying. Failure to store urine may lead to various forms of incontinence (mainly urgency and stress incontinence), and failure to empty can lead to urinary retention, which may result in detrusor underactivity (DU) and underactive bladder (UAB). A disturbed filling/storage function can, at least theoretically, be improved by agents decreasing detrusor activity, increasing bladder capacity, and/or increasing outlet resistance [Wein, 2012].

Many drugs have been tried, but the results are often disappointing, partly due to poor treatment efficacy and/or side effects. The development of pharmacologic treatment of the different forms of urinary incontinence has been slow, but several promising targets and drug principles have been identified [Andersson 2007; 2011c; 2015; 2016; Colli et al., 2007; Athanasopoulos and Cruz, 2011; Yeo et al., 2013; Zucché et al. 2014; Sacco and Bientinesi, 2015; Bechis et al. 2015].

In this report, we update the recommendations from the 2012 International Consensus meeting [Andersson et al., 2013]. The most relevant information obtained since the last meeting is briefly reviewed and summarised. Agents specifically used for treatment of urinary tract infections and interstitial cystitis, have not been included. Our clinical drug recommendations are based on evaluations made using a modification of the Oxford system (Table 1). The terminology used is that recommended by the International Continence Society (ICS) [Abrams et al., 2002].

I. PUBLICATION SEARCHES

The review undertook a comprehensive search of all major literature databases and the abstract books from several major conferences: American Urological Association, ICS, European Association of Urology, International Urogynaecological Association, International Consultation of Incontinence and Societe Internationale d’Urologie.

2. CENTRAL NERVOUS CONTROL

In the adult individual, the normal micturition reflex is mediated by a spinobulbospinal pathway, which passes through relay centers in the brain (Figures 1-4).

In infants, the central pathways seem to be organised as on-off switching circuits, but after the age of four to six years, voiding is initiated voluntarily by the cerebral cortex [de Groat et al., 1999; Beckel and Holstege, 2011]. Studies in humans and animals have identified areas in the brainstem and diencephalon (Figure 5) that are specifically implicated in micturition control, including Barrington’s nucleus or the pontine micturition center (PMC) in the dorsomedial pontine tegmentum [Fowler et al., 2008]. These structures directly excite bladder motoneurons and indirectly inhibit urethral sphincter motoneurons via inhibitory interneurons in the medial sacral cord. The peri-aqueductal grey (PAG) receives bladder filling information, and the pre-optic area of the hypothalamus is probably involved in the initiation of micturition. According to PET-scan and functional imaging studies in humans, these supraspinal regions are active during micturition [Blok et al., 1998; Nour et al., 2000; Athwal et al., 2001; Griffiths et al., 2007, 2008; Hruz et al., 2008; Mehnert et al., 2008; Tadic et al., 2008; Griffiths, 2011; Deruyver et al., 2016].

3. PERIPHERAL NERVOUS CONTROL

Bladder emptying and urine storage involve a complex pattern of efferent and afferent signalling in the parasympathetic, sympathetic, somatic, and sensory nerves. These nerves are parts of reflex pathways, which either keep the bladder in a non-contracted state, enabling urine storage at low intravesical pressure, or which initiate micturition by relaxing the outflow region and contracting the bladder smooth muscle. Contraction of the detrusor smooth muscle and relaxation of the outflow region result fromactivation of parasympathetic neurones located in the sacral parasympathetic nucleus (SPN) in the spinal cord at the level of S2-S4 [de Groat et al., 1993; Beckel and Holstege, 2011]. The postganglionic neurones in the pelvic nerve mediate the excitatory input to the human detrusor smooth muscle by releasing acetylcholine (ACh) acting on muscarinic receptors. However, an atropine-resistant component has been demonstrated, particularly in functionally and morphologically altered human bladder tissue (see below). The pelvic nerve also conveys parasympathetic fibres to the outflow region and the urethra. These fibres exert an inhibitory effect and thereby relax the outflow region. This is mediated partly by release of nitric oxide [Andersson and Persson, 1993], although other transmitters might be involved [Bridgewater and Brading, 1993; Hashimoto et al., 1993; Werkström et al., 1995].

Most of the sympathetic innervation of the bladder and urethra originates from the intermediolateral nucleus in the thoraco-lumbar region (T10-L2) of the spinal cord [Beckel and Holstege, 2011]. The axons travel either through the inferior mesenteric ganglia and the hypogastric nerve, or pass through the paravertebral chain and enter the pelvic nerve. Thus, sympathetic signals are conveyed in both the hypogastric and pelvic nerves [Lincoln and Burnstock, 1993].

The predominant effects of the sympathetic innervation of the lower urinary tract are inhibition of the parasympathetic pathways at spinal and ganglion levels (demonstrated in animals), and mediation of contraction of the bladder base and the urethra (shown in animals and man, see Andersson, 1993). However, the adrenergic innervation of the bladder body is believed to inactivate the contractile mechanisms in the detrusor directly. Noradrenaline (norepinephrine) is released in response to electrical stimulation of detrusor tissues in vitro, and the normal response of detrusor tissues to released noradrenaline is relaxation [Andersson, 1993].

The somatic innervation of the urethral rhabdosphincter and of some perineal muscles (for example compressor urethrae and urethrovaginal sphincter), is provided by the pudendal nerve [Beckel and Holstege, 2011]. These fibers originate from sphincter motor neurons located in the ventral horn of the sacral spinal cord (levels S2-S4) in a region called Onuf’s (Onufrowicz’s) nucleus.

Most of the sensory innervation of the bladder and urethra reaches the spinal cord via the pelvic nerve and dorsal root ganglia (Kanai and Andersson, 2010; De Wachter, 2011). In addition, some afferents travel in the hypogastric nerve. The sensory nerves of the striated muscle in the rhabdosphincter travel in the pudendal nerve to the sacral region of the spinal cord [Lincoln and Burnstock, 1993].

The most important afferents for the micturition process are myelinated Aδ-fibres and unmyelinated C-fibres travelling in the pelvic nerve to the sacral spinal cord, conveying information from receptors in the bladder wall to the spinal cord. The Aδ-fibres respond to passive distension and active contraction, thus conveying information about bladder filling [Janig and Morrison, 1986]. C-fibres have a high mechanical threshold and respond primarily to chemical irritation of the bladder mucosa [Habler et al., 1990] or cold [Fall et al., 1990].
Figure 1: Components of the micturition reflex.

Figure 2: Activity in the micturition reflex during storage. The pontine micturition center is inhibited by impulses from the prefrontal cortex, afferent impulses unable to initiate micturition. Activities in the hypogastric and pudendal nerves keep the bladder relaxed and the outflow region contracted.
Figure 3: Activity in the micturition reflex during voluntary voiding. The inhibitory impulses from the prefrontal cortex pontine micturition center are removed and afferent impulses are able to initiate micturition. Activities in the hypogastric and pudendal nerves are inhibited, the outflow region is relaxed, and the bladder is contracted by the activity in the pelvic nerve.

Figure 4: Detrusor overactivity. Despite the inhibitory impulses from the prefrontal to the cortex pontine micturition center the enhanced (?) afferent impulses are able to initiate micturition.
Following chemical irritation, the C-fibre afferents exhibit spontaneous firing when the bladder is empty and increased firing during bladder distension [Habler et al., 1990]. These fibres are normally inactive and are therefore termed “silent fibres” [de Groat and Yoshimura, 2001; 2015].

4. PATHOGENESIS OF BLADDER CONTROL DISORDERS

As pointed out previously, bladder control disorders can be divided into two general categories: disorders of filling/storage and disorders of voiding [Wein, 2012]. Storage problems can occur as a result of weakness or anatomical defects in the urethral outlet, causing stress urinary incontinence. Failure to store also occurs if the bladder is overactive, as in the overactive bladder (OAB) syndrome. The prevalence varies with the criteria used for diagnosis, but according to Irwin et al. (2006), using the ICS definition of 2002 [Abrams et al., 2002], the overall prevalence of OAB, based on computer assisted telephone interviews (the EPIC study) was 11.8%; rates were similar in men and women and increased with age [Irwin et al., 2006]. A similar study based on a cross Canada telephone survey found the prevalence of OAB to be 13% in men and 14.7% in women [Herschorn et al., 2008]. In a Finnish study, taking into account bother, the prevalence of clinically meaningful OAB, was was much lower than reported in these studies [Vaughan et al., 2011].

OAB (symptomatic diagnosis) is often assumed to be caused by detrusor overactivity (DO: urodynamic diagnosis), even if this does not always seem to be the case [Hyman et al., 2001; Digesu et al., 2003; Hashim and Abrams, 2004]. DO/OAB can occur as a result of sensitization of afferent nerve terminals in the bladder or outlet region, changes of the bladder smooth muscle secondary to denervation, or consequent upon damage to the central nervous system (CNS) inhibitory pathways, as can be seen in various neurological disorders, such as multiple sclerosis, cerebrovascular disease, Parkinson’s disease, brain tumors, and spinal cord injury [Andersson and Pehrson, 2003; Ouslander, 2004; Banakhar et al., 2012; Meng et al., 2012; Wein and Dmochowski, 2012; Michel and Igawa, 2015]. Urinary retention and overflow incontinence can be observed in patients with urethral outlet obstruction (e.g. prostate enlargement), decreased detrusor contractility, or both), neural injury, and/or diseases that damage nerves (e.g. diabetes mellitus), or in those who are taking drugs that depress the neural control of the bladder or bladder smooth muscle directly [Wein, 2012].

5. BLADDER CONTRACTION

Normal bladder contraction in humans is mediated mainly through stimulation of muscarinic receptors in the detrusor muscle [Andersson and Wein, 2004] (Figure 6). Atropine resistance, i.e. contraction of isolated bladder muscle in response to electrical nerve stimulation after pretreatment with atropine, has been demonstrated in most animal species, but seems to be of little importance in normal human bladder muscle [Andersson, 1993; Bayliss et al., 1999; Rouget et al., 2014]. However, atropine-resistant (non-adrenergic, non-cholinergic: NANC) contractions have been reported in normal human detrusor and may be caused mainly by adenosine triphosphate (ATP) [Andersson, 1993; Bayliss et al., 1999, Rouget et al., 2014]. However, atropine-resistant (non-adrenergic, non-cholinergic: NANC) contractions have been identified in several species (rabbit, cat, rat, and human), various studies suggested that multiple purinergic excitatory receptors are present in the bladder [de Groat and Yoshimura, 2001; Ford and Cockayne, 2011; Burnstock, 2013; Ford and Undem., 2013; North and Jarvis, 2013; Andersson, 2015]. Immunohistochemical experiments with specific antibodies for different P2X receptors showed that P2X1 receptors are the dominant subtype in membranes of
rat detrusor muscle and vascular smooth muscle in the bladder. Excitatory receptors for ATP are present in parasympathetic ganglia, afferent nerve terminals, and urothelial cells [de Groat and Yoshimura, 2001]. P2X3 receptors, which have been identified in small-diameter afferent neurons in dorsal root ganglia, have also been detected immunohistochemically in the wall of the bladder and ureter in a suburothelial plexus of afferent nerves. In P2X3 knockout mice, afferent activity induced by bladder distension was significantly reduced [Cockayne et al., 2000; Ford et al., 2006; Ruggieri et al., 2006; Ford and Cockayne, 2011; Burnstock, 2013]. These data indicate that purinergic receptors are involved in mechanosensory signaling in the nonprimate mammalian bladder.

A significant degree of atropine resistance may exist in morphologically and/or functionally changed bladders, and has been reported to occur in hypertrophic bladders [Sjögren et al., 1982], interstitial cystitis [Paleza et al., 1993], neurogenic bladders [Wammack et al., 1995], and in the aging bladder [Yoshida et al., 2001]. The importance of the NANC component to detrusor contraction in vivo, normally, and in different micturition disorders, remains to be established [Andersson, 2006].

The neurotransmitter ACh acts on two classes of receptors, the nicotinic and the muscarinic receptors. While the former plays a role in the signal transduction between neurones or between neurones and skeletal muscle (e.g. in the distal urethra), the signal transduction between parasympathetic nerves and smooth muscle of the detrusor involves muscarinic receptors [Abrams and Andersson, 2007]. Importantly, the endogenous muscarinic receptor agonist ACh is not necessarily derived only from parasympathetic nerves in the urinary bladder, but can also be formed and released non-neuronally by the urothelium [Benschleiper et al., 2007; Mansfield et al., 2005; Zarghooni et al., 2007; Andersson, 2011a; Birder and Andersson, 2013]. Five subtypes of muscarinic receptors have been cloned in humans and other mammalian species, which are designated M1-5 [Caulfield and Birdsall 1998; Giglio and Tobin, 2009]. Based upon structural criteria and shared preferred signal transduction pathways, the subtypes can be grouped into M1, M3 and M5 on the one hand and the subtypes M2 and M4 on the other. The former prototypically couple via pertussis toxin-insensitive Gq proteins to stimulation of a phospholipase C followed by elevation of intracellular calcium and activation of a protein kinase C, whereas the latter prototypically couple via pertussis toxin-sensitive Gi proteins to inhibition of adenylyl cyclase and modulation of several ion channels [Caulfield and Birdsall 1998]. While sensitive molecular techniques such as reverse transcriptase polymerase chain reaction can detect mRNA for all five subtypes in the mammalian bladder [Abrams et al., 2006; Hegde, 2006], studies at the protein level, e.g. based upon radioligand binding, have typically detected only M2 and M3 receptors, with the former dominating quantitatively [Abrams et

![Figure 6: Muscarinic M3 receptor-mediated detrusor activation. Calcium influx and activation of the Rhokinase system are the main pathways mediating activation of the contractile system in the detrusor.](image-url)
al., 2006; Hegde et al., 1997; Hegde, 2006; Andersson, 2011]. Inhibitory pre-junctional muscarinic receptors have been classified as M2 in the rabbit and rat, and M4 in the guinea-pig, rat and human (d’Agostini et al., 1997; see Andersson, 2011) bladder. These receptors appear to be of the M1 subtype in the rat and rabbit urinary bladder, but have also been detected in human bladders. The muscarinic facilitatory mechanism seems to be upregulated (M3 receptors) in overactive bladders from chronic spinal cord transected rats.

Apparently, most muscarinic receptors in the bladder are found on the smooth muscle cells of the detrusor. While the detrusor expresses far more M2 than M3 receptors, it appears that detrusor contraction under physiological conditions is largely if not exclusively mediated by the M3 receptor [Hegde et al., 1997; Chess-Williams et al., 2001; Fetscher et al., 2002; Kories et al., 2003; Schneider et al., 2004a; b]. Studies in knock-out mice confirm this conclusion [Matsui et al., 2000; 2002; Stengel et al., 2002; Ehler et al., 2007]. Under physiological conditions M2 receptor-selective stimulation causes little contraction [Schneider et al., 2005a], but rather appears to act mainly by inhibiting β-adrenoceptor-mediated detrusor relaxation [Hegde et al., 1997; Ehler et al., 2007; Matsui et al., 2003]. It has been proposed that M2 receptors can also directly elicit bladder contraction under pathological conditions [Braverman et al., 1998a, b; 2002; 2003; 2006; Pontari et al., 2003], but such observations have not been confirmed by other investigators using distinct methodological approaches [Schneider et al., 2005a; b].

Based upon the prototypical signalling pathway of M3 receptors [Cauldfield and Birdsall, 1998] and the presence of phospholipase C stimulation by muscarinic agonists in the bladder [Kories et al., 2003; Schneider et al., 2005a] it had originally been believed that muscarinic receptor-mediated contraction is largely mediated by an activation of phospholipase C [Ouslander, 2004]. While some earlier data had supported this concept, it now appears clear that, at least in rat, mice and humans, muscarinic receptor-mediated bladder contraction occurs largely independent of phospholipase C [Schneider et al., 2004a; b; Wegener et al., 2004; Frazier et al., 2007]. Rather, alternative signalling pathways such as opening of L-type calcium channels and activation of a rho-kinase (Figure 6) appear to contribute to muscarinic receptor-mediated bladder contraction in a major way [Frazier et al., 2008]. More recently, muscarinic receptors have also been identified in the urothelium [Chess-Williams, 2002; Kumar et al., 2005]. Similarly to the findings in bladder smooth muscle, the muscarinic receptors in the urothelium mainly belong to the M2 and M3 subtype, with the former dominating quantitatively [Mansfield et al., 2005; Bschleiper et al., 2007]. At present the functional role of muscarinic receptors in the urothelium has largely been studied indirectly, i.e. by investigating the effects of urothelium removal or of administration of pharmacological inhibitors. These data indicate that muscarinic stimulation of the urothelium causes release of an as yet unidentified factor which inhibits detrusor contraction [Hawthorn et al., 2000; Wuest et al., 2005; Sadananda et al., 2008]. Some data indicate that muscarinic receptors in the urothelium may partly act by releasing nitric oxide (NO) [Andersson et al., 2008]. Muscarinic receptor blockade in urothelial cells may also reduce ATP release induced by stretch [Young et al., 2012]. Thus, it appears that muscarinic receptors in the urothelium also contribute to the regulation of overall bladder function but their specific roles in health and disease have not been fully established.

Assuming an involvement of muscarinic receptors in physiological voiding contractions of the bladder, numerous studies have explored whether an overactivity of the muscarinic system may play a causative role in bladder dysfunction. This could involve, e.g., an enhanced expression of such receptors and/or an increased functional responsiveness. In vitro, an increased sensitivity to muscarinic receptor stimulation was found in both idiopathic and neurogenic overactive human detrusors [Stevens et al., 2006]. However, according to Michel and Barendrecht [2008] the overall balance of available studies suggests that the muscarinic receptor system is not hyperactive under conditions of DO and, if anything, can be even hypoactive [Michel and Barendrecht, 2008b]. This does not exclude a contribution to DO of ACh and muscarinic receptor stimulation during bladder filling (see below). It appears that the contribution of muscarinic mechanisms to the overall regulation of bladder contractility decreases in favour of non-cholinergic mechanisms under pathological conditions [Yoshida et al., 2001; 2008; Rapp et al., 2005]. These observations may help to explain the moderate efficacy of muscarinic receptor antagonists relative to placebo in controlled clinical studies [Herbison et al., 2003; Chapple et al., 2005; 2008; Novara et al., 2008; Shamlayan et al., 2008; Buser et al., 2012].
It has been estimated that more than 50 million people in the developed world are affected by urinary incontinence, and an abundance of drugs has been used for treatment (Table 2). Helfand and co-workers showed that in a cohort of 7,244,501 patients over 45 years with an OAB diagnosis, 24.4% of these were treated mainly with antimuscarinic agents; 75.6% went untreated. Only 25.6% of those treated were men. (Helfand et al., 2010). As underlined by several other subcommittees, drugs may be efficacious in some patients, but they do have side effects, and frequently are not continued indefinitely. Hence it would be worth considering them as an adjunct to conservative therapy.

1. ANTIMUSCARINIC (ANTICHOLINERGIC) DRUGS

Mechanism of action. Antimuscarinics block, more or less selectively, muscarinic receptors irrespective of location [Abrams and Andersson, 2007; Andersson, 2011a; Sellers and Chess-Williams, 2012] (Figure 7). The common view is that in OAB/DO, the drugs act by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by ACh, released from activated cholinergic (parasympathetic) nerves. Thereby, they decrease the activity of the bladder to contract. However, antimuscarinic drugs act mainly during the storage phase, decreasing urgency and increasing bladder capacity, and during this phase, there is normally no parasympathetic input to the lower urinary tract [Andersson, 2004, 2011b]. Furthermore, antimuscarinics are usually competitive antagonists.

This implies that when there is a massive release of ACh, as during micturition, the effects of the drugs should be decreased, otherwise the reduced ability of the detrusor to contract would eventually lead to urinary retention. Undeniably, high doses of antimuscarinics can produce urinary retention in humans, but in the dose range used for beneficial effects in OAB/DO (Figure 8), there is little evidence for a significant reduction of the voiding contraction [Finney et al., 2006]. However, there is good experimental evidence that the drugs act during the storage phase by decreasing the activity in afferent nerves (both C- and Aδ-fibres) from the bladder [De Laet et al., 2006; Ijima et al., 2007] (Figure 9).

As mentioned previously, muscarinic receptors are found on bladder urothelial cells where their density can be even higher than in detrusor muscle. The role of the urothelium in bladder activation has attracted much interest [Andersson, 2002a; Birder and de Groat, 2007, Birder and Andersson, 2013], but whether the muscarinic receptors on urothelial cells can influence micturition has not yet been established. Yoshida and colleagues [2004; 2006; 2008] found that there is basal ACh release in human bladder. This release was resistant to tetrodotoxin and much diminished when the urothelium was removed; thus, the released ACh was probably of non-neuronal origin and, at least partly, generated by the urothelium. There is also indirect clinical evidence for release of ACh during bladder filling. Smith et al. [1974]
found that in patients with recent spinal-cord injury, inhibition of ACh breakdown by use of cholinesterase inhibitors could increase resting tone and induce rhythmic contractions in the bladder. Yossepowitch et al. [2001] inhibited ACh breakdown with edrophonium in a series of patients with disturbed voiding or urinary incontinence. They found a significant change in sensation and decreased bladder capacity, induction or amplification of involuntary detrusor contractions, or significantly decreased detrusor compliance in 78% of the patients with the symptom pattern of overactive bladder, but in no patients without specific complaints suggesting DO. Thus, during the storage phase, ACh and ATP may be released from both neuronal and non-neuronal sources (eg, the urothelium) and directly or indirectly (by increasing detrusor smooth muscle tone excite afferent nerves in the suburothelium and within the detrusor. These mechanisms may be important in the pathophysiology of OAB/DO and represent possible targets for antimuscarinic drugs.

**Pharmacologic properties.** Generally, antimuscarinics can be divided into tertiary and quaternary amines [Guay, 2003; Abrams and Andersson, 2007]. They differ with regards to lipophilicity, molecular charge, and even molecular size, tertiary compounds generally having higher lipophilicity and molecular charge than quaternary agents. Atropine, darifenacin, fesoterodine (and its active metabolite 5-hydroxymethyl-tolterodine), oxybutynin, propiverine, solifenacin, and tolterodine, are tertiary amines. They are generally well absorbed from the gastrointestinal tract and should theoretically be able to pass into the CNS, dependent on their individual physicochemical properties. High lipophilicity, small molecular size, and less charge will increase the possibilities to pass the blood brain barrier, but in some cases, such as darifenacin, that is compensated by active transport out of the CNS by the product of the MDR1 gene. Quaternary ammonium compounds, like propantheline and trospium, are not well absorbed, pass into the CNS to a limited extent, and have a low incidence of CNS side effects [Guay, 2003]. They still produce well-known peripheral antimuscarinic side effects, such as accommodation paralysis, constipation, increases in heart rate, and dryness of mouth.

Many antimuscarinics are metabolized by the P450 enzyme system to active and/or inactive metabolites [Guay, 2003]. The most commonly involved P450 enzymes are CYP2D6, and CYP3A4. The metabolic conversion creates a risk for drug-drug interactions, resulting in either reduced (enzyme induction) or increased (enzyme inhibition, substrate competition) plasma concentration/effect of the antimuscarinic and/or interacting drug. Antimuscarinics secreted by the renal tubules (eg trospium) may theoretically be able to interfere with the elimination of other drugs using this mechanism. Some antimuscarinics and their active metabolites are excreted in urine in amounts that may affect the mucosal muscarinic receptors from the luminal side. This has not yet been demonstrated to imply superior clinical efficacy [Andersson et al., 2008b].
Antimuscarinics are still the most widely used treatment for urgency and urgency incontinence [Andersson, 2004, Andersson et al., 2009]. However, currently used drugs lack selectivity for the bladder, and effects on other organ systems may result in side effects, which limit their usefulness. For example, all antimuscarinic drugs are contraindicated in untreated narrow angle glaucoma.

Theoretically, drugs with selectivity for the bladder could be obtained, if the subtype(s) mediating bladder contraction, and those producing the main side effects of antimuscarinic drugs, were different. Unfortunately, this does not seem to be the case. One way of avoiding many of the antimuscarinic side effects is to administer the drugs intravesically. However, this is practical only in a limited number of patients.

Several antimuscarinic drugs are and have been used for treatment of OAB/DO. For some of them, documentation of effects is not based on randomized controlled trials (RCTs) satisfying currently required criteria, and some drugs can be considered as obsolete (e.g., emepronium). Information on these drugs has not been included, but can be found elsewhere [Andersson, 1988; Andersson et al., 1999].

1.1. Antimuscarinics with "Specific" Action

Below data on the different antimuscarinics are presented. These drugs are assumed to block only muscarinic receptors (motivating the term "specific"). The amount of information for the individual drugs varies, and so does the degree of details from the different studies presented. However, the information has been chosen to give a reasonable efficacy and adverse effect profile of each individual drug.

1.1.1 Atropine Sulfate

Atropine (dl-hyoscyamine) is rarely used for treatment of OAB/DO because of its systemic side effects, which preclude its use as an oral treatment. However, in patients with neurogenic DO, intravesical atropine may be effective for increasing bladder capacity without causing any systemic adverse effects, as shown in open pilot trials [Ekström et al., 1992; Glickman et al., 1995; Deaney et al., 1998; Enskat et al., 2001; Fader et al. 2007]. It appears that intravesical atropine may be as effective as intravesical oxybutynin in patients with neurogenic DO [Fader et al., 2007].

The pharmacologically active antimuscarinic component of atropine is l-hyoscyamine. Although still used, few clinical studies are available to evaluate the antimuscarinic activity of l-hyoscyamine sulfate [Muskat et al., 1996]. For assessment, see Table 2.

1.1.2 Darifenacin Hydrobromide

Darifenacin is a tertiary amine with moderate lipophilicity, well absorbed from the gastrointestinal tract after oral administration, and extensively metabolised in the liver by the cytochrome P450 isoforms CYP3A4 and CYP2D6, the latter saturating within the therapeutic range [Skerjanec, 2006]. UK-148,993, UK-73,689, and UK-88862 are the three main circulating darifenacin metabolites of which only UK-148,993 is said to have significant anti-muscarinic activity. However, available information suggests that various metabolites of darifenacin contribute little to its clinical effects [Michel and Hegde, 2006]. The metabolism of darifenacin by CYP3A4 suggests that co-administration of a potent inhibitor of this enzyme may be effective for increasing bladder capacity without causing any systemic adverse effects, as shown in open pilot trials [Ekström et al., 1992; Glickman et al., 1995; Deaney et al., 1998; Enskat et al., 2001; Fader et al. 2007].
Darifenacin has been developed as a controlled-release formulation, which allows once-daily dosing. Recommended dosages are 7.5 and 15 mg per day. The clinical effectiveness of the drug has been documented in several RCTs [Haab et al., 2004; Cardozo and Dixon 2005; Steers et al., 2005; Chapple et al., 2005; Foote et al., 2005; Hill et al., 2006; Haab et al., 2006; Zinner et al., 2006, Chapple et al., 2007; Abrams et al., 2008, Chancellor et al., 2008; Dwyer et al., 2008, for reviews, see Guay, 2005; Zinner, 2007; Novara et al., 2008; Chapple et al., 2008b]. Haab et al. [2004] reported a multicentre, double-blind, placebo-controlled, parallel-group study which enrolled 561 patients (19–88 years; 85% female) with OAB symptoms for more than 6 months, and included some patients with prior exposure to antimuscarinic agents. After washout and a 2-week placebo run-in, patients were randomised (1:4:2:3) to once-daily oral darifenacin controlled-release tablets: 3.75 mg (n = 53), 7.5 mg (n = 229) or 15 mg (n = 115) or matching placebo (n = 164) for 12 weeks. Patients recorded daily incontinence episodes, micturition frequency, bladder capacity (mean volume voided), frequency of urgency, severity of urgency, incontinence episodes resulting in a change of clothing or pads and nocturnal awakenings due to OAB using an electronic diary during weeks 2, 6 and 12 (directly preceding clinic visits). Tolerability data were evaluated from adverse event reports. Darifenacin 7.5 mg and 15 mg had a rapid onset of effect, with significant improvement compared with placebo being seen for most parameters at the first clinic visit (week 2). Darifenacin 7.5 mg and 15 mg, respectively, was significantly superior to placebo for (median) improvements in micturition frequency (7.5 mg: –1.6; 15 mg: –1.7; placebo –0.8, frequency of urgency per day (–2.0; –2.0; –0.9), and number of incontinence episodes leading to a change in clothing or pads (–4.0; –4.7; –2.0). There was no significant reduction in nocturnal awakenings due to OAB. The most common adverse events were mild-to-moderate dry mouth and constipation with a CNS and cardiac safety profile comparable to placebo. No patients withdrew from the study as a result of dry mouth and discontinuation related to constipation was rare (0.6% placebo versus 0.9% darifenacin).

In a dose titration study on 395 OAB patients, darifenacin, allowing individualized dosing (7.5 or 15 mg), was found to be effective and well-tolerated [Steers et al., 2005]. A 2-year open label extension study of these investigations [i.e., Haab et al., 2004; Steers et al., 2005], confirmed a favorable efficacy, tolerability and safety profile [Haab et al., 2006].

A review of the pooled darifenacin data from the three phase III, multicentre, double-blind clinical trials in patients with OAB was reported by Chapple et al. [2005] After a 4-week washout/run-in period, 1,059 adults (85% female) with symptoms of OAB (urgency incontinence, urgency and frequency) for at least six months were randomized to once-daily oral treatment with darifenacin: 7.5 mg (n = 337) or 15 mg (n = 334) or matching placebo (n = 388) for 12 weeks. Efficacy was evaluated using electronic patient diaries that recorded incontinence episodes (including those resulting in a change of clothing or pads), frequency and severity of urgency, micturition frequency, and bladder capacity (volume voided). Safety was evaluated by analysis of treatment-related adverse events, withdrawal rates and laboratory tests. Relative to baseline, 12 weeks of treatment with darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week (7.5 mg, –8.8 [–68.4%; placebo –54%, P<0.001]; 15 mg, –10.6 [–76.8%; placebo 58%, P<0.001]). Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation, although together these resulted in few discontinuations (darifenacin 7.5 mg 0.6% of patients; darifenacin 15 mg 2.1%; placebo 0.3%). The incidence of CNS and cardiovascular adverse events were comparable to placebo. The results were confirmed in other RCTs, including also a pooled analysis of three phase III studies in older patients (≥65 years), showing that darifenacin (7.5 and 15 mg) had an excellent efficacy, tolerability and safety profile [Foote et al., 2005, Zinner et al., 2005; Hill et al. 2006].

The time-to effect with darifenacin was analysed in a pooled analysis of efficacy and safety data from 1,059 patients participating in three double-blind 12-week studies Khullar et al [2011]. Darifenacin significantly improved all OAB symptoms as early as 6 to 8 days.

One of the most noticeable clinical effects of antimuscarinics is their ability to reduce urgency and allow patients to postpone micturition. A study was conducted to assess the effect of darifenacin, on the ‘warning time’ associated with urinary urgency. This was a multicenter, randomized, double-blind, placebo-controlled study consisting of 2 weeks’ washout, 2 weeks’ medication-free run-in and a 2-week treatment phase [Cardozo and Dixon, 2005]. Warning time was defined as the time from the first sensation of urgency to voluntary micturition or incontinence
and was recorded via an electronic event recorder at baseline (visit 3) and study end (visit 4) during a 6-hour clinic-based monitoring period, with the subject instructed to delay micturition for as long as possible. During each monitoring period, up to three urgency-void cycles were recorded. Of the 72 subjects who entered the study, 67 had warning time data recorded at both baseline and study end and were included in the primary efficacy analysis (32 on darifenacin, 35 on placebo). Darifenacin treatment resulted in a significant (p<0.004) increase in mean warning time with a median increase of 4.3 minutes compared with placebo (darifenacin group from 4.4 to 1.8 minutes; placebo from 7.0 to -1.0 minutes). Overall, 47% of darifenacin-treated subjects compared with 20% receiving placebo achieved a >30% increase in mean warning time. There were methodological problems associated with this study; it utilized a dose of 30 mg (higher than the dose recommended for clinical use), the treatment period was short, it was conducted in a clinical-centred environment, the methodology carried with it a significant potential training effect, and the placebo group had higher baseline values than the treatment group. In another warning time study [Zinner et al., 2006] on 445 OAB patients, darifenacin treatment (15 mg) resulted in numerical increases in warning time, however, these were not significant compared to placebo.

Further studies have demonstrated that darifenacin treatment is associated with clinically relevant improvements on health related quality of life (HRQoL) in patients with OAB [Abrams et al., 2008], and such improvements were sustained as shown in a two-year extension study [Dwyer et al., 2008]. It was shown that neither the positive effects on micturition variables, nor on HRQoL produced by darifenacin (7.5 and 15 mg) were further enhanced by a behavioural modification programme including timed voiding, dietary modifications and Kegel exercises [Chancellor et al., 2008a].

Since darifenacin is a substrate for the P-glycoprotein drug efflux transporter [Miller et al., 2011; Chancellor et al., 2012], which is present both in the blood-brain and blood-ocular barriers, several clinical studies have been devoted to investigate possible effect of darifenacin on cognition. Neither in healthy volunteers (19-44 years) and healthy subjects (≥60 years), nor in volunteers 65 years or older, could any effect of darifenacin (3.75-15mg daily) be demonstrated, compared to placebo [Kay and Wesnes, 2005; Lipton et al., Kay et al., 2006; Kay and Ebinger 2008; Chancellor et al., 2012].

To study whether darifenacin had any effect on QT/QTc intervals [Serra et al., 2005] performed a 7-day, randomized, parallel-group study (n = 188) in healthy volunteers receiving once-daily darifenacin at steady-state therapeutic (15 mg) and supratherapeutic (75 mg) doses, alongside controls receiving placebo or moxifloxacin (positive control, 400 mg) once daily. No significant increase in QTcF interval could be demonstrated compared with placebo. Mean changes from baseline at pharmacokinetic T_max versus placebo were -0.4 and -2.2 milliseconds in the darifenacin 15mg and 75 mg groups, respectively, compared with +11.6 milliseconds in the moxifloxacin group (P < .01). The conclusion was that darifenacin does not prolong the QT/QTc interval.

Darifenacin 15 mg per day given to healthy volunteers did not change heart rate significantly compared to placebo [Olshansky et al., 2008].

The impact of darifenacin on constipation has been assessed in an analysis of the Phase III, IIIb and IV darifenacin published trials [Tack et al., 2012]. The pooled Phase III data, suggested 14.8% (50/337) of patients on darifenacin 7.5 mg/day and 21.3% (71/334) on 15 mg/day experienced constipation. Only 0.6% and 1.2% of patients taking darifenacin 7.5mg/day and 15mg /day, respectively, stopped treatment as a result of constipation. Furthermore, 3.3% [11/337] and 6.6% [22/334], in the darifenacin 7.5 mg/day and 15 mg/day, groups required concomitant laxative medications. At the end of a long-term study (2 years), the incidence of constipation was 20.9% (150/716) and 5.6% (40/716) of patients initiated use of fiber supplements, stool softeners or laxatives [Tack et al. 2012].

### Assessment

Darifenacin has a well-documented beneficial effect in OAB/DO (Table 2), and tolerability and safety seems acceptable.

#### 1.1.3 Fesoterodine Fumarate

Fesoterodine functions as an orally active prodrug that is converted to the active metabolite 5-hydroxymethyltolterodine (5-HMT) by non-specific esterases [Michel, 2008a; Malhotra et al., 2009a]. This compound, which is chemically identical to the 5-hydroxy metabolite of tolterodine, is a non-subtype selective muscarinic receptor antagonist [Ney et al., 2008]. All of the effects of fesoterodine in man are thought to be mediated via 5-HMT, since the parent compound remains undetectable upon oral dosing. 5-HMT is metabolized in the liver, but a significant part of 5-HMT is excreted renally without additional metabolism. Since the renal clearance of 5-HMT is about 250 mL/min, with >15% of the administered fesoterodine dose excreted as unchanged 5-HM, this raises the possibility that 5-HMT also could work from the luminal side of the bladder [Michel, 2008]. The bioavailability of fesoterodine, averaging 52%, was independent of food intake and the drug may be taken with or without a meal [Malhotra et al., 2009b]. Peak plasma concentration of 5-HMT is reached at 5 h following oral administration and has a half-life of 7–9 h [Malhotra et al., 2008]. The suggested starting dose, 4 mg/day, can be used in patients with moderately impaired renal or hepatic function due to the combination of renal excretion and hepatic metabolism of 5-HMT [Malhotra et al., 2009c; de Mey et al., 2011].
The clinical efficacy and tolerability of fesoterodine have been documented in several RCTs [Chapple et al., 2007; 2008c; Nitti et al., 2007; Dmochowski et al., 2010a; Herschorn et al., 2010; Kaplan et al., 2011; Nitti et al., 2010; see Dell’Utri et al., 2012]. In a multicenter, double-blind, double-dummy RCT with tolterodine ER, 1,132 patients were enrolled and received treatment [Chapple et al., 2007]. The trial showed that both the 4 and 8 mg doses of fesoterodine were effective in improving symptoms of OAB, with the 8 mg dose having a greater effect at the expense of a higher rate of dry mouth. There appeared to be little difference between fesoterodine 4 mg and tolterodine ER. Only one subject from the fesoterodine 8 mg group and one subject from the tolterodine ER group withdrew from the study due to dry mouth. The dose-response relationship was confirmed in another study that pooled data from two phase III RCTs [Kullar et al., 2008]. Fesoterodine 8 mg performed better than the 4 mg dose in improving urgency and UUI as recorded by 3-day bladder diary, offering the possibility of dose titration. Subsequently the Eight Trial, a large randomised double blind placebo controlled trial compared fesoterodine 8 mg and 4 mg (n=1,745; who completed the study) (Chapple et al., 2014). At 12 weeks UUI, urgency, micturition frequency, diary dry rates, PPBC, UPS and OAB-q scores were significantly better with fesoterodine 8 mg compared to 4 mg or placebo. Dry mouth and constipation rates were 26.1% and 4%, 12.9% and 1.5%, 3.4% and 1.8% in the fesoterodine 8 mg, 4 mg and placebo groups, respectively (Chapple et al., 2014).

A head to head placebo controlled trial has been completed comparing fesoterodine 8 mg to tolterodine extended release 4 mg and placebo [Herschorn et al., 2010]. The study randomized 1,590 patients to assess the primary outcome of reduced urgency incontinence episodes at 12 weeks. Fesoterodine produced statistically significant improvements in urgency incontinence episodes, complete dry rates (64.0% vs. 57.2%, p = 0.015), mean voided volume per void (+32.9 ml vs. +23.5 ml, p = 0.005), and in patients’ assessments of bladder related problems as measured by OAB questionnaire (except sleep domain), Patient Perception of Bladder Condition (40% vs. 33% with > 2 point improvement, p < 0.001), and Urgency Perception Scale (46% vs. 40% with improvement, p = 0.014) compared with tolterodine. The clinical significance of these statistically significant findings is questionable as there was no difference between agents with respect to number of micturitions, urgency episodes, and frequency-urgency sum per 24 hours. The improved efficacy of fesoterodine came at the cost of greater dry mouth (27.8% vs. 16.4%), headache (5.6% vs. 3.4%), constipation (5.4% vs. 4.1%), and withdrawal rates (6% vs. 4%). Nonetheless, this first head to head trial comparing two drugs in class supports the use of fesoterodine 8 mg for additional benefit over tolterodine ER 4 mg.

Wyndaele et al. [2009] reported the first flexible-dose open-label fesoterodine trial, which was conducted at 80 different centres worldwide and comprised 516 participants (men and women) >18 years who self-reported OAB symptoms for at least 3 months before screening and had been treated with either tolterodine or tolterodine ER within 2 years without symptom improvement. Approximately 50% opted for dose escalation to 8 mg at week 4. Significant improvements from baseline to week 12 were observed in micturitions, urgency urinary incontinence episodes, micturition-related urgency episodes and severe micturition-related urgency episodes per 24 h. Significant improvements from baseline were observed in QoL parameters. Dry mouth (23%) and constipation (5%) were the most common adverse events; no safety issues were identified.

The largest double-blind, double-dummy, flexible-dose fesoterodine RCT, which was conducted at 210 different centres with a total of 2,417 patients enrolled, was performed by Kaplan et al. [2010]. All patients were healthy, >18 years of age and self-reported OAB symptoms for at least 3 months. The 960 patients who received fesoterodine 8 mg showed significantly greater mean improvements at week 12 in most efficacy parameters (diary variables) than those receiving either tolterodine ER or placebo; UUI and urgency episodes, micturition frequency and MVV. No statistically significant changes were shown in reduction of nocturnal micturitions compared with the tolterodine group, whereas when comparing the mean changes in nighttime micturition with the placebo group a significant difference was found. This phase III study confirmed the superiority of fesoterodine 8 mg over tolterodine ER 4 mg for improving of UUI and urgency episodes and 24-h micturitions but not for MVV and nocturia. In another RCT of flexible-dose fesoterodine, Dmochowski et al. [2010] reported statistically significant improvements at week 12 in the mean number of micturition per 24 h and in both UUI and urgency episodes. Between groups, difference in nocturnal micturition was not statistically significant.

A subsequent pooled analysis of 2 phase III trials confirmed superiority of fesoterodine 8 mg to tolterodine ER 4 mg [Ginsberg et al., 2013]. In women fesoterodine 8 mg was superior to tolterodine at 12 weeks in UUI, urgency, micturition episodes, diary dry rates, PPBC, UPS and OAB-q scores. In men superiority with fesoterodine 8 mg was only demonstrated for severe urgency and the symptom bother domain of the OAB-q. In women, dry mouth rates were 29%, 15%, 6%, constipation rates were 5%, 4%, 2%, urinary retention rates were <1%, <1%, 0% for fesoterodine 8 mg, tolterodine ER 4 mg and placebo, respectively. In men, dry mouth rates were 21%, 13%, 5%, constipation rates were 5%, 3%, 1%, and urinary retention rates were 2%, <1%, 2% for fesoterodine 8 mg, tolterodine ER 4 mg and placebo, respectively [Ginsberg et al., 2013].

Kaplan et al. [2014] assessed fesoterodine 8 mg and placebo in patients who had not responded to tolterodine ER 4 mg (<50% reduction in UUI). At week 12 UUI and urgency episodes were significantly better in
the fesoterodine group but micturition episodes and diary dry rates were statistically no different compared to placebo. Patients with > 50% and >70% UUI episodes were greater in the fesoterodine 8mg group at 8 weeks. Furthermore, at 12 weeks, improvements in favor of fesoterodine compared to placebo were seen in PPBC, UPDS and OAB-q. Dry mouth and constipation were seen in 16.6 and 3.9% in the fesoterodine group and 4 and 1.3% in the placebo group, respectively [Kaplan et al., 2014].

Little is known on the impact of antimuscarinics on nocturnal urgency. Weiss et al. [2013], explored this is a multi-center randomized double blind placebo controlled 12-week flexible dosing trial in the US. In the fesoterodine group 61% were escalated at the clinicians’ discretion to the 8mg dose. Nocturnal urgency episodes (~1.28 vs -1.07), nocturnal micturition episodes, nocturnal frequency-urgency sum (urgency sensations were rated on a 1-5 scale), were significantly better in the fesoterodine group. Interestingly, UUI per 24 hours was not statistically different between fesoterodine and placebo in this trial and the authors acknowledge there is no minimally important difference in nocturnal urgency episodes to ascertain clinical significance definitively. However, in an Asian post-hoc analysis of a double-blind placebo controlled trial of fesoterodine 4 and 8 mg involving 555 patients, fesoterodine was not statistically better than placebo in reducing nocturnal micturition episodes at 12 weeks [Yokoyama et al. 2014]. If patients with a nocturnal polyuris index of > 33% were excluded, fesoterodine 8mg was statistically better than placebo in reducing nocturnal micturition episodes. Undisturbed sleep increased in both fesoterodine arms (4mg – 80 minutes; 8mg – 74 minutes) but was only statistically significant in the 4mg dose compared with placebo (54 minutes). Significant improvements in the sleep / energy domain of the KHQ was seen in both fesoterodine groups compared to placebo.

Nitti et al. [2010] determined whether the presence of DO in patients with OAB and urgency urinary incontinence was a predictor of the response to treatment with fesoterodine in a phase 2 randomized, multicentre, placebo-controlled trial. They concluded that regardless of the presence of DO, the response to fesoterodine treatment was dose-proportional and associated with significant improvements in OAB symptoms, indicating that the response to OAB pharmacotherapy in patients with UUI was independent of the urodynamic diagnosis of DO.

Kelleher et al. [2008] evaluated the effect of fesoterodine on HRQoL in patients with OAB syndrome. Pooled data from two randomized placebo-controlled phase III studies [Chapple et al., 2007; Nitti et al., 2007] were analysed. Eligible patients were randomized to placebo or fesoterodine 4 or 8 mg for 12 weeks; one trial also included tolterodine extended release (tolterodine-ER) 4 mg. By the end of treatment, all active-treatment groups had significantly improved HRQoL compared with those on placebo. In a post hoc analysis of data pooled from these studies, significant improvements in all KHQ domains, ICIQ-SF scores, and bladder related problems were observed at months 12 and 24 compared to open label baseline [Kelleher et al., 2012]. The authors concluded that treatment satisfaction was high throughout the open-label treatment regardless of gender and age.

A large post marketing study from Korea has confirmed the efficacy of fesoterodine in OAB [Kim et al. 2016]. The mean duration of symptoms was 165 days but interestingly, 63% had symptom duration of less than a week. Of the patients included, 92.7% (2879/3107), 76.8% (2387/3107), and 37.5% (1164/3107) reported having symptoms of urinary frequency, urgency, and UUI, respectively and mean fesoterodine treatment duration was 83.2 ± 75.3 days. Frequency, urgency and UUI per 24 hours declined from 12.1 to 8.0, 3.7 to 1.3, and 1.1 to 0.3, respectively (all p < 0.001). Utilising the PPBC questionnaire the majority of patients reported their bladder condition caused some very minor problems (43.0%, 1265/2939) or no problems at all (22.2%, 651/2939). Adverse events were reported in 8.2%, with dry mouth in 5.4% and constipation in 1.5% [Kim et al. 2016].

Longer term effects were analysed in a pooled analysis of 2 open label extension studies which demonstrated sustained improvement in OAB with fesoterodine [Sand et al. 2012]. Mean duration of exposure was 21 months with 51% of patients receiving fesoterodine for ≥ 24 months. 77% elected to remain on fesoterodine 8mg during the open label extension. Discontinuations were seen in 51% before the 24-month visit with insufficient clinical response, adverse events or withdrawal of consent being the main reasons for stopping treatment. Significant improvements were seen in UUI, urgency and micturition episodes over the study period compared to open label baseline. The most common adverse events were dry mouth and constipation. Significant improvements in all KHQ domains (except general health domain), ICIQ-SF and perception of bladder related problems were seen at 12 and 24 months compared to the open label baseline [Kelleher et al. 2012]. During the extension study treatment satisfaction was seen in 96% and 97% at 12 and 24 months, respectively.

A post-hoc analysis of 2 fixed dose trials, stratified by age, suggested fesoterodine 4 and 8 mg doses were efficacious compared to placebo in those < 75 years of age, but only fesoterodine 8mg in those ≥ 75 years of age [Kraus et al. 2010]. As a result, the SOPHIA trial recruited patients ≥ 65 years of age with at least 30% of the population being older than 75 years of age, in this flexible fesoterodine dosing placebo controlled study [Wagg et al., 2013]. At week 4, 52% and 66% opted for dose escalation in the fesoterodine 4mg and placebo groups, respectively. At week 8 de-escalation was allowed and occurred in 4% and 3% in the fesoterodine and placebo groups, respectively. Urgency, severe urgency, micturition and nocturnal micturition episodes, as well as pad use significantly
improved in the fesoterodine group compared to placebo at 12 weeks. However, in the 46% who were OAB wet no significant difference in UUI episodes were demonstrated between the groups. Patient reported outcomes using the TBS, PPBC, UPS, OAB-S were significantly greater in the fesoterodine group compared to placebo. Age stratification is less than or greater than 75 years of age did not alter the results. Mini mental state examination did not change from baseline to end of study and was not different between groups. Dry mouth and constipation rates were 33.9% vs 5.3% and 8.9% vs 2.5% in the fesoterodine and placebo groups, respectively. Central nervous system adverse events occurred very rarely and 6 patients went into retention (5 in the active arm). The authors concluded that fesoterodine was tolerated well and was efficacious in an elderly population [Wagg et al., 2013; 2015]). Subsequently Wagg et al. [2014], have published on a 12-week label extension of this trial. Of the original 655 patients in the SOPHIA trial, 581 completed the open label extension with approximately half the population being male. Significant improvements were observed in bladder diary measures as well as patient reported outcome measures in those that originally had placebo who switched to fesoterodine and efficacy was maintained in those that were originally treated with fesoterodine by study end. Treatment withdrawal due to emergent adverse events were 9.1% in those switched to fesoterodine from placebo and 1.3% in those that continued with fesoterodine [Wagg et al. 2014]. Dubeau et al. [2014], looked at the use of fesoterodine with dose escalation/de-escalation design vs placebo in a vulnerable elderly population with complex co-morbidities. Patients had to have moderate bladder problems based on PPBC, UUI 2-15 episodes, daytime frequency ≥ 8, vulnerable elderly score (VES-13) of ≥ 3 and a MMSE ≥ 20. The proportion of patients who completed the study were similar in both groups. Approximately 50% of the population were greater than 75 years of age and both groups had complex patients with functional impairment and polypharmacy. Significant reductions in daytime micturition, daytime and nocturnal urgency, UUI episodes per 24 hours and a reduction for the need of absorbent products was seen with fesoterodine compared to placebo. A greater proportion reported improvements in their bladder condition based on PPBC and OAB-q scores and satisfaction were better in the fesoterodine group compared to placebo. In the fesoterodine group 9.3% vs 5% in the placebo group discontinued treatment due to adverse events. Dry mouth and constipation rates were 23.5% and 11%, respectively, in the fesoterodine group. Urinary retention occurred in 3.2% in those treated with fesoterodine but only 3/9 patients were catheterized. No significant changes in MMSE were observed. No significant changes in blood pressure or heart rate were observed in either group until end of study and there were no deaths [Dubeau et al. 2014]. Malhotra et al. [2010] performed a thorough QT study to investigate the effects of fesoterodine on cardiac repolarization in a parallel-group study. Subjects were randomly assigned to receive double-blind fesoterodine 4 mg, fesoterodine 28 mg, or placebo or open-label moxifloxacin 400 mg (positive control) for 3 days. Electrocardiograms (ECGs) were obtained on Days -1 (baseline), 1, and 3. The primary analysis was the time-averaged changes from baseline for Fridericia’s-corrected QT interval (QTcF) on Day 3. Among 261 subjects randomized to fesoterodine 4 mg (n = 64), fesoterodine 28 mg (n = 68), placebo (n = 65), or moxifloxacin 400 mg (n = 64), 256 completed the trial. The results indicated that fesoterodine is not associated with QTc prolongation or other ECG abnormalities at either therapeutic or supratherapeutic doses.

Assessment

Fesoterodine has a well-documented beneficial effect in OAB (Table 2) and has been studied in a variety of patient populations, and the adverse event profile seems acceptable.

1.1.4 Imidafenacin

Imidafenacin (KRP-197/ONO-8025,4-(2-methyl-1H-imidazol-1-yl)-2,2-diphenylbutanamide) is an antagonist for the muscarinic ACh receptor with higher affinities for M3 and M1 receptors than for the M2 receptor. Metabolites of imidafenacin (M-2, M-4 and M-9) had low affinities for muscarinic ACh receptor subtypes [Kobayashi et al., 2007a, b]. The drug blocks pre- as well as postjunctional muscarinic receptors and was shown to block both detrusor contractions and acetylcholine release [Murakami et al., 2003]. The receptor binding affinity of imidafenacin in vitro was found to be significantly lower in the bladder than submaxillary gland or colon [Yamada et al., 2011], and in rats orally administered imidafenacin distributes predominantly to the bladder and exerts more selective and longer-lasting effect here than on other tissues. Whether this can be translated to the human situation has to be established before claims of clinical bladder selectivity can be made.

Imidafenacin is well absorbed from the gastrointestinal tract and its absolute bioavailability in human is 57.8% [Ohmori et al. 2007; Ohno et al. 2008]. It is rapidly absorbed with maximum plasma concentration occurring 1-3h after oral administration [Ohno et al. 2008]. Metabolites in the plasma are produced mainly by first-pass effects. The major enzymes responsible for the metabolism of the drug are CYP3A4 and UGT1A4. The oxidative metabolism is reduced by concomitant administration of CYP3A4 inhibitors. In contrast, imidafenacin and its metabolites have no inhibitory effect on the CYP-mediated metabolism of concomitant drugs [Kanayama et al. 2007].

Kitagawa et al. [2011] reported that the subjective efficacy of imidafenacin was observed from 3 days after the commencement of administration and that mean total OABSS decreased gradually during 2 weeks after administration.
A randomized, double-blind, placebo-controlled phase II dose-finding study in Japanese OAB patients was performed to evaluate the efficacy, safety/tolerability, and dose-response relationship of imidafenacin [Homma et al., 2008a]. Overall, 401 patients were enrolled and randomized for treatment with 0.1 mg of imidafenacin/day (99 patients), 0.2 mg of imidafenacin/day (100), 0.5 mg of imidafenacin/day (101), or a placebo (101). After 12 weeks of treatment, the number of incontinence episodes was reduced in a dose-dependent manner, and a significant difference between the imidafenacin treatment and the placebo was observed (P < 0.0001). Compared with the placebo, imidafenacin caused significant reductions in urgency incontinence, voiding frequency, and urinary urgency, and a significant increase in the urine volume voided per micturition. Imidafenacin was also well tolerated. The incidence of dry mouth in the imidafenacin groups increased dose-dependently. Even though the percentage of patients receiving 0.5 mg/day who discontinued treatment due to dry mouth was high (8.9%), the percentages in the 0.1 mg/day and 0.2 mg/day groups (1.0% and 0.0%, respectively) were comparable with that in the placebo group (0.0%).

A randomized, double-blind, placebo- and propiverine-controlled trial of 781 Japanese patients with OAB symptoms were conducted by Homma et al. [2009]. They were randomized to imidafenacin 0.1mg twice daily (324), propiverine 20mg once daily (310), or a placebo (147). After 12 weeks of treatment, a significantly larger reduction in the mean number of incontinence episodes was observed in the imidafenacin group than in the placebo group (P < 0.0001). The non-inferiority of imidafenacin compared with propiverine was confirmed for the reduction in using incontinence episodes (P = 0.0014, non-inferiority margin: 14.5%). Imidafenacin was well tolerated. The incidence of adverse events with imidafenacin was significantly lower than with propiverine (P = 0.0101). Dry mouth, the most common adverse event, was significantly more common in the propiverine group than in the imidafenacin group. There were no significant increases in either the imidafenacin or placebo group in the mean QTc interval, whereas there was a significant increase in the mean QTc interval in the propiverine group (P < 0.0001). However, there were no clinical arrhythmia and clinical arrhythmic events in any of the treatment groups. Similar results have also been published in A population of OAB patients in Korea [Park et al., 2014]. In this non-inferiority trial comparing imidafenacin (0.1mg twice daily) to propiverine (20 mg once daily), both drugs significantly improved OAB parameters and quality of life measures. Severity of dry mouth was better in the imidafenacin group. The authors concluded that imidafenacin was non-inferior to propiverine with a better adverse event profile [Park et al. 2014]. The long-term safety, tolerability, and efficacy imidafenacin 0.1 mg twice daily was studied in Japanese OAB patients [Homma and Yamaguchi, 2008b], of whom 478 received treatment and 376 completed a 52-week program. Imidafenacin was well tolerated, the most common adverse event being a dry mouth (40.2% of the patients). Long-term treatment did not produce an increase in the frequency of adverse events compared with short-term treatment. A significant efficacy of the drug was observed from week 4 through week 52. After 52 weeks, imidafenacin produced mean changes from baseline in the number of incontinence episodes (-83.51%), urgency incontinence episodes (-84.21%), voiding frequency (-2.35 micturitions/day), urgency episodes (-70.53%), and volume voided per micturition (28.99 mL). There were also significant reductions from baseline in all domains of the King’s Health Questionnaire. received the treatment and 376 patients completed the 52-week program. Imidafenacin had no significant effects on the corrected QT interval, vital signs, results from laboratory tests, or post-void residual volume. A 52-week prospective, open randomized comparative study to evaluate the efficacy and tolerability of imidafenacin (0.2 mg/day) and solifenacin (5 mg/day) was conducted in a total of 41 Japanese patients with untreated OAB [Zaitsu et al., 2011]. They were randomly assigned to imidafenacin and solifenacin groups. There was no difference in OABSS and KHQ scores between the two groups, but the severity and incidence of adverse events caused by the drugs showed increased differences between the groups with time. The severity of dry mouth and the incidence of constipation were significantly lower in the imidafenacin group (P = 0.0092 and P = 0.0013, resp.). An important limitation of this study is the low number of patients. Only 25 patients (17 males 8 females) were available for long-term analysis. Similar results were reported by Yokoyama et al. [2013] in their comparative long term study with equivalent efficacy and better tolerability for imidafenacin compared to solifenacin but high discontinuation rates in both arms at study end.

Two small open labelled studies and a post-hoc analysis of a large multi-center RCT of imidafenacin have suggested benefits on nocturia and/or nocturnal polyuria [Kadekawa et al., 2012; Wada et al., 2012; Yokoyama et al., 2013]. Wada et al. [2012] reported improvements in OAB symptoms, Pittsburgh Sleep Quality Index scores, nocturia episodes and nocturnal polyuria in patients older than 75 years with imidafenacin 0.1 mg twice daily. Patients whose main complaint was nocturia were treated with 0.1mg daily and after 4 weeks were allowed a dose escalation to 0.2 mg daily if required. This group showed significant improvements with regards to nocturia as well as other OAB parameters. OAB symptom score and IPSS-QoL index score [Kadekawa et al., 2012]. A stratified analysis of a a large RCT showed that in 46 patients with nocturia and nocturnal polyuria (>33% urine production at night) imidafenacin 0.1mg twice daily after 12 weeks of treatment significantly reduced night-time micturition, nocturnal percentage of 24-hour production, and the interval to the first night-time void was significantly longer compared to placebo [Yokoyama et al., 2013].
In Korea a multi-center a non-inferiority phase IV trial of imidafenacin 0.1mg twice daily versus fesoterodine 4mg was conducted [Lee et al., 2013]. No significant differences were observed between the 2 treatments for OAB symptoms of KHQ scores. Dry mouth rates were 39.4 and 37.3% in the imidafenacin and fesoterodine groups, respectively and no statistically differences were shown for adverse events, blood pressure, pulse or residual volume between the groups. In another post marketing surveillance study imidafenacin was shown to be safe with dry rates of 8.5% and no significant deterioration in MMSE at 48 weeks, with an acceptable mild cognitive impairment conversion to dementia rate (3.6% ) [Sakakibara et al., 2014].

Assessment
Imidafenacin is effective and has an acceptable tolerability (Table 2). However, the drug is not yet widely available in the Western countries.

1.1.5 Propantheline Bromide
Propantheline is a quaternary ammonium compound, non-selective for muscarinic receptor subtypes, which has a low (5 to 10%) and individually varying biological availability. It is metabolized (metabolites inactive) and has a short halflife (less than 2 h) [Beermann et al., 1972]. It is usually given in a dose of 15 to 30 mg 4 times daily, but to obtain an optimal effect, individual titration of the dose is necessary, and often higher dosages are required. Using this approach in 26 patients with detrusor overactivity contracts [Blaivas et al., 1980] in an open study obtained a complete clinical response in all patients but one, who did not tolerate more than propantheline 15 mg four times daily. The range of dosages varied from 7.5 to 60 mg fourtimes daily. In contrast, Thüroff et al. [1991] comparing the effects of oxybutynin 5 mg three times daily, propantheline 15 mg three times daily, and placebo, in a randomized, double-blind, multicenter trial on the treatment of frequency, urgency and incontinence related to DO (154 patients), found no differences between the placebo and propantheline groups. In another randomized comparative trial with crossover design (23 women with idiopathic DO), and with dose titration, Holmes et al. [1991] found no differences in efficacy between oxybutynin and propantheline. Controlled randomized trials (n=6) reviewed by Thüroff et al [1998], confirmed a positive, but varying, response to the drug.

1.1.6 Solifenacin Succinate
Solifenacin succinate (YM905) is a tertiary amine and well absorbed from the gastrointestinal tract (absolute bioavailability 90%). The mean terminal half-life is 45-68 hours [Kuipers et al., 2002; Smulders et al., 2002; 2004]. It undergoes significant hepatic metabolism involving the cytochrome P450 enzyme system (CYP3A4). In subjects who received a single oral dose of 10 mg solifenacin on day 7 of a 20-day regimen of ketoconazole administration (200 mg) Cmax and AUCo-ibt were increased by only approximately 40% and 56%, respectively [Swart et al., 2006]. Solifenacin has a modest selectivity for M3 over M2 (and M1) receptors [Abrams and Andersson, 2007]. Supporting an effect on sensory function by solifenacin, 15 women with DO receiving 10 mg/day of the drug showed an increase in the area under the bladder-volume sensation curve [Lowenstein et al., 2012] Solifenacin also increased maximum bladder capacity, a finding in agreement with other studies [Tanaka et al., 2010; Hsiao et al., 2011]

Two large-scale phase 2 trials with parallel designs, comprising men and women, were performed [Smith et al., 2002; Chapple et al., 2004a]. The first dosering study evaluated solifenacin 2.5 mg, 5 mg, 10 mg, and 20 mg and tolterodine (2 mg twice daily) in a multinational placebo-controlled study of 225 patients with urodynamically confirmed DO [Chapple et al., 2004a]. Patients received treatment for 4 weeks followed by 2 weeks of follow-up. Inclusion criteria for this and subsequent phase 3 studies of patients with OAB included at least 8 micturitions per 24 hours and either one episode of incontinence or one episode of urgency daily as recorded in 3-day micturition diaries. Micturition frequency, the primary efficacy variable, was statistically significantly reduced in patients taking solifenacin 5 mg (-2.21), 10 mg (-2.47), and 20 mg (-2.75), but not in patients receiving placebo (-1.03) or tolterodine (-1.79). This effect was rapid with most of the effect observed at the earliest assessment visit, 2 weeks after treatment initiation. In addition, there was numerically greater reductions in episodes of urgency and incontinence when compared with placebo. Study discontinuations due to adverse events were similar across treatment groups, albeit highest in the 20-mg solifenacin group. As the 5 mg and 10 mg doses caused lower rates of dry mouth than tolterodine, and superior efficacy outcomes relative to placebo, these dosing strengths were selected for further evaluation in large-scale phase 3 studies.
The second dose-ranging study of solifenacin 2.5 mg to 20 mg was carried out in the United States (USA) [Smith et al., 2002]. This trial included 261 evaluable men and women receiving solifenacin or placebo for 4 weeks followed by a 2-week follow-up period. Micturition frequency was statistically significantly reduced relative to placebo in patients receiving 10 mg and 20 mg solifenacin. The number of micturitions per 24 hours showed reductions by day 7 and continued to decrease through day 28; day 7 was the earliest time point tested in solifenacin trials and these findings demonstrate efficacy as early as one week. The 5 mg, 10 mg, and 20 mg dosing groups experienced statistically significant increases in volume voided; the 10 mg solifenacin dose was associated with statistically significant reductions in episodes of incontinence.

In one of the early RCTs, a total of 1077 patients were randomized to 5 mg solifenacin, 10 mg solifenacin, tolterodine (2 mg twice daily), or placebo [Chapple et al., 2004b]. It should be noted that this study was powered only to compare active treatments to placebo. Compared with changes observed in the 5 mg, 10 mg, and 20 mg solifenacin doses (5 mg: -1.63, 61%; 10 mg: -1.57, 52%), a statistically significant decrease was observed in the 10 mg solifenacin 5 mg (-2.37) and 10 mg (-2.81). Solifenacin was well tolerated, with few patients discontinuing treatment. Incidences of dry mouth were 4.9% with placebo, 14.0% with solifenacin 5 mg, 21.3% with solifenacin 10 mg, and 18.6% with tolterodine 2 mg twice daily.

Cardozo et al. [2004] randomized 911 patients to 12-week once daily treatment with solifenacin 5 mg, solifenacin 10 mg or placebo. The primary efficacy variable was change from baseline to study end point in mean number of micturitions per 24 hours. Secondary efficacy variables included changes from baseline in mean number of urgency, nocturia and incontinence episodes per 24 hours, and mean volume voided per micturition. Compared with changes obtained with placebo (-1.6), the number of micturitions per 24 hours was statistically significantly decreased with solifenacin 5 mg (-2.37) and 10 mg (-2.81). A statistically significant decrease was observed in the number of all incontinence episodes with both solifenacin 5 mg, 10 mg, and 20 mg solifenacin. The number of urgency episodes per 24 hours was statistically significantly decreased with solifenacin 5 mg (-2.85) and 10 mg (-2.42), incontinence (-1.60 vs -0.83), urgency incontinence (-1.42 vs -0.83), and pad usage (-1.72 vs -1.19). More solifenacin treated patients became continent by study endpoint (59 vs 49%) and reported improvements in perception of bladder condition (-1.51 vs -1.33) assessments. However, this was accompanied by an adverse event incidence which was greater with solifenacin than with tolterodine. Dry mouth and constipation (mild + moderate + severe) were the most common (solifenacin 30 and 6.4%, tolterodine 23 and 2.5%). The majority of side effects were mild to moderate in nature, and discontinuations were comparable and low (5.9 and 7.3%) in both groups. In the SUNRISE trial solifenacin 5/10mg was significantly effective in reducing urgency and urgency bother when compared to placebo with changes noticeable as early as day 3 [Cardozo et al. 2008]. In this flexible dose trial, 591 patients received solifenacin 5mg at 8 weeks, and 46.5% requested a dose increase to 10mg and were further randomized for 8 weeks into solifenacin 5 or 10 mgs [Cardozo et al. 2013]. Those that requested dose escalation had a greater severity of OAB at baseline. Solifenacin 10 mg at end of study compared to week 8 was statistically better than solifenacin 5mg for maximum urgency intensity, total urgency score and micturition frequency. PPBC and treatment satisfaction were not statistically different between the groups. Adverse events were generally low and dry mouth rates were 0.7 and 5.7% for solifenacin 5 and 10 mg, respectively [Cardozo et al. 2013].

Luo et al. [2012] performed a systematic review and meta-analysis of solifenacin RCTs and provided a comprehensive assessment regarding the efficacy and tolerability was maintained over the study period [Haab et al., 2005].

The STAR trial [Chapple et al., 2005; 2007] was a prospective, double blind, double-dummy, two-arm, parallel-group, 12-week study was conducted to compare the efficacy and safety of solifenacin 5 or 10 mg and TOLTER-ER 4 mg once daily in OAB patients. The primary efficacy variable was micturition frequency. After 4 weeks of treatment patients had the option to request a dose increase, but were dummyed throughout as approved product labelling only allowed an increase for those on solifenacin. The results showed that solifenacin, with a flexible dosing regimen, was “non-inferior” to tolterodine concerning the primary effect variable, micturition frequency. However, solifenacin showed significant greater efficacy to tolterodine in decreasing urgency episodes (-2.85 vs -2.42), incontinence (-1.60 vs -0.83), urgency incontinence (-1.42 vs -0.83), and pad usage (-1.72 vs -1.19). More solifenacin treated patients became continent by study endpoint (59 vs 49%) and reported improvements in perception of bladder condition (-1.51 vs -1.33) assessments. However, this was accompanied by an adverse event incidence which was greater with solifenacin than with tolterodine. Dry mouth and constipation (mild + moderate + severe) were the most common (solifenacin 30 and 6.4%, tolterodine 23 and 2.5%). The majority of side effects were mild to moderate in nature, and discontinuations were comparable and low (5.9 and 7.3%) in both groups. In the SUNRISE trial solifenacin 5/10mg was significantly effective in reducing urgency and urgency bother when compared to placebo with changes noticeable as early as day 3 [Cardozo et al. 2008]. In this flexible dose trial, 591 patients received solifenacin 5mg at 8 weeks, and 46.5% requested a dose increase to 10mg and were further randomized for 8 weeks into solifenacin 5 or 10 mgs [Cardozo et al. 2013]. Those that requested dose escalation had a greater severity of OAB at baseline. Solifenacin 10 mg at end of study compared to week 8 was statistically better than solifenacin 5mg for maximum urgency intensity, total urgency score and micturition frequency. PPBC and treatment satisfaction were not statistically different between the groups. Adverse events were generally low and dry mouth rates were 0.7 and 5.7% for solifenacin 5 and 10 mg, respectively [Cardozo et al. 2013].
A number of studies and reviews have further documented the effects of solifenacin [Cardozo et al., 2006; Chapple et al., 2006; Maniscalco et al., 2006, see also Chapple et al., 2005; Maniscalco et al., 2008; Toglia et al., 2009; Vardy et al., 2009; Bolduc et al., 2010; Serrels et al., 2010; Luo et al., 2012], including men with OAB without bladder outlet obstruction [Kaplan et al., 2010] In a pooled analysis of four RCTs, Abrams and Swift [2005] demonstrated positive effects on urgency, frequency and nocturia symptoms in OAB dry patients. In an analysis of four phase III clinical trials, Brubaker and FitzGerald [2007] confirmed a significant effect of solifenacin 5 and 10 mg on nocturia in patients with OAB (reductions of nocturia episodes with 5 mg: -0.6, p<0.025; with 10 mg: -0.6, p<0.001 vs placebo: -0.4) but without nocturnal polyuria. A positive impact on nocturia and sleep quality in patients with OAB treated with solifenacin has also been reported in other studies [Takao et al., 2011; Yokoyama et al., 2011; Kelleher et al. [2006] and Staskin and Te [2006] presented data showing efficacy in patients with mixed incontinence.

A pooled analysis of four studies confirmed the efficacy and tolerability of solifenacin 5 and 10 mg in elderly (≥ 65 years) patients, and also showed a high level of persistence in a 40-week extension trial [Wagg et al., 2006]. Post-hoc analysis of two 12-week, open-label, flexible-dosing studies on 2645 patients over 65 years of age with OAB, revealed that solifenacin was associated with improvements in measures assessing patients’ perception of their bladder problems, symptom bother, and aspects of health-related quality of life [Capo et al., 2011]. Solifenacin was equally well tolerated in younger (<65 years) and older (>65 years) patients [Herschorn et al., 20011b]. An exploratory pilot study with single doses of solifenacin 10 mg to 12 elderly volunteers suggested no clear propensity to impair cognitive functions [Wesnes et al., 2009]. In the SENIOR study 26 patients with mild cognitive impairment were assessed with 3 treatments of 21 days each (solifenacin 5 mg, oxybutynin 5 mg twice daily and placebo) with suitable washout periods between treatments [Wagg et al., 2013]. Neither solifenacin nor oxybutynin was associated with significant changes from baseline in power of attention, continuity of attention, quality of working memory, quality of episodic memory, and speed of memory. However, in a post-hoc secondary analysis, oxybutynin was associated with significant decreases in power and continuity of attention versus placebo at 1-2h post-dose.

Improvement of QoL by solifenacin treatment has been documented in several studies [Kelleher et al., 2005; Garely et al., 2006]. In 30 patients with multiple sclerosis, van Rey and Heesakkers [2011] improved OAB symptoms as well as neurogenic disease-specific QoL measures.

Recently the SONIC trial assessed efficacy and tolerability of solifenacin in patients with multiple sclerosis (MS) and spinal cord injury (SCI) in a prospective randomized phase IIIb/IV parallel group study [Amarenco et al., 2015]. Approximately a quarter of the patients were taking muscle relaxants to help with spasticity. Patients were randomized to solifenacin 5mg, solifenacin 10mg, oxybutynin 5mgs three times daily or placebo for 4 weeks after a placebo run-in. The primary analysis was solifenacin 10mg vs placebo. The majority of MS patients were female and the majority of SCI patients were male. The primary endpoint of maximum cystometric capacity was significantly increased with solifenacin 10mg (134 mL) compared with placebo (5 mL). Furthermore, significant improvements were also observed with regards to bladder volume at first contraction and at first leak as well as detrusor pressure at first leak. PPBC and I-QoL sub scales significantly improved in favor of solifenacin 10mg compared to placebo. Significant improvements were also seen for oxybutynin compared to placebo but the trial was not designed to compare outcomes of the different active treatments [Amarenco et al., 2015]. The overall incidence of adverse events were low and dry mouth rates were 2.3%, 4.2%, 7.8% and 17% for placebo, solifenacin 5 mg, solifenacin 10mg and oxybutynin 5 mgs three times daily, respectively.

Persistence with solifenacin use has recently been assessed in a 12-month multi-center observational study involving 1018 OAB patients from Korea [Kim et al. 2016]. At the final study follow-up at 52 weeks only 22.1% of patients were still using solifenacin. Persistence rates were 72.4%, 45.8% and 31.1% at 12, 24 and 36 weeks. Reasons for discontinuation included symptom improvement in 30.4%, lack of efficacy in 13.4% and switch to another antimuscarinic in 10.8%. Older patients and females were more likely to persist with the treatment and nocturia episodes was negatively associated with persistence [Kim et al. 2016].

A non-interventional observational study in men alone (n=799) was conducted in multiple centers in Germany in a real life practice setting [Burger et al. 2014]. In this 12 week study the majority were taking solifenacin 5mg at study end (71%) and only 1.9% discontinued the treatment. Significant improvement in OAB symptoms were observed. In a subgroup of men with mild to moderate dementia, MMSE did not change significantly over the 12 weeks. Unusually dry mouth was only reported in 1.1% and mean PVR did not change. In 80% PVR did not change and in only 2.2% was the change ≥ 50 mL. No retention of urine was observed [Burger et al., 2014].

A recent trial assessed the use of solifenacin 5mg in patients with de novo OAB symptoms after an obturator mid urethral synthetic sling and compared this to a group who was stress incontinence treatment naïve [Serati et al., 2014]. Women with a pre-existing diagnosis of DO or who had OAB symptoms were excluded as were patients with significant voiding dysfunction or persistent stress incontinence. At 3-month follow-up, interestingly, the reduction in all OAB symptoms, PGI-I and OAB-q SF scores were
significantly better in the stress incontinent naïve group compared with the de novo OAB group [Serati et al., 2014].

Information on solifenacin treatment in children is scarce. Chart review of 138 children with therapy resistant OAB, treated with solifenacin, increased mean voided volume and improved continence [Hoebek et al., 2009]. Recently an open labelled study utilizing solifenacin doses 1.25-10mg in children with refractory incontinence was reported [Nadeau et al., 2014]. In total 112 girls and 132 boys were included (191 had IDO and 53 NDO) with mean age of 9.2 years at start of treatment. Significant improvements were seen in urodynamic parameters, PPBC. UI episodes with the dry rate being 36%. Treatment outcomes were more successful for IDO than NDO. The majority of patients reported no side effects (n=175).

In female volunteers, aged 19 to 79 years, the effect of 10 mg and 30 mg solifenacin on the QT interval was evaluated at the time of peak solifenacin plasma concentration in a multi-dose, randomized, double-blind, placebo and positive-controlled (moxifloxacin 400 mg) trial [Product monograph, Vesicare]. The QT interval prolonging effect appeared greater for the 30 mg (8 msec, 13: 90%CI) compared to the 10 mg (2 msec, -3, 6) dose of solifenacin. Although the effect of the highest solifenacin dose (three times the maximum therapeutic dose) studied did not appear as large as that of the positive control moxifloxacin at its therapeutic dose, the confidence intervals overlapped. This study was not designed to draw direct statistical conclusions between the drugs or the dose levels.

Michel et al. [2008] studied cardiovascular safety and overall tolerability of solifenacin in routine clinical use in a 12-week, open-label, post-marketing surveillance study. They concluded that "in real-life conditions, i.e. with inclusion of large numbers of patients with cardi-vascular co-morbidities and taking comedations, therapeutically effective doses of solifenacin did not increase heart rate or blood pressure”.

**Assessment**

Solifenacin has a well-documented beneficial effect in OAB/DO (Table 2), and the adverse event profile seems acceptable.

### 1.1.7 Tolterodine Tartrate

Tolterodine is is a tertiary amine, rapidly absorbed and extensive metabolized by the cytochrome P450 system (CYP 2D6). The major active 5-hydroxymethyl metabolite (5-HMT) has a similar pharmacological profile as the mother compound [Nilvebrant et al., 1997a], and significantly contributes to the therapeutic effect of tolterodine [Brynne et al., 1997; Brynne et al., 1998]. Both tolterodine and 5-HMT have plasma half-lives of 2-3 h, but the effects on the bladder seem to be more long-lasting than could be expected from the pharmacokinetic data. Urinary excretion of tolterodine accounted for <1-2.4 % of the dose; 5 – 14% of 5-HMT is eliminated in the urine (Brynne et al., 1997). Whether or not the total antimuscarinic activity of unchanged tolterodine and 5-HMT excreted in urine is sufficient to exert any effect on the mucosal signaling mechanisms has not been established. However, the preliminary studies by Kim et al. [2006] and Chuang et al. [2008], do not support such an effect.

The relatively low lipophilicity of tolterodine and even lesser one of 5-HMT, implies limited propensity to penetrate into the CNS, which may explain a low incidence of cognitive side effects [Hills et al., 1998; Clemett et al., 2001; Salvatore et al., 2008]. However, tolterodine may disturb sleep in subjects unable to form the even less lipophilic 5-HMT due to a low activity of CYP 2D6 [Diefenbach et al., 2008].

Tolterodine has no selectivity for muscarinic receptor subtypes, but is claimed to have functional selectivity for the bladder over the salivary glands [Stahl et al., 1995; Nilvebrant et al. 1997b]. In healthy volunteers, orally given tolterodine in a high dose (6.4 mg) had a powerful inhibitory effect on micturition and also reduced stimulated salivation 1 hour after administration of the drug [Stahl et al., 1995]. However, 5 hours after administration, the effects on the urinary bladder were maintained, whereas no significant effects on salivation could be demonstrated.

Animal experiments have suggested that antimuscarinics may affect signaling from the bladder [Andersson, 2011b]. Confirming data in humans were found by Vijaya et al. [2012]. In a randomized, placebo-controlled study, they evaluated the effect of tolterodine on urethral and bladder afferent nerves in women with DO in comparison to placebo by studying the changes in the current perception threshold (CPT). They found a significantly increased CPT value at 5 (described as urgency) and 250 Hz upon both urethral and bladder stimulation after 1 week of treatment. When compared with placebo, women taking tolterodine had significantly increased bladder CPT values at 5 Hz (P-value <0.05).

Tolterodine is available as immediate-release (TOLT-IR; 1 or 2 mg; twice daily dosing) and extended-release (TOLT-ER) forms (2 or 4 mg; once daily dosing). The ER form seems to have advantages over the IR form in terms of both efficacy and tolerability [Van Kerrebroeck et al. 2001].

Several randomised, double blind, placebo-controlled studies on patients with OAB/DO (both idiopathic and neurogenic DO), have documented a significant reduction in micturition frequency and number of incontinence episodes [Hills et al., 1998; Clemett et al., 2001; Salvatore et al., 2008]. Comparative RCTs such as the OBJECT (Overactive Bladder: Judging Effective Control and Treatment), and the OPERA (Overactive Bladder; Performance of Extended Release Agents) studies have further supported its effectiveness.

The OBJECT trial compared oxybutynin ER (OXY-ER) 10 mg once daily with TOLT-IR 2 mg twice daily
[Appell et al., 2001] in a 12-week randomized, double blind, parallel-group study including 378 patients with OAB. Participants had between 7 and 50 episodes of urgency incontinence per week and 10 or more voids in 24 hours. The outcome measures were the number of episodes of urgency incontinence, total incontinence, and micturition frequency at 12 weeks adjusted for baseline. At the end of the study, OXY-ER was found to be significantly more effective than TOLT-IR in each of the main outcome measures adjusted for baseline (see also below: oxybutynin chloride). Dry mouth, the most common adverse event, was reported by 33% and 28% of participants taking OXY-ER and TOLT-IR, respectively. Rates of central nervous system and other adverse events were low and similar in both groups. The authors concluded that OXY-ER was more effective than TOLT-IR and that the rates of dry mouth and other adverse events were similar in both treatment groups.

In the OPERA study [Dioikno et al., 2003], OXY-ER at 10 mg/d or TOLT-ER at 4 mg/d were given for 12 weeks to women with 21 to 60 urgency incontinence episodes per week and an average of 10 or more voids per 24 hours. Episodes of incontinence episodes (primary end point), total (urgency and non-urgency) incontinence, and micturition were recorded in seven 24-hour urinary diaries at baseline and at weeks 2, 4, 8 and 12 and compared. Adverse events were also evaluated. Improvements in weekly urgency incontinence episodes were similar for the 790 women who received OXY-ER (n=391) or TOLT-ER (n=399). OXY-ER was significantly more effective than TOLT-ER in reducing micturition frequency, and 23.0% of women taking OXY-ER reported no episodes of urinary incontinence compared with 16.8% of women taking TOLT-ER. Dry mouth, usually mild, was more common with OXY-ER. Adverse events were generally mild and occurred at low rates, with both groups having similar discontinuation of treatment due to adverse events. The conclusions were that reductions in weekly urgency incontinence and total incontinence episodes were similar with the two drugs. Dry mouth was more common with OXY-ER, but tolerability was otherwise comparable, including adverse events involving the central nervous system.

In the ACET (Antimuscarinic Clinical Effectiveness Trial) [Sussman and Garely, 2002] study, which consisted of two trials, patients with OAB were randomized to 8 weeks of open-label treatment with either 2 mg or 4 mg of once-daily TOLT-ER (study one) and to 5 mg or 10 mg of OXY-ER (study two). A total of 1289 patients were included. Fewer patients prematurely withdrew from the trial in the TOLT-ER 4 mg group (12%) than either the OXY-ER 5 mg (19%) or OXY-ER 10 mg groups (21%). More patients in the OXY-ER 10 mg group than the TOLT-ER 4 mg group withdrew because of poor tolerability (13% vs. 6%). After 8 weeks, 70% of patients in the TOLT-ER 4 mg group perceived an improved bladder condition, compared with 60% in the TOLT-ER 2 mg group, 59% in the OXY-ER 5 mg group and 60% in the OXY-ER 10 mg group. Dry mouth was dose-dependent with both agents, although differences between doses reached statistical significance only in the oxybutynin trial (OXY-ER 5 mg vs. OXY-ER 10 mg; p=0.05). Patients treated with TOLT-ER 4 mg reported a significantly lower severity of dry mouth compared with OXY-ER 10 mg. The conclusion that the findings suggest improved clinical efficacy of TOLT-ER (4 mg) than of OXY-ER (10 mg) is weakened by the open label design of the study.

Zinner et al. [2002] evaluated the efficacy, safety, and tolerability of TOLT-ER in older (> or =65) and younger (<65) OAB patients, in a 12-week RCT including 1015 patients with urgency incontinence and urinary frequency. Patients were randomized to treatment with TOLT-ER 4 mg once daily (n = 507) or placebo (n = 508) for 12 weeks. Efficacy, measured with micturition charts (incontinence episodes, micturitions, volume voided per micturition) and subjective patient assessments, safety, and tolerability endpoints were evaluated, relative to placebo. Compared with placebo, significant improvements in micturition chart variables with TOLT-ER showed no age-related differences. Dry mouth (of any severity) was the most common adverse event in both the TOLT-ER and placebo treatment arms, irrespective of age (<65: ER 22.7%, placebo 8.1%; > or =65: ER 24.3%, placebo 7.2%). A few patients (<2%) experienced severe dry mouth. No central nervous system (cognitive functions were not specifically studied), visual, cardiac (electrocardiogram), or laboratory safety concerns were noted in this study. Withdrawal rates due to adverse events on TOLT-ER 4 mg qd were comparable in the two age cohorts (<65: 5.5%; > or =65: 5.1%).

The central symptom in the OAB syndrome is urgency. Freeman et al. [2003] presented a secondary analysis of a double-blind, placebo-controlled study evaluating the effect of once-daily TOLT-ER on urinary urgency in patients with OAB. Patients with urinary frequency (eight or more micturitions per 24 hours) and urgency incontinence (five or more episodes per week) were randomized to oral treatment with TOLT-ER 4 mg once daily (n=398) or placebo (n=374) for 12 weeks. Efficacy was assessed by use of patient perception evaluations. Of patients treated with TOLT-ER, 44% reported improved urgency symptoms (compared with 32% for placebo), and 62% reported improved bladder symptoms (placebo, 48%). The proportion of patients unable to hold urine upon experiencing urgency was decreased by 58% with TOLT-ER, compared with 32% with placebo (P<.001).

In the IMprovement in Patients: Assessing symptomatic Control with Tolterodine ER (IMPACT) study [Elinoff et al., 2005], the efficacy of TOLT-ER for patients' most bothersome OAB symptom was investigated in an open label, primary care setting. Patients with OAB symptoms for ≥3 months received TOLT-ER (4 mg once daily) for 12 weeks. By week 12, there were significant reductions in patients' most bothersome symptom: incontinence, urgency episodes,
nocturnal and daytime frequency. The most common adverse events were dry mouth (10%) and constipation (4%), and it was concluded that in primary care practice, bothersome OAB symptoms can be effectively and safely treated with TOLT-ER, even in patients with comorbid conditions.

Various aspects of the efficacy and tolerability of tolterodine have been further documented in a number of RCTs [Abrams et al., 2006; Dmochowski et al., 2007a; b; Bharucha et al., 2008; Choo et al., 2008; Coyne et al., 2008; Kaplan et al., 2008a; Rogers et al., 2008; Rovner et al., 2008a; b see further: Novara et al., 2008; Chappell et al., 2008]. Importantly, the QTc effects of tolterodine were determined in a cross-over designed QT study of recommended (2 mg twice daily) and supratherapeutic (4 mg twice daily) doses of tolterodine, moxifloxacin (400 mg once daily), and placebo was performed. No subject receiving tolterodine exceeded the clinically relevant thresholds of 500 ms absolute QTc or 60ms change from baseline, and it was concluded that tolterodine does not have a clinically significant effect on QT interval [Malhotra et al., 2007].

Olsansky et al. [2008] compared the effects on heart rate of TOLT-ER 4 mg/day with those of darifenacin 15 mg/day in healthy volunteers. They found that tolterodine, but not darifenacin, significantly increased mean heart rate per 24 hours. The proportion of subjects with an increase >5 beats/min was significantly greater in those receiving TOLT-ER (25% than with darifenacin (8.9%).

Hsiao et al. [2011] compared the urodynamical effects, therapeutic efficacy and safety of solifenacin [5 mg] versus tolterodine ER [4 mg] treatment in women with the OAB syndrome. Both solifenacin and tolterodine had similar urodynamical effects, therapeutic efficacy and adverse events, however, tolterodine had a greater effect in increasing heart rate than solifenacin.

In a prospective, open study, Song et al. [2006] compared the effects of bladder training and/or tolterodine as first line treatment in female patients with OAB. One hundred and thirty-nine female patients with OAB were randomized to treatment with bladder training (BT), tolterodine (2 mg twice daily) or both for 12 weeks. All treatments were efficacious, however, combination therapy was the most effective. Mattiasson et al. [2003] compared the efficacy of tolterodine 2 mg twice daily plus simplified bladder training (BT) with tolterodine alone in patients with OAB in a multicenter single blind study. At the end of the study the median percentage reduction in voiding frequency was greater with tolterodine + BT than with tolterodine alone (33% vs. 25%; p<0.001), while the median percentage increase in volume voided per void was 31% with tolterodine + BT and 20% with tolterodine alone (P<0.001). There was a median of 81% fewer incontinence episodes than at baseline with tolterodine alone, which was not significantly different from that with tolterodine + BT (-87%). It was concluded that the effectiveness of tolterodine 2mg twice daily can be augmented by a simplified BT regimen. However, Millard et al. [2004] investigated whether the combination of tolterodine plus a simple pelvic floor muscle exercise program would provide improved treatment benefits compared with tolterodine alone in 480 patients with OAB. Tolterodine therapy for 24 weeks resulted in significant improvement in urgency, frequency, and incontinence, however, no additional benefit was demonstrated for a simple pelvic floor muscle exercise program. In a 16-week, multicenter, open label study tolterodine extended release plus behavioral intervention resulted in high treatment satisfaction and improved bladder diary variables in patients who had previously been treated and were dissatisfied with tolterodine or other antimuscarinics [Klutke et al., 2009]. More recently the combination of intravaginal oestriadiol and tolterodine has been assessed to ascertain its impact on OAB [Ellington et al., 2016]. After 12 weeks of monotherapy with either tolterodine ER 4mg or oestradiol no significant differences in OAB symptom score or bladder diary was seen between the groups although within group changes were observed. In the extension study the addition of tolterodine ER to intravaginal oestriadiol significantly improved OAB symptom bother score when compared to oestriadiol alone [Ellington et al., 2016].

A large, 26-week, multicenter, randomized, double-blind, placebo-controlled, three-period crossover study enrolled women aged ≥ 18 years that were diagnosed with OAB and reported ≥ 8 micturitions/24 hr and ≥ 4 urgency episodes/week on 5-day bladder diary at baseline [Marenencak et al. [2011]. Subjects were randomized to 1 of 10 treatment sequences and received three of five treatments, each for 4 weeks with 4-week washout periods: standard-dose pregabalin/tolterodine ER (150 mg twice daily [BID]/4 mg once daily [QD], n=102), pregabalin alone (150 mg BID, n=105), tolterodine ER alone (4 mg QD, n=104), low-dose pregabalin/tolterodine ER (75 mg BID/2 mg QD, n=105), and placebo (n=103). Subjects completed 5-day diaries at the end of treatment and washout periods. The primary endpoint was change from baseline to week 4 in mean voided volume (MVV) per micturition. Baseline-adjusted changes in MVV were significantly greater after treatment with standard-dose pregabalin/tolterodine ER (39.5 ml) versus tolterodine ER alone (15.5 ml; P<0.0001), and with pregabalin alone (27.4 ml) versus tolterodine ER alone (P=0.005) and placebo (11.9 ml; P=0.0006). Treatments were generally well tolerated; discontinuation rates due to adverse events were 4%, 2%, 5%, 0%, and 1% with standard- and low-dose pregabalin/tolterodine ER, pregabalin, tolterodine ER, and placebo, respectively. See further section on Combinations.

Dmochowski et al. [2014] have recently assessed a new formulation of IR tolterodine 2mg with delayed release pilocarpine 9mg slow release twice daily. In this double-blind crossover trial with open label extension, combination of tolterodine and pilocarpine and...
tolterodine alone were better than placebo at improving daily incontinence and micturition episodes, however, were no different compared to each other. Dry mouth as assessed by VAS (0-100) were 20.9, 28.7 and 40.4 for placebo, tolterodine / pilocarpine and tolterodine alone, respectively. Other parameters such as general discomfort around the mouth and difficulty swallowing / chewing showed similar trends. The incidence of dry mouth in tolterodine / pilocarpine was similar to placebo (3.9% vs 5.3%). In the extension study patients were randomized to tolterodine 3mg and pilocarpine 13.5 mg twice daily or tolterodine ER 4mg once daily. Incidence of dry mouth were similar in the 2 groups despite the tolterodine / pilocarpine combination having 50% more tolterodine [Dmochowski et al. 2014].

Assessment

Both the IR and ER forms of tolterodine have a well-documented effect in OAB/DO (Table 2), and are well tolerated.

1.1.8 Trospium Chloride

Trospium is a quaternary ammonium compound with a biological availability less than 10% [Fusgen and Hauri, 2000; Doroshenko et al., 2005]. The drug has a plasma half-life of approximately 20 h, and is mainly (60% of the dose absorbed) eliminated unchanged in the urine. The concentration obtained in urine seems to be enough to affect the mucosal signaling system in the intestine. The concentration obtained in urine seems to be enough to affect the mucosal signaling system in a rat model [Kim et al., 2005]. Whether or not it contributes to the clinical efficacy of the drug remains to be established.

Trospium is not metabolized by the cytochrome P450 enzyme system [Beckmann-Knopp et al., 1999; Doroshenko et al., 2005]. It is expected to cross the blood-brain barrier to a limited extent since it is a substrate for the drug-efflux transporter P-glycoprotein, which restricts its entry into the brain [Geyer et al., 2009]. This was demonstrated by Staskin et al. [2010], showing that trospium chloride levels in CSF samples were undetectable on Day 10 at steady-state peak plasma concentration concurrent with measureable peak plasma values. Clinically, trospium seems to have no negative cognitive effects [Fusgen and Hauri, 2000; Todorova et al., 2001; Wiedemann et al., 2002; Staskin et al., 2010; Chancellor et al., 2012].

Trospium has no selectivity for muscarinic receptor subtypes. In isolated detrusor muscle, it was more potent than oxybutynin and tolterodine to antagonize carbachol-induced contractions [Uckert et al., 2000].

Several RCTs have documented positive effects of trospium both in neurogenic [Stöhrer, et al., 1991; Madersbacher et al., 1995; Menarini et al., 2006] and non-neurogenic DO [Allousi et al., 1998; Cardozo et al., 2000; Junemann et al., 2000; Halaska et al., 2003; Zinner et al., 2004a; Rudy et al., 2006; Staskin et al., 2007; Dmochowski et al., 2008]. In a placebo-controlled, double blind study on patients with non-neurogenic DO [Stöhrer et al., 1991], the drug was given twice daily in a dose of 20 mg over a 3-week period. It increased maximum cystometric capacity, decreased maximal detrusor pressure and increased compliance in the treatment group, whereas no effects were noted in the placebo group. Side effects were few and comparable in both groups. In another RCT including patients with spinal cord injuries and neurogenic DO, trospium and oxybutynin were equieffective; however, trospium seemed to have fewer side effects [Madersbacher et al., 1995].

The effect of trospium in urgency incontinence has been documented in several RCTs. Allousi et al. [1998] compared the effects of the drug with those of placebo in 309 patients in a urodynamic study of 3-weeks duration. Trospium 20 mg was given twice daily. Significant increases were noted in volume at first involuntary contraction and in maximum bladder capacity. Cardozo et al. [2000] investigated 208 patients with DO, who were treated with trospium 20 mg twice daily for two weeks. Also in this study, significant increases were found in mean volume at first unstable contraction (from 233 to 299 ml; placebo 254 to 255 ml) and in maximum bladder capacity (from 329 to 356 ml; placebo 345 to 335 ml) in the trospium treated group. Trospium was well tolerated with similar frequency of adverse effects as in the placebo group. Jünemann et al. [2000] compared trospium 20 mg twice daily with tolterodine 2 mg twice daily in a placebo-controlled double-blind study on 232 patients with urodynamically proven DO, urgency incontinence without demonstrable DO, or mixed incontinence. Trospium reduced the frequency of micturition, which was the primary endpoint, more than tolterodine and placebo, and also reduced the number of incontinence episodes more than the comparators. Dry mouth was comparable in the trospium and tolterodine groups (7 and 9%, respectively).

Halaska et al. [2003] studied the tolerability and efficacy of trospium chloride in doses of 20 mg twice daily for long-term therapy in patients with urgency syndrome. The trial comprised a total of 358 patients with urgency syndrome or urgency incontinence. After randomisation in the ratio of 3:1, participants were treated continuously for 52 weeks with either trospium chloride (20 mg twice daily) or oxybutynin (5 mg twice daily). Urodynamic measurements were performed at the beginning, and at 26 and 52 weeks to determine the maximal cystometric bladder capacity. Analysis of the micturition diary clearly indicated a reduction of the micturition frequency, incontinence frequency, and a reduction of the number of urgency episodes in both treatment groups. Mean maximum cystometric bladder capacity increased during treatment with trospium chloride by 92 ml after 26 weeks and 115 ml after 52 weeks (P=0.001). Further comparison with oxybutynin did not reveal any statistically significant differences in urodynamic variables between the drugs. Adverse events occurred in 65% of the patients treated with trospium and 77% of those treated with oxybutynin. The main symptom encountered in both treatment groups was dryness of the mouth. An overall assessment for each of the drugs
revealed a comparable efficacy level and a better benefit-risk ratio for trospium than for oxybutynin due to better tolerability.

Zinner et al. [2004a] treated 523 patients with symptoms associated with OAB and urgency incontinence with 20 mg trospium twice daily or placebo in a 12-week, multicenter, parallel, double-blind, placebo controlled trial. Dual primary end points were change in average number of toilet voids and change in urgency incontinent episodes per 24 hours. Secondary efficacy variables were change in average of volume per void, voiding urgency severity, urinations during day and night, time to onset of action and change in Incontinence Impact Questionnaire. By week 12, trospium significantly decreased average frequency of toilet voids per 24 hours (-2.37) and urgency incontinent episodes 59% compared to placebo (-1.29; 44%). It significantly increased average volume per void (32 ml; placebo: 7.7) ml, and decreased average urgency severity and daytime frequency. All effects occurred by week 1 and all were sustained throughout the study. Nocturnal frequency decreased significantly by week 4 (-0.43; placebo: 0.17) - and Incontinence Impact Questionnaire scores improved at week 12. Trospium was well tolerated. The most common side effects were dry mouth (21.8%; placebo 6.5%), constipation (9.5%; placebo 3.8%) and headache (6.5%; placebo 4.6%). In a large US multicenter trial with the same design, and including 658 patients with OAB, Rudy et al. [2006] confirmed the data by Zinner et al [2004a], both with respect to efficacy and adverse effects.

Dose escalation seems to improve therapeutic efficacy. In a 12-week, randomised, double-blind, phase IIIb study including 1658 patients with urinary frequency plus urgency incontinence received trospium chloride 15 mg TID (n = 828) or 2.5 mg oxybutynin hydrochloride TID (n = 830). After four weeks, daily doses were doubled and not readjusted in 29.2% (242/828) of patients in the trospium group, and in 23.3% (193/830) in the oxybutynin group, until the end of treatment. At study end, there were no relevant differences between the "dose adjustment" subgroups and the respective "no dose adjustment" subgroups (trospium: P = 0.249; oxybutynin: P = 0.349). After dose escalation, worsening of dry mouth was higher in both dose adjusted subgroups compared to the respective "no dose adjustment" subgroups (P < 0.001). Worsening of dry mouth was lower in the trospium groups than in the oxybutynin groups [Bödeker et al., 2010].

An extended release formulation of trospium allowing once daily dosing, has been introduced [Silver et al., 2010], and its effects tested in controlled trials [Dmochowski et al., 2008; Staskin et al., 2009; Chancellor et al., 2010; MacDiarmid et al., 2011; Sand et al., 2011a; b; Zinner et al., 2011]. These studies demonstrated similar efficacy as found with previous formulations, but include experiences in e.g., elderly patients (>75 years), obese patients, and in patients who use multiple concomitant medications. In the pooled analysis of 2 large phase III trials (n=1027), trospium chloride extended release 60 mg once daily significantly improved micturition and UUI episodes per 24 hours compared to placebo [Staskin et al. 2009]. Furthermore, trospium was superior to placebo in the OAB symptom composite score, urgency episodes and mean voided volume. Dry mouth and constipation were the 2 commonest adverse events being 10.7% and 8.5% with trospium compared to 3.7% and 1.5% with placebo. The pooled analysis of the long-term extension study (n=667) with extended release once daily trospium chloride 60 mg daily also showed benefit in managing OAB [Zinner et al. 2011]. Significant improvements were seen in the placebo to trospium group and efficacy maintained in the trospium to trospium group by end of study. Approximately 85% of the population felt their symptoms were improved with trospium chloride treatment. Furthermore, significant improvements in quality of life were demonstrated when using the KHQ.

Intravesical application of trospium may be an interesting alternative. Frölich et al. [1998] performed a randomised, single-blind, placebo-controlled, monocentre clinical trial in 84 patients with urgency or urgency incontinence. Compared to placebo, intravesical trospium produced a significant increase in maximum bladder capacity and a decrease of detrusor pressure accompanied by an increase of residual urine. There was an improvement in uninhibited bladder contractions. No adverse events were reported. Interestingly, intravesical trospium does not seem to be absorbed [Walter et al., 1999], thus offering an opportunity for treatment with minimal systemic antimuscarinic effects.

### Assessment

Trospium has a well-documented effect in OAB/DO, and tolerability and safety seems acceptable (Table 2).

#### 1.2. Antimuscarinics with "Mixed" Action

Some drugs used for treatment of the OAB syndrome/DO have been shown to have more than one mechanism of action. They all have a more or less pronounced antimuscarinic effect and, in addition, an often poorly defined "direct" action on bladder muscle. For several of these drugs, the antimuscarinic effects can be demonstrated at much lower drug concentrations than the direct action, which may involve blockade of voltage operated Ca2+ channels. Most probably, the clinical effects of these drugs can be explained mainly by an antimuscarinic action. Among the drugs with mixed actions was terodiline, which was withdrawn from the market because it was suspected to cause polymorphic ventricular tachycardia (torsade de pointes) in some patients [Connolly et al., 1991; Stewart et al., 1992].

### 1.2.1 Oxybutynin Chloride

Oxybutynin is a tertiary amine that is well absorbed, and undergoes extensive upper gastrointestinal and...
first-pass hepatic metabolism via the cytochrome P-450 system (CYP3A4) into multiple metabolites. The primary metabolite, N-desethyloxybutynin (DEO) has pharmacological properties similar to the parent compound [Waldeck et al., 1997], but occurs in much higher concentrations after oral administration [Hughes et al., 1992]. It has been implicated as the major cause of the troublesome side effect of dry mouth associated with the administration of oxybutynin. It seems reasonable to assume that the effect of oral oxybutynin to a large extent is exerted by the metabolite. The occurrence of an active metabolite may also explain the lack of correlation between plasma concentration of oxybutynin itself and side effects in geriatric patients reported by Ouslander et al. [1988]. The plasma half-life of the oxybutynin is approximately 2 hours, but with wide interindividual variation [Hughes et al., 1992; Douchamps et al., 1988].

Oxybutynin has several pharmacological effects in vitro, some of which seem difficult to relate to its effectiveness in the treatment of DO. It has both an antimuscarinic and a direct muscle relaxant effect, and, in addition, local anesthetic actions. The latter effect may be of importance when the drug is administered intravesically, but probably plays no role when it is given orally. In vitro, oxybutynin was 500 times weaker as a smooth muscle relaxant than as an antimuscarinic agent [Kachur et al., 1988]. Most probably, when given systemically, oxybutynin acts mainly as an antimuscarinic drug. Oxybutynin has a high affinity for muscarinic receptors in human bladder tissue and effectively blocks carbachol-induced contractions [Waldeck et al., 1997; Nilvebrant et al., 1988]. The drug was shown to have slightly higher affinity for muscarinic M1 and M3 receptors than for M2 receptors [Nilvebrant et al., 1986; Norhona-Blob et al., 1991], but the clinical significance of this is unclear.

The immediate release (IR) form of oxybutynin (OXY-IR) is recognized for its efficacy and most of the newer anti-muscarinic agents have been compared to it once efficacy over placebo has been determined. In general, the new formulations of oxybutynin and other anti-muscarinic agents offer patients efficacy roughly equivalent to that of OXY-IR, and the advantage of the newer formulations lies in improved dosing schedules and side-effect profile [Appell et al., 2001; Diokno et al., 2003; Dmochowski et al., 2002]. An extended release oxybutynin (OXY-ER) once daily oral formulation and an oxybutynin transdermal delivery system (OXY-TDS) are available. OXY-TDS offers a twice-weekly dosing regimen and the potential for improved patient compliance and tolerability. Some of the available formulations of oxybutynin were overviewed by McCrery and Appell [2006].

1.2.1.1 Immediate-Release Oxybutynin (OXY-IR)

Several controlled studies have have shown that OXY-IR is effective in controlling DO, including neurogenic DO [Yarker et al., 1995; Andersson and Chapple, 2001]. The recommended oral dose of the IR form is 5 mg three times daily or four times daily, even if lower doses have been used. Thüroff et al. [1998] summarized 15 randomized controlled studies on a total of 476 patients treated with oxybutynin. The mean decrease in incontinence was recorded as 52% and the mean reduction in frequency per 24 h was 33% (data on placebo not presented). The overall “subjective improvement” rate was reported as 74% (range 61% - 100%). The mean percent of patients reporting an adverse effect was 70% (range 17% - 93%). Oxybutynin, 7.5 to 15 mg/day, significantly improved quality of life of patients suffering from overactive bladder in a large open multicenter trial. In this study, patients’ compliance was 97% and side effects, mainly dry mouth, were reported by only 8% of the patients [Amarenco et al., 1998]. In nursing home residents (n=75), Ouslander et al. [1995] found that oxybutynin did not add to the clinical effectiveness of prompted voiding in a placebo-controlled, double blind, cross-over trial. On the other hand, in another controlled trial in elderly subjects (n=57), oxybutynin with bladder training was found to be superior to bladder training alone [Szonyi et al., 1995].

Several open studies in patients with spinal cord injuries have suggested that oxybutynin, given orally or intravesically, can be of therapeutic benefit [Szollár et al., 1996; Kim et al., 1996].

The therapeutic effect of OXY-IR on DO is associated with a high incidence of side effects (up to 80% with oral administration). These are typically antimuscarinic in nature (dry mouth, constipation, drowsiness, blurred vision) and are often dose-limiting [Baigrie et al., 1988; Jonville et al., 1992]. The effects on the electrocardiogram of oxybutynin were studied in elderly patients with urinary incontinence [Hussain et al., 1998]; no changes were found. It cannot be excluded that the commonly recommended dose 5 mg x 3 is unnecessarily high in some patients, and that a starting dose of 2.5 mg x 2 with following dose-titration would reduce the number of adverse effects [Amarenco et al., 1998].

1.2.1.2 Extended Release Oxybutynin (OXY-ER)

This formulation was developed to decrease liver metabolite formation of desethyloxybutynin (DEO) with the presumption that it would result in decreased side effects, especially dry mouth, and improve patient compliance with remaining on oxybutynin therapy [see Arisco et al., 2009]. The formulation utilizes an osmotic system to release the drug at a controlled rate over 24 hours distally primarily into the large intestine where absorption is not subject to first-pass metabolism in the liver. This reduction in metabolism is meant to improve the rate of dry mouth complaints when compared to OXY-IR. DEO is still formed through the hepatic cytochrome P-450 enzymes, but clinical trials have indeed demonstrated improved dry mouth rates compared with OXY-IR [Appell et al.,
The effects of OXY-ER have been well documented [Siddiqui et al., 2004]. In the OBJECT study [Appell et al., 2001], the efficacy and tolerability of 10 mg OXY-ER was compared to a twice daily 2 mg dose of TOLT-IR. OXY-ER was statistically more effective than the TOLT-IR in weekly urgency incontinence episodes (OXY-ER from 25.6 to 6.1%; TOLT-IR 24.1 to 7.8), total incontinence (OXY-ER from 28.6 to 7.1%; TOLT-IR 27.0 to 9.3), and frequency (OXY-ER from 91.8 to 67.1%; TOLT-IR 91.6 to 71.5) and both medications were equally well tolerated. The basic study was repeated as the OPERA study [Diokno et al., 2003] with the difference that this study was a direct comparison of the two extended-release forms, OXY-ER (10 mg) and TOLT-ER (4 mg) and the results were quite different. In this study there was no significant difference in efficacy for the primary endpoint of urgency incontinence, however, TOLT-ER had a statistically lower incidence of dry mouth. OXY-ER was only statistically better at 10 mg than TOLT-ER 4 mg in the reduction of the rate of urinary frequency. These studies made it clear that in comparative studies IR entities of one drug should no longer be compared with ER entities of the other.

Greater reductions in urgency and total incontinence have been reported in patients treated in dose-escalation studies with OXY-ER. In two randomized studies, the efficacy and tolerability of OXY-ER were compared with OXY-IR. In a 1999 study [Anderson et al., 1999], 105 patients with urgency or mixed incontinence were randomized to receive 5-30 mg OXY-ER once daily or 5 mg of OXY-IR 1-4 times/day. Dose titrations began at 5 mg and the dose was increased every 4-7 days until one of three endpoints was achieved. These were 1) the patient reported no urgency incontinence during the final two days of the dosing period; 2) the maximum tolerable dose was reached; the maximum allowable dose (30 mg for OXY-ER or 20 mg for OXY-IR) was reached. The mean percentage reduction in weekly urgency and total incontinence episodes was statistically similar between OXY-ER and OXY-IR but dry mouth was reported statistically more often with OXY-IR. In the 2000 study [Versi et al., 2000], 226 patients were randomized between OXY-ER and OXY-IR with weekly increments of 5 mg daily up to 20 mg daily. As in the 1999 study, OXY-ER again achieved a >80% reduction in urgency and total incontinence episodes and a significant percentage of patients became dry. A negative aspect of these studies is that there were no naïve patients included, as all patients were known responders to oxybutynin. Similar efficacy results have been achieved, however, with OXY-ER in a treatment-naïve population [Gleason et al., 1999].

In an RCT comparing different daily doses of oxybutynin (5, 10 and 15 mg), Corcos et al. [2006] found a significant dose-response relationship for both urgency incontinence episodes and dry mouth. The greatest satisfaction was with 15 mg oxybutynin/day.

In a multicentre, prospective, observational, flexible-dosing Korean study, Yoo et al. [2012] investigate the prescription pattern and dose distribution of OXY-ER in patients the OAB syndrome in actual clinical practice. The dosage of for each patient was adjusted after discussions of efficacy and tolerability between doctor and patient, over a 12-week treatment period. Efficacy was measured by administering the Primary OAB Symptom Questionnaire (POSQ) before and after treatment. Patients were also administered, the patient perception of treatment benefit (PPTB) questionnaire at the end of the study. Of the 809 patients enrolled, 590 (73.2%) continued to take study medication for 12 weeks. Most patients were prescribed 5–10 mg / day oxybutynin ER as both starting and maintenance doses, with a dose escalation rate of only 14.9%. All OAB symptoms evaluated by the POSQ were improved; 94.1% of patients reported benefits from treatment and 89.3% were satisfied.

1.2.1.3 Transdermal Oxybutynin (OXY-TDS)

Transdermal delivery also alters oxybutynin metabolism reducing DEO production to an even greater extent than OXY-ER. A study [Davila et al., 2001] comparing OXY-TDS with OXY-IR demonstrated a statistically equivalent reduction in daily incontinence episodes (from 7.3 to 2.3: 66% for OXY-TDS, and 7.4 to 2.6: 72% for OXY-IR), but much less dry mouth (38% for OXY-TDS and 94% for OXY-IR). In another study [Dmochowski et al., 2002] the 3.9-mg daily dose patch significantly (vs placebo) reduced the mean number of daily incontinence episodes (from 4.7 to 1.9; placebo from 5.0 to 2.9), while reducing average daily urinary frequency confirmed by an increased average voided volume (from 165 to 198 ml; placebo from 175 to 182 ml). Furthermore, dry mouth rate was similar to placebo (7% vs 8.3%). In a third study [Dmochowski et al., 2003a] OXY-TDS was compared not only to placebo but to TOLT-ER. Both drugs equivalently and significantly reduced daily incontinence episodes and increased the average voided volume, but TOLT-ER was associated with a significantly higher rate of antimuscarinic adverse events. The primary adverse event for OXY-TDS was application site reaction pruritis in 14% and erythema in 8.3% with nearly 9% feeling that the reactions were severe enough to withdraw from the study, despite the lack of systemic problems.

The pharmacokinetics and adverse effect dynamics of OXY-TDS (3.9 mg/day) and OXY-ER (10 mg/day) were compared in healthy subjects in a randomized, 2-way crossover study [Appell et al., 2003]. Multiple blood and saliva samples were collected and pharmacokinetic parameters and total salivary output were assessed. OXY-TDS administration resulted in greater systemic availability and minimal metabolism.
to DEO compared to OXY-ER which resulted in greater salivary output in OXY-TDS patients and less dry mouth symptomatology than when taking OXY-ER.

Dmochowski et al. [2005] analyzing the combined results of two RCTs concluded that transdermal oxybutynin was shown to be efficacious and well tolerated. The most common systemic side effect was dry mouth (7.0% vs placebo 5.3%). Application site erythema occurred in 7% and pruritus in 16.1%. Also Cartwright and Cardozo [2006], reviewing published and presented data concluded that transdermal oxybutynin has a good balance between efficacy and tolerability with a rate of systemic antimuscarinic side effects lower that with oral antimuscarinics; however, this benefit was offset by the rate of local skin reaction. The reviews of Sahai et al. [2008] and Staskin and Salvatore [2010] largely confirmed these conclusions, which also have been supported by further studies [Cartwright et al., 2011].

In a Japanese population of OAB an alternative daily 73.5mg transdermal oxybutynin patch was assessed against propiverine 20mg daily and placebo [Yamaguchi et al., 2014]. Approximately 570 patients were in the active arms and 380 in placebo. At 12 weeks, the oxybutynin patch was significantly superior than placebo and non-inferior to propiverine for daily micturition episodes. Urgency and voided volume was better compared to placebo for transdermal oxybutynin, however urgency incontinence episodes and nocturia were no different. Furthermore 8 out of 9 domains assessed utilising the KHQ were better for transdermal oxybutynin compared to placebo suggesting better quality of life in this group. Dry mouth and constipation were seen in 6.5% and 0.7%, 13.2% and 5%, and 1.8% and 1% in the transdermal oxybutynin, propiverine and placebo groups, respectively. In the transdermal oxybutynin group application site dermatitis was seen in 31.8%, with site erythema in 5.6%.

Recently the transdermal patch (3.9mg/day) has been shown to be subjectively effective in a small paediatric population but with 35% skin site irritation and 20% discontinuation rate [Gleason et al., 2014].

1.2.1.4 Oxybutynin Topical Gel

Given the efficacy and tolerability of the transdermal application, limited only by skin site reactions, a gel formulation was developed. oxybutynin topical gel (OTG) was approved by the US FDA in January 2009. OTG is applied once daily to the abdomen, thigh, shoulder, or upper arm area [Staskin et al., 2009]. The 1g application dose delivers approximately 4 mg of drug to the circulation with stable plasma concentrations and a "favorable" N-desethoxyxybutynin metabolite: oxybutynin ratio believed to minimizing antimuscarinic side effects [Staskin and Robinson, 2009].

In a multicenter RCT, 789 patients (89% women) with urgency-predominant incontinence were assigned to OTG or placebo once daily for 12 weeks [Staskin et al., 2009]. The mean number of urgency episodes, as recorded by 3-day voiding diary, was reduced by 3.0 episodes per day versus 2.5 in the placebo arm ($P < 0.0001$). Urinary frequency decreased by 2.7 episodes per day and voided volume increased by 21 mL (versus 2.0 episodes [$P = 0.0017$] and 3.8 mL [$P = 0.0018$], respectively, in the placebo group). Dry mouth was reported in 6.9% of the treatment group versus 2.8% of the placebo group. Skin reaction at the application site was reported in 5.4% of the treatment group versus 1.0% in the placebo arm. It was felt that improved skin tolerability of the gel over the OXY transdermal patch delivery system was secondary to lack of adhesive and skin occlusion. The gel dries rapidly upon application and leaves no residue; person-to-person transference via skin contact is largely eliminated if clothing is worn over the application site [Dmochowski et al., 2011]. The evolution of the transdermal gel allows greater patient tolerability and improved compliance. This was confirmed by Sand et al. [2012] showing that in 704 women with OAB OTG significantly reduced the number (mean ± standard deviation) of daily incontinence episodes (OTG, $-3.0 ± 2.8$ episodes; placebo, $-2.5 ± 3.0$ episodes), reduced urinary frequency, increased voided volume, and improved select health-related quality-of-life domains vs placebo. Dry mouth was the only drug-related adverse event significantly more common with OTG (7.4%) than with placebo (2.8%).

Another 3% topical oxybutynin gel has been assessed in a phase III randomised placebo controlled trial (randomised n=626) [Goldfischer et al. 2015]. This product is administered via a metered dose pump dispenser and was hypothesised to have less adverse events. Furthermore, it is made with propylene glycol to help with skin permeation. Two doses of 84mg/day and 56 mg/day of the 3% topical oxybutynin were assessed against placebo gel in this population of patients with urgency and/or urge predominant mixed incontinence. The 84 mg / day dose was statistically better than placebo after 12 weeks in improving weekly UI episodes (primary endpoint) and also daily urinary frequency and urine voided volumes. The lower dose of 56mg / day was not statistically better than placebo. Dry mouth and application site erythema was seen in 12.1% and 3.3% in the 84 mg / day group compared to 5% and 0.5% in the placebo arm.

1.2.1.5 Other Administration Forms

Rectal administration [Collas and Malone-Lee, 1997] was reported to have fewer adverse effects than the conventional tablets.

Administered intravesically, oxybutynin has in several studies been demonstrated to increase bladder capacity and produce clinical improvement with few side effects, both in neurogenic and in other types of DO, and both in children and adults [Lose and Norgaard, 2001; Fader et al., 2007; George et al., 2007; Guerra et al., 2008], although adverse effects may occur [Kasabian et al., 1994; Palmer et al., 1997]. More recently a phase II exploratory randomized placebo controlled trial (n=323) of intra-vaginal oxybutynin
ring was conducted based on the premise that there is a shared lymphovascular network between the vagina and bladder [Gittelman et al. 2014]. Approximately one quarter of the patients had an accidental fallout of the ring. Both formulations of 4 and 6 mg were better than placebo at reducing weekly UI episodes when compared to placebo. Dry rates, frequency and UUI episodes were also statistically better in the 6mg intravaginal oxybutynin group compared to placebo. UTI, dry mouth and vaginal discharge were the commonest adverse events. UTI and dry mouth rates were 11.6% and 10.2% in the 6mg oxybutynin group, 9.1% and 4.9% in the 4mg oxybutynin group and 4.5% and 2.6% in the placebo groups.

### 1.2.1.6 Effects on Cognition

Several studies have documented the possibility that oxybutynin may have negative effects on cognitive functions, particularly in the elderly population [see section on “Considerations in the Elderly”], but also in adults and in children [see, e.g., Kay et al., 2006; Klausner and Steers, 2007; Kay and Ebinger, 2008]. This factor should be taken into consideration when prescribing the drug.

#### Assessment

Oxybutynin has a well-documented efficacy in the treatment of OAB/DO (Table 2). Despite the adverse effect profile, it is still an established therapeutic option.

### 1.2.2 Propiverine Hydrochloride

Several aspects of the preclinical, pharmacokinetic, and clinical effects of propiverine were reviewed by Madersbacher and Murz [2001]. The drug is rapidly absorbed ($t_{\text{max}}$ 2 h), but has a high first pass metabolism, and its biological availability is about 50%. Propiverine is an inducer of hepatic cytochrome P450 enzymes in rats in doses about 100-times above the therapeutic doses in man [Walter et al., 2003]. Several active metabolites are formed which quantitatively and qualitatively differ from the mother compound [Haustein et al., 1988; Muller et al., 1993; Wuest et al., 2006; Zhu et al., 2008; Sugiyama et al., 2008]. Most probable these metabolites contribute to the clinical effects of the drug, but their individual contributions have not been clarified [Michel and Hegde, 2006]. The half-life of propiverine itself is about 11-14 h. An extended release preparation was shown to be effective [Junemann et al., 2006; May et al., 2008]. Oral absorption of propiverine is site dependent and influenced by dosage form and circadian-time-dependent elimination processes [May et al., 2008].

Propiverine has combined antimuscarinic and calcium antagonistic actions [Haruno, 1992; Tokuno et al., 1993]. The importance of the calcium antagonistic component for the drug’s clinical effects has not been established. Propiverine has no selectivity for muscarinic receptor subtypes. The effects of propiverine on cardiac ion channels and action potentials were investigated by Christ et al. [2008]. Propiverine blocked in a concentration-dependent manner HERG channels expressed in HEK293 cells, as well as native I(Kr) current in ventricular myocytes of guinea pig. However, action potential duration was not prolonged in guinea-pig and human ventricular tissue, and the investigators concluded that their results did not provide evidence for an enhanced cardiovascular safety risk with the drug.

Propiverine has been shown to have beneficial effects in patients with DO in several investigations. Thüroff et al [1998] collected 9 randomized studies on a total of 230 patients, and found a 17% reduction in micturations per 24 hours, a 64 ml increase in bladder capacity, and a 77% (range 33-80%) subjective improvement. Side effects were found in 14% (range 8-42%). In patients with neurogenic DO, controlled clinical trials have demonstrated propiverine’s superiority over placebo [Stöhrer et al., 1999]. Propiverine also increased bladder capacity and decreased maximum detrusor contractions. Controlled trials comparing propiverine, flavoxate and placebo [Wehnert et al., 1989], and propiverine, oxybutynin and placebo [Wehnert et al., 1992; Madersbacher et al., 1999], have confirmed the efficacy of propiverine, and suggested that the drug may have equal efficacy and fewer side effects than oxybutynin. In a comparative RCT including 131 patients with neurogenic DO, propiverine and oxybutynin were compared [Stöhrer et al., 2007]. The drugs were found to be equally effective in increasing bladder capacity and lowering bladder pressure. Propiverine caused a significantly lower frequency of dry mouth than oxybutynin. Recently the once daily extended release formulation of propiverines was compared to immediate release propiverine in a trial with 66 patients suffering with NDO [Stöhrer et al. 2013]. The primary endpoint was change in reflex volume which was improved and comparable between the two formulations. However, continence rates were statistically better in the ER group compared to IR. Adverse events were similar with dry mouth rates 27% and 24% for ER and IR formulations, respectively.

Also in children and adolescents with neurogenic DO, propiverine was found to be effective [Schulte-Baukloh et al., 2006; Grigoleit et al., 2006], with a low incidence rate of adverse events: <1.5% [Grigoleit et al., 2006]. A randomized, double-blind, placebo-controlled trial with parallel-group design in children aged 5–10 yr was performed by Marschall-Kehrel et al. [2009]. Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. Decrease in voiding frequency per day was the primary efficacy parameter; secondary endpoints included voided volume and incontinence episodes. There was a significant decrease in voiding frequency episodes for propiverine versus placebo. Superiority could also be demonstrated for voided volume and incontinence episodes per day. Propiverine was well-tolerated: 23% of side-effects were reported for propiverine and 20% for placebo.
In a randomised, double-blind, multicentre clinical trial, patients with idiopathic DO were treated with 15 mg propiverine twice daily or 2 mg TOLT-IR twice daily over a period of 28 days [Junemann et al., 2005]. The maximum cystometric capacity was determined at baseline and after 4 weeks of therapy. The difference of both values was used as the primary endpoint. Secondary endpoints were voided volume per micturition, evaluation of efficacy (by the investigator), tolerability, post void residual urine, and quality of life. It was found that the mean maximum cystometric capacity increased significantly (p < 0.01) in both groups. The volume at first urgency and the frequency/volume chart parameters also showed relevant improvements during treatment. The most common adverse event, dry mouth, occurred in 20 patients in the propiverine group and in 19 patients in the tolterodine group. The scores for the quality of life improved comparably in both groups.

Madersbacher et al. [1999] compared the tolerability and efficacy of propiverine (15 mg three times daily) oxybutynin (5 mg twice daily) and placebo in 366 patients with urgency and urgency incontinence in a randomized, double-blind placebo-controlled clinical trial. Urodynamic efficacy of propiverine was judged similar to that of oxybutynin, but the incidence of dry mouth and the severity of dry mouth were judged less with propiverine than with oxybutynin. Dorschner et al. [2000] investigated in a double-blind, multicentre, placebo-controlled, randomized study, the efficacy and cardiac safety of propiverine in 98 elderly patients (mean age 68 years), suffering from urgency, urgency incontinence or mixed urgency-stress incontinence. After a 2-week placebo run-in period, the patients received propiverine (15 mg three times daily) or placebo (three times daily) for 4 weeks. Propiverine caused a significant reduction of the micturition frequency (from 8.7 to 6.5) and a significant decrease in episodes of incontinence (from 0.9 to 0.3 per day). The incidence of adverse events was very low (2% dryness of the mouth under propiverine – 2 out of 49 patients). Resting and ambulatory electrocardiograms indicated no significant changes. The cardiac safety of propiverine was further studied by Donath et al. [2011] in two comprehensively designed monocentric ECG studies (including 24 healthy females, followed by a second study on 24 male patients with coronary heart disease (CHD) and a pathological Pardee-Q-wave in the ECG). Both studies were placebo-controlled and compared the effects of single (30 mg s.i.d.) and multiple dosing (15 mg t.i.d.) of propiverine hydrochloride in a crossover design over 6 and 13 days, respectively. They were performed to investigate the influence of propiverine hydrochloride and its main metabolite propiverine-N-oxide on cardiac function with regard to QTc prolongation, QTc dispersion and T-wave shape. No negative effects on cardiac safety could be demonstrated.

Abrams et al. [2006] compared the effects of propiverine and oxybutynin on ambulatory urodynamic monitoring parameters, safety, and tolerability in OAB patients. Patients (n=77) received two of the following treatments during two 2-week periods: propiverine 20 mg once daily, propiverine 15 mg three times daily, oxybutynin 5 mg three times daily, and placebo. They found that oxybutynin 15 mg was more effective than propiverine 20 mg in reducing symptomatic and asymptomatic involuntary detrusor contractions in ambulatory patients. Oxybutynin had a higher rate of dry mouth, and propiverine had a more pronounced effect on gastrointestinal, cardiovascular, and visual function.

Yamaguchi et al. [2007] performed a multicentre, 12-week, double-blind phase III trial in Japanese men and women with OAB (1593 patients were randomized and 1584 were treated), comparing solifenacin 5 or 10 mg, propiverine 20 mg, and placebo. Changes at endpoint in number of voids/24 hours, urgency, incontinence, urgency incontinence and nocturia episodes, volume voided/void, restoration of continence and quality of life (QoL) were examined. It was found that at endpoint, there were greater reductions in mean (SD) voids/24 hours with all drug regimens than with placebo. All active treatments improved the volume voided and QoL vs placebo; solifenacin 10 mg reduced nocturia episodes and significantly improved urgency episodes and volume voided vs propiverine 20 mg, and solifenacin 5 mg caused less dry mouth. Solifenacin 10 mg caused more dry mouth and constipation than propiverine 20 mg. Wada et al. [2011] performed a prospective nonrandomized crossover study of female OAB patients, assigned alternately to treatment with propiverine (20 mg) for 8 weeks then solifenacin (5 mg) for 8 weeks or solifenacin for 8 weeks then propiverine for 8 weeks. At baseline, 8th week and 16th week, symptoms were assessed using overactive bladder symptom score (OABSS). Of the 121 patients enrolled 83 were analysed. Both drugs were effective. Urgency was further improved after switching from propiverine to solifenacin, but not after switching from solifenacin to propiverine. Solifenacin was better tolerated than propiverine.

In another multicenter, prospective, parallel, double blind, placebo-controlled trial, Lee et al. [2010] studied the effects of 30 mg propiverine/day in 264 OAB patients (mean age 52.2 years), 221 of whom had efficacy data available from baseline and at least one on-treatment visit with >75 compliance. The study was focused on improving urgency. Overall, among patients treated with propiverine, 39% rated their treatment as providing ‘much benefit’, compared with 15 % in the placebo group. Adverse events reported by 32 (22.5%) and 10 (12.7%) patients in the propiverine and placebo group were all tolerable.

Recently the extended release formulation of propiverine was compared to the extended release formulation of tolterodine in a non-inferiority trial with approximately 150 patients in each study arm [Leng et al., 2016]. Statistically more significant reductions were seen for propiverine ER compared with tolterodine ER. Discontinuation rates because of adverse events were more in the tolterodine ER group compared to propiverine ER (7.4% vs 3.1%). Based on
the way the study was designed and powered the authors concluded that ER propiverine was non-inferior to ER tolterodine [Leng et al., 2016].

Masumori et al. [2011] examined prospectively the efficacy and safety of propiverine 20mg / day in patients with OAB symptoms who poorly responded to previous treatment with solifenacin, tolterodine or imidafenacin. Of 73 patients enrolled (29 males and 44 females, median age 71 years), 52 completed the protocol treatment. The OABSS was significantly improved by propiverine treatment. The scores of OAB symptoms (time between micturitions, urge and urgency) except daytime frequency also improved significantly. No increase in PVR was observed. The most frequent adverse event was dry mouth (13.7%), followed by constipation (6.8%).

In a non-controlled study in patients with wet OAB the efficacy of propiverine on symptoms and quality of life was confirmed [Komatsu et al. [2009]].

### Assessment

Propiverine has a documented beneficial effect in the treatment of OAB/DO (Table 2), and seems to have an acceptable side effect profile.

#### 1.2.3 Flavoxate Hydrochloride

Flavoxate is often discussed as a drug with mixed actions, however, its main mechanism of action may not be antimuscarinic. Flavoxate is well absorbed, and oral bioavailability appeared to be close to 100% [Guay, 2003]. The drug is extensively metabolized and plasma half-life was found to be 3.5 h [Sheu et al., 2001]. Its main metabolite (3-methylflavone-8-carboxylic acid, MFCA) has been shown to have low pharmacological activity [Cazzulani et al., 1988; Caine et al., 1991]. The main mechanism of flavoxate’s effect on smooth muscle has not been established. The drug has been found to possess a moderate calcium antagonistic activity, to have the ability to inhibit phosphodiesterase, and to have local anesthetic properties; no antimuscarinic effect was found [Guarneri et al., 1994]. Uckert et al. [2000], on the other hand, found that in strips of human bladder, the potency of flavoxate to reverse contraction induced by muscarinic receptor stimulation and by electrical field stimulation was comparable. It has been suggested that pertussis toxin-sensitive G-proteins in the brain are involved in the flavoxate-induced suppression of the micturition reflex, since intracerebroventricularly or intrathecally administered flavoxate abolished isovolumetric rhythmic bladder contractions in anesthetized rats [Oka et al., 1996].

The clinical effects of flavoxate in patients with DO and frequency, urgency and incontinence have been studied in both open and controlled investigations, but with varying rates of success [Ruffman, 1988]. Stanton [1973] compared emepronium bromide and flavoxate in a double-blind, cross-over study of patients with detrusor overactivity and reported improvement rates of 83% and 66% after flavoxate or emepronium bromide, respectively, both administered as 200 mg 3 times daily. In another double-blind, cross-over study comparing flavoxate 1200 mg/day with that of oxybutynin 15 mg daily in 41 women with idiopathic motor or sensory urgency, and utilising both clinical and urodynamic criteria, Milani et al. [1993] found both drugs effective. No difference in efficacy was found between them, but flavoxate had fewer and milder side effects. Other investigators, comparing the effects of flavoxate with those of placebo, have not been able to show any beneficial effect of flavoxate at dosages up to 400 mg three times daily [Briggs et al., 1980; Chapple et al., 1990; Dahm et al., 1995]. In general, few side effects have been reported during treatment with flavoxate. On the other hand, its efficacy, compared to other therapeutic alternatives, is not well documented (Table 2).

### Assessment

No RCTs seem to have been performed with flavoxate during the last decade. The scarcity of documented clinical efficacy should be considered before using the drug.

#### 1.3. Clinical Use of Antimuscarinics

The clinical relevance of efficacy of antimuscarinic drugs relative to placebo has been questioned. Herison et al. [2003] stated in a widely discussed article: “Anticholinergics produce significant improvements in overactive bladder symptoms compared with placebo. The benefits are, however, of limited clinical significance” Large meta-analyses of studies performed with the currently most widely used drugs [Chapple et al., 2005; 2008; Novara et al., 2008], clearly show that antimuscarinics are of significant clinical benefit. Novara et al. [2008] reviewed 50 RCTs and 3 pooled analyses, which they considered of good methodological quality. They concluded that still more clinical studies are needed to decide which of the drugs should be used as first-, second-, or third-line treatment. Reviewing information from more than 12,000 references, Chapple et al. [2008], based their conclusions (“antimuscarinics are efficacious, safe, and well tolerated treatments”) on 73 RCTs selected for their meta-analysis. It was recommended that since the profiles of each drug (see below) and dosage differ, these factors should be considered in making treatment choices.

The durability of the effects of antimuscarinics is not known and the relapse rate of symptoms after discontinuation of treatment has not been systematically studies. In 173 women with OAB symptoms for >6 months, Lee et al. [2011a] studied in a prospective, randomized, open-label, trial what happened 3 months after the patients had been successfully treated for 1, 3, or 6-months. The relapse rate was 62%, and the request for treatment was 65 %, indirectly suggesting an efficacy of treatment. None of the antimuscarinic drugs in common clinical use (darifenacin, fesoterodine, mirabegron, oxybutynin, propiverine, solifenacin, tolterodine or trospium) is ideal as...
a first-line treatment for all OAB/DO patients. Optimal treatment should be individualized, implying that the patient’s comorbidities and concomitant medications, and the pharmacological profiles of the different drugs, should be taken into consideration [Chapple et al., 2008].

To compare the effects of different antimuscarinic drugs for OAB symptoms, Madhuvrata et al. [2012] analysed 86 trials, 70 with parallel and 16 with crossover designs (31,249 adults). They concluded that when the prescribing choice is between oral immediate release oxybutynin or tolterodine, tolterodine might be preferred for reduced risk of dry mouth. ER preparations of oxybutynin or tolterodine might be preferred to immediate release preparations because there is less risk of dry mouth. Comparing solifenacin and immediate release tolterodine, solifenacin might be preferred for better efficacy and less risk of dry mouth. Fesoterodine might be preferred over ER tolterodine for superior efficacy, but has higher risk of withdrawal due to adverse events and higher risk of dry mouth.

Several studies have documented that the persistence with prescribed antimuscarinic therapy for overactive bladder is low [Kelleher et al., 2005; Basra et al., 2008; Sears et al., 2010; Wagg et al., 2012]. The most common causes seem to be lack of efficacy and adverse effects. However, there is some evidence suggesting that the tolerability of the different antimuscarinics may differ. Wagg et al. [2012] analysed prescription data for patients receiving antimuscarinics for treatment of the OAB syndrome over a 12-month period. At 12 months, they found that the proportions of patients still on their original treatment were: solifenacin 35%, tolterodine ER 28%, propiverine 27%, oxybutynin ER 26%, trospium 26%, tolterodine IR 24%, oxybutynin IR 22%, darifenacin 17%, and flavoxate 14%. The longest mean persistence was reported for solifenacin (187 days versus 77 – 157 days for the other treatments). Similar trends in other healthcare systems have been reported [Mauseth et al., 2013; Kalder et al. 2014]. Gomes et al. [2012] compared the persistence of oxybutynin or tolterodine therapy among older patients newly prescribed one of these drugs. This was a retrospective cohort study of Ontarians aged 66 years and older. Persistence with treatment was defined on the basis of refills for the drug within a grace period equal to 50% of the prescription duration. The authors identified 31,996 patients newly treated with oxybutynin and 24,855 newly treated with tolterodine. After 2 years of follow-up, persistence on oxybutynin (9.4%) was significantly lower than that on tolterodine (13.6%, p < 0.0001). The median time to discontinuation of oxybutynin and tolterodine was 68 and 128 days, respectively. Kessler et al. [2011] analysed 69 trials enrolling 26’229 patients with OAB with the aim was to compare adverse events of antimuscarinics using a network meta-analytic approach that overcomes shortcomings of conventional analyses. They found similar overall adverse event profiles for darifenacin, fesoterodine, transdermal oxybutynin, propiverine, solifenacin, tolterodine, and trosispium chloride, but not for oxybutynin orally administered when currently used starting dosages were compared. They concluded that most currently used antimuscarinics seem to be equivalent first choice drugs to start the treatment of OAB, except for oral oxybutynin dosages of ≥ 10 mg/day, which may have more unfavorable adverse event profiles. Another systematic review concluded that persistence rates regardless of antimuscarinic was generally poor, with median rates 12-39.4% at 12 months and 6-12% at 24 months [Veenboer and Bosch, 2014]. Risk factors for discontinuation included younger age group, use of IR formulations and oxybutynin.

Even if the use of antimuscarinics is associated with many adverse effects, they are generally considered to be ‘safe’ drugs. However, among the more serious concerns related to their use is the risk of cardiac adverse effects, particularly QT prolongation and induction of polymorphic ventricular tachycardia (torsade de pointes), and increases in heart rate (HR) [Andersson and Olshansky, 2007; Andersson et al., 2011].

QT prolongation and its consequences are not related to blockade of muscarinic receptors, but rather linked to inhibition of the hERG potassium channel in the heart.

However, the experiences with terodiline, an antimuscarinic drug that caused torsade de pointes in patients [Connolly et al., 1991; Stewart et al., 1992], have placed the whole drug class under scrutiny.

The parasympathetic actions on the heart (Figure 10) oppose the excitatory actions of the sympathetic nervous system, and slows the heart rate (Figure 11). An elevated resting HR has been linked to overall increased morbidity and mortality, particularly in patients with cardiovascular diseases. The prevalence of CV comorbidities was found to be significantly higher in patients with than without OAB [Andersson et al., 2010]. Since mean changes in HR reported in population studies might not be applicable to an individual patient, and particularly in patients at risk of cardiac disease, even moderate increases in HR might be harmful. The potential of the different antimuscarinic agents to increase HR and/or prolong the QT time has not been extensively explored for all agents in clinical use. Differences between drugs cannot be excluded, but risk assessments based on available evidence are not possible.

Antimuscarinics are recommended in treating OAB when lifestyle interventions have failed. However, many guidelines would recommend when one antimuscarinic fails due to lack of efficacy or poor tolerability that a second and even third should be tried. A recent retrospective medicine and pharmacy claims analysis in the US linked to a one-time patient survey of members with OAB-wet was recently reported with the specific aim of assessing antimuscarinic treatment patterns and outcomes [Chancellor et al., 2016]. A total of 620 patients were finally included after ex-
clusions. Patients cycled through 1-6 unique antimuscarinics. In general adherence to the medication was poor and 35% of the population used ≥ 2 antimuscarinics. Moreover, UI episodes and burden was fairly-consistent despite antimuscarinic cycling and whether patients continued or discontinued their medication. Discontinuation rates were high being 71% of the whole population at study end. Approximately 89% of patients continued to be bothered by their bladder symptoms and requested additional help, whether or not they remained on antimuscarinics. The study suggests that antimuscarinic cycling does not have a positive impact on patients in terms of UI. As a result, alternative therapies should be sought for patients who have failed 1-2 antimuscarinics. It seems logical that if there is inadequate efficacy with 1 antimuscarinic that the maximum dose should be trialled in those with a flexible dosing option especially if the lower dose had an acceptable adverse event profile.

In those where tolerability is an issue switching to an alternative muscarinic is also reasonable. However, thereafter treatment should be escalated to include non-antimuscarinic options.

The use of antimuscarinics to treat the storage component of lower tract symptoms in combination with other classes of drugs is increasing. Furthermore, the evidence base to support this is also expanding. Details of the use of antimuscarinics in combination with β3-AR agonist agents to treat refractory OAB, in combination with alpha blockers and 5 alpha reductase inhibitors to combat lower urinary tract symptoms attributable to benign prostatic enlargement are covered in later sections of this chapter (see section on Combinations).

2. β-ADRENOCEPTOR AGONISTS

In isolated human bladder, non-subtype selective β-AR agonists like isoprenaline have a pronounced inhibitory effect, and administration of such drugs can increase bladder capacity in man [Andersson, 1993]. However, the β-ARs of the human bladder were shown to have functional characteristics typical of neither β1-, nor β2- ARs, since they could be blocked by propranolol, but not by practolol or metoprolol (β1) or butoxamine (β2) [Nergard et al., 1977; Larsen, 1979].

On the other hand, early receptor binding studies using subtype selective ligands, suggested that the β-ARs of the human detrusor are primarily of β2 subtype [Andersson, 1993], and favourable effects on DO were reported in open studies with selective β2-AR agonists such as terbutaline [Lindholm and Lose, 1986]. In a double-blind investigation clenbuterol 0.01 mg 3 times daily was shown to have a good therapeutic effect in 15 of 20 women with DO [Gruneberger, 1984]. Other investigators, however, have not been able to show that non-subtype selective β-ARs ago-
Figure 10: Cardiac control via the autonomic nervous system. Acetylcholine, released from parasympathetic nerve terminals, activate muscarinic receptors that mediate decrease in heart rate, decrease in force of contraction, and decrease in conduction velocity.

Figure 11: Autonomic receptors controlling heart rate. Acetylcholine, released from parasympathetic nerve terminals, activate muscarinic $M_2$ receptors that mediate a decrease in heart rate. Inhibition of these receptors by antimuscarinics may increase heart rate.
Figure 12: During bladder filling, there is normally no parasympathetic nervous outflow to the bladder and no release of acetylcholine (ACh). The sympathetic nervous system is active and releases noradrenaline (NA) that via β3 adrenoceptors stimulates adenyl cyclase (AC) and generation of cyclic AMP (cAMP) which mediates relaxation of the bladder. In addition, β3-adrenoceptor stimulation activate K+ channels, stimulating outflow of K+, which causes hyperpolarisation and inhibition of Ca2+ inflow.

Figure 13: During voiding, the parasympathetic system is activated, releasing acetylcholine (ACh) which causes bladder contraction, directly via muscarinic M3 receptor stimulation, and indirectly by inhibition of adenyl cyclase (AC) via stimulation of muscarinic M2 receptors. The sympathetic nerve activity is turned off. In vivo exogenous stimulation of the β3-adrenoceptors by β3-adrenoceptor agonists is not sufficient to inhibit the muscarinic receptor mediated activation, which implies that the voiding contraction is not compromised.
The generally accepted mechanism by which \( \beta \)-ARs induce detrusor relaxation in most species, is activation of adenyl cyclase with the subsequent formation of cAMP (Figures 12 and 13). However, there is evidence suggesting that in the bladder K+ channels, particularly BKCa channels, may be more important in \( \beta \)-AR mediated relaxation than cAMP [Hudman et al., 2000; Frazier et al., 2005; Uchida et al., 2005; Frazier et al., 2008]. \( \beta_3 \)-AR agonists have generally been considered to relieve OAB symptoms by relaxing detrusor muscle, inhibiting spontaneous contractile activity in the detrusor \((in\ vitrō:\ microcontractions;\ in\ vīvō:\ non-voiding\ contractions)\), and reducing bladder afferent activity (Figure 14) [Biers et al., 2006; Takasu et al., 2007; Aizawa et al., 2012; Gillespie et al., 2012; Hatanaka et al., 2013; Igawa and Michel, 2013]. However, Gillespie and colleagues have questioned the accepted view on the mode and site of action of \( \beta_3 \)-AR agonists [Eastham and Gillespie, 2013; Gillespie et al., 2015a; 2015b; Granato et al., 2015], and suggested that effects on neither spontaneous microcontractions, nor on non-voiding contractions in e.g., obstructed rats, can fully explain the effects of mirabegron. Assuming that acetylcholine (ACh) release from cholinergic terminals during bladder filling contributes to OAB symptoms, the finding that activation of pre-junctional \( \beta_3 \)-ARs may down-regulate ACh release resulting in an inhibitory control of parasympathetic activity, may be of importance [Rouget et al., 2014; D’Agostino et al., 2015].

Since \( \beta \)-ARs are present in the urothelium, their possible role in bladder relaxation has been investigated [Murakami et al., 2007; Otsuka et al., 2008]. Murakami et al. [2007] found that the relaxation responses of the detrusor were not influenced by the urothelium. However, isoprenaline was more potent at inhibiting carbachol contractions in the presence of the urothelium than in its absence. It was suggested that this might reflect the release of an inhibitory factor from the urothelium. Further support for this hypothesis was given by Otsuka et al. [2008]. However, to what extent a urothelial signaling pathway contributes \( in\ vitrō\) and \( in\ vīvō\) to the relaxant effects of \( \beta \)-AR agonists in general, and \( \beta_3 \)-AR agonists specifically, remains to be elucidated.

The in vivo effects of \( \beta_3 \)-AR agonists on bladder function have been studied in several animal models. It has been shown that compared with other agents (including antimuscarinics), \( \beta_3 \)-AR agonists increase bladder capacity with no change in micturition pressure and the residual volume [Fujimura et al., 1999; Woods et al., 2001; Takeda et al., 2002; Kaidoh et al., 2002; Igawa et al., 2010]. For example, Hicks et al. [2007] studied the effects of the selective \( \beta_3 \)-AR agonist, GW427353, in the anesthetized dog and found that the drug evoked an increase in bladder capacity under conditions of acid evoked bladder hyperactivity, without affecting voiding.

A number of \( \beta_3 \)-AR selective agonists are currently being evaluated as potential treatment for OAB (Fig-
DRUGS USED FOR TREATMENT OF OVERACTIVE BLADDER SYMPTOMS/DETRUSOR OVERACTIVITY

Figure 15: Stimulation by highly selective β3-adrenoceptor agonists like mirabegron may inhibit bladder afferent activity in both Aδ- and C-fibres. From Aizawa et al., Eur Urol. 2012 Dec;62(6):1165-73

ure 15) but so far the only drug approved for treatment in humans is mirabegron. The effects of mirabegron in men and women with OAB have been summarised in several recent reviews [Chapple et al., 2014; Cui et al., 2014; Rossanese et al., 2015], and also in men with both voiding and OAB symptoms [Suarez et al. 2013; Otsuki et al., 2013].

2.1. Mirabegron

Takusagawa et al. [2012] found that mirabegron was rapidly absorbed after oral administration. It circulates in the plasma as the unchanged form, its glucuronic acid conjugates and other metabolites. Of the administered dose, 55% is excreted in urine, mainly as the unchanged form, and 34% is recovered in feces, almost entirely as the unchanged form. Mirabegron is highly lipophilic and is metabolised in the liver via multiple pathways, mainly by cytochrome P450 3A4 and 2D6 (CYP2D6) [van Gelderen et al., 2009]. In a Phase I pharmacokinetic study, sixteen healthy volunteers, phenotyped as either poor or extensive metabolisers of CYP2D6 were enrolled. They received a 160-mg single oral dose after overnight fasting. Poor metabolisers excreted a slightly higher urinary fraction of mirabegron (15.4±4.2%) than extensive metabolisers (11.7±3.0%). T_max in both extensive and poor metabolizers was about 2 hours and the terminal elimination half-life (t1/2) approximately 23-25 hours.

Chapple et al. [2008] reported the results of a phase IIA trial of mirabegron in patients with OAB. The Blossom trial, conducted in several European countries, was a proof of concept study. It enrolled 314 patients with OAB symptoms - 262 patients were randomly assigned to 4 groups: placebo, mirabegron 100 mg bid, mirabegron 150 mg bid, and tolterodine 4 mg qd for a 4-week treatment period. The primary endpoint was efficacy, and the primary efficacy variable was the change in the mean number of micturitions per 24 hours as recorded on a frequency/volume chart. In both mirabegron groups significant improvements in the mean number of micturitions per 24 hours were found compared with the placebo group (−2.19 and −2.21 vs. −1.18, respectively). Mean volume voided was dose-dependently increased in the mirabegron groups, and the change reach significance in the mirabegron 150 mg group. Urgency episodes per 24 hours decreased significantly in both mirabegron groups compared with the placebo group. No severe adverse events were reported and treatment was generally well tolerated. A small, mean increase in pulse rate with mirabegron 150 mg (5 beats per minute) was demonstrated, but this was not associated with a clinically significant increase in adverse events such as tachycardia and palpitations. This successful phase IIA trial was followed by a phase IIB trial in OAB patients carried out in Europe [Chapple et al., 2010]. This trial was a dose-ranging study of once-daily mirabegron (an extended release formula of mirabegron) with multiple arms (placebo, mirabegron 25 mg, 100 mg, 150 mg, and 200 mg qd, for a 12-week treatment period), and the primary endpoint was to evaluate the dose-response relationship on efficacy.

The mean number of micturitions per 24 hours decreased dose-dependently, and the decreases were statistically significant with mirabegron 50 mg, 150, and 200 mg compared with placebo. The mean volume voided per micturition increased dose-dependently, and the increases were significant with mirabegron 50 mg and more. Adverse events were experienced by 45.2% of the patients - the incidence of adverse events was similar among all treatment groups (placebo 43.2% vs. mirabegron 43.8-47.9%). The overall discontinuation rate owing to adverse events was 3.2% (placebo 3.0% vs. mirabegron 2.4-5.3%). The most commonly reported adverse events considered treatment-related was gastrointestinal
disorders, including constipation, dry mouth, dyspepsia, and nausea. There was no patient-reported acute retention. No significant difference in ECG parameters between the groups was demonstrated. However, a small but significant increase in mean pulse rate was observed after mirabegron 100 mg and 200 mg (1.6 and 4.1 beats per minute, respectively), although this was not in association with an increase in cardiovascular adverse events.

Nitti et al. [2011] reported on a phase III multicentre, randomized, double-blind, parallel-group, placebo-controlled trial of mirabegron in North America. They enrolled 1328 patients ≥18 years with OAB symptoms for ≥3 months. Patients who completed a 2-week, single-blind, placebo-run-in and had ≥8 micturitions/24 h and ≥3 urgency episodes/72 h (with or without incontinence) during a 3-day micturition diary period, were randomized to receive placebo, or mirabegron 50 or 100 mg once daily for 12 weeks. Co-primary endpoints were change from baseline to final visit (study end) in the mean number of incontinence episodes/24 h and micturitions/24 h. Efficacy was assessed according to patient micturition diaries and safety assessments included adverse event (AE) reporting. Patients were randomized and received study drug (placebo: n=453; mirabegron 50 mg: n=442; mirabegron 100 mg: n=433). Mean age was 60.1 years, 74.3% were female, 29.7% had urgency incontinence, 38.1% had mixed stress/urgency incontinence with urgency predominant and 32.2% had frequency without incontinence. At the final visit, mirabegron 50 and 100 mg showed statistically significant improvements in the co-primary efficacy endpoints and mean volume voided/micturition compared with placebo. Statistically significant benefits were achieved at the first-measured time point of Week 4. The incidence of AEs was similar across the placebo and mirabegron 50 and 100 mg groups (50.1, 51.6 and 46.9%, respectively). The most common (≥3%) AEs in any treatment group were hypertension (6.6, 6.1 and 4.9%, respectively), urinary tract infection (1.8, 2.7 and 3.7%), headache (2.0, 3.2 and 3.0%) and nasopharyngitis (2.9, 3.4 and 2.5%).

Khullar et al. [2011] performed a similarly designed study in Europe and Australia, enrolling 1978 patients, which included a fourth arm in which tolterodine SR 4 mg was used as a comparator. Like the American study, Khullar et al. [2011] found that mirabegron caused a statistically significant improvement from baseline compared with placebo in the number of urgency incontinence episodes and number of micturitions per 24 hours. Mirabegron 50 and 100 mg was numerically superior to tolterodine in these two key OAB symptoms, but the study was not powered for further analysis. Mirabegron 50 and 100 mg was well tolerated, no differences being found between the placebo arm and the two mirabegron arms. In particular the incidence of hypertension or UTI were identical. In contrast with tolterodine, no increased dry mouth incidence was observed with mirabegron.

Otsuki et al. [2013] reported on the efficacy and safety of mirabegron in a predominantly male population of OAB patients. In this prospective, non-randomized, controlled study, patients with at least one episode of urgency per week and scoring at least 2 for urinary urgency in the Overactive Bladder Symptom Score (OABSS) were enrolled. Fifty-two patients (36 men) with newly diagnosed OAB received mirabegron 50 mg once daily, and 45 (36 men) with OAB refractory to antimuscarinics switched to mirabegron, and another 27 patients (18 men) with newly diagnosed OAB received antimuscarinics and served as controls. Patients on a stable α1-AR blocker dose for treatment of LUTS were allowed in the study, but those with a PVR greater than 100 ml were excluded. Mirabegron achieved significant improvements in all efficacy outcomes (OABSS: Overactive Bladder Symptom Score and IPSS: International Prostate Symptom Score). In patients with newly diagnosed OAB, improvements were not significantly different to those achieved by antimuscarinics. Mirabegron was well tolerated and did not significantly change PVRs. However, these encouraging results for mirabegron in treating male OAB should be interpreted with caution in view of the limitations of the study, which included small patient numbers, lack of randomization, and a suboptimal treatment period for the indication.

In a study by Chapple et al. [2013] assessing the 12-months safety and efficacy of mirabegron, tolterodine was used as active control. There were no significant differences in efficacy between drugs. However, whether mirabegron has similar efficacy to antimuscarinics awaits direct comparison studies. Mirabegron seems to have definite advantages over the antimuscarinics with respect to adverse events. Dry mouth and constipation are essentially non-existent in comparison to placebo [Chapple et al., 2013; 2014; Cui et al., 2014; Rossanese et al., 2015].

Mirabegron 50 mg and solifenacin 5 mg were recently compared in OAB patients dissatisfied with previous antimuscarinic treatment. The Beyond study [Batista et al., 2015] was a randomized, double-blind, phase IIIb, noninferiority study that enrolled male and female patients aged ≥18 years old, with symptoms of OAB for ≥3 months, who were dissatisfied with their previous antimuscarinic drug due to lack of efficacy.

### Assessment

Mirabegron has a documented beneficial effect in the treatment of OAB/DO (Table 2), and seems to have an acceptable side effect profile.

#### 2.2. New Developments

Thiagamoorthy et al. [2015] reviewed “novel and putative” β3-AR agonists for management of OAB, including CL-316243, TRK-380, AJ-9677, BRL37344. Another agent, vibegron, was claimed to have an overall superior preclinical profile compared to MK-0634, which was discontinued due to unacceptable
structure-based toxicity in preclinical species [Edmonson et al., 2016]. Even if these agents have been reported as being in development, no clinical data have been published, and it may be questioned whether any of them can be regarded as “novel and putative”. Phase II and III randomised, double blind, placebo controlled studies of ritodirbeegron in patients with OAB has been initiated and completed, but the results have not been published and it seems that that the primary efficacy endpoint of the studies was not met. No new clinical trials with ritodirbeegron seem to have been initiated.

Efficacy and safety of solabegron (GW427353) have been reported in a phase II multicenter, randomized, proof-of-concept trial in 258 women with wet OAB. The drug produced a statistically significant difference in percent change from baseline to week 8 in incontinence episodes over 24 h (primary outcome) when compared with placebo (p=0.025) and was well tolerated [Ohlstein et al., 2012].

There seems to be a number of β3-AR agonists in the pipeline some of which are under development. However, it is uncertain which, if any, will come to market and be available for the management of OAB.

3. DRUGS ACTING ON MEMBRANE CHANNELS

3.1. Calcium Antagonists.

Calcium channels play an important role in the regulation of free intracellular calcium concentrations and thereby contribute to the regulation of smooth muscle tone [Berridge, 2008] Two major groups of calcium channels include the voltage-gated [Caterall et al., 2003] and the store-operated channels [Leung et al., 2008]. While both can contribute to the maintenance of smooth tone in general, store-operated calcium channels apparently contribute only to a limited if any extent to the regulation of bladder smooth muscle tone [Schneider et al., 2004; a; b]. On the other hand, various types of voltage-operated calcium channels have been implicated in the regulation of bladder smooth muscle including Q-type [Frew and Lundy, 1995] and L-type channels [Wuest et al., 2007]. The latter appears to be of particular importance as inhibitors of L-type channels have repeatedly been shown to inhibit bladder contraction in vitro with tissue from multiple mammalian species, including humans [Frazier et al., 2008]. However, the relative importance of L-type channels may be somewhat less in humans than in other mammalian species [Wuest et al., 2007]. In confirmation of the role of L-type calcium channels, it has been shown that knock-out mice lacking a crucial subunit of this channel exhibit a markedly impaired bladder contractility [Wegener et al., 2004].

While these in vitro data suggest a possible role for calcium channel inhibitors, particularly those of L-type channels, in the treatment of DO and incontinence, only limited clinical studies are available in this regard. One urodynamic study compared the effects of intravesical installation of the calcium channel inhibitor verapamil, the muscarinic receptor antagonists oxybutynin and trospium and placebo to patients with urgency or urgency incontinence. While the two muscarinic receptor antagonists significantly increased bladder capacity, verapamil treatment was not associated with relevant changes in bladder function [Fröhlich et al., 1998]. In a clinical study of limited size the calcium channel inhibitor nimodipine (30 mg per day) did not significantly improve the number of incontinence episodes as compared to placebo [Naglie et al., 2002]. Larger studies with clinical endpoints related to effects of calcium channel inhibitors have not been reported in continent patients (based upon a Medline search using the MeSH terms “calcium channel blockers” and “urinary incontinence”). Moreover, it should be noted that despite a long-standing and wide-spread use of calcium channel inhibitors in the treatment of cardiovascular disease, there are no major reports on impaired bladder contractility as a side effect of such treatment. The reasons for the discrepancy between the promising in vitro and the lack of clinical data are not fully clear, but it may relate to pharmacokinetic properties of the currently used drugs which may insufficiently either reach or penetrate bladder tissue in therapeutically administered doses.

At present, there is no clinical evidence to support a possible use of calcium channel inhibitors in the treatment of bladder dysfunction (Table 2). No new information has been added since the assessment in 2008 [Andersson et al., 2009; 2013].

3.2. Potassium Channel Openers

In a similar fashion to calcium channels, potassium channels also contribute to the membrane potential of smooth muscle cells and hence to the regulation of smooth muscle tone. Numerous types of potassium channels exist [Gutman et al., 2003; Petkov et al., 2012; 2014]. With regard to bladder function, ATP-dependent (KATP) and big calcium-activated (BKCa) channels have been studied most intensively. The BKCa channels also appear to be important physiologically as their activation can cause hyperpolarization of bladder smooth muscle cells and by this mechanism they can contribute to the relaxation of bladder smooth muscle by, e.g., β-adrenoceptor agonists [Frazier et al., 2008]. Openers of both KATP [Howe et al., 1995; Hu et al., 1997; Martin et al., 1997] and BKCa channels [Hu et al., 1997; Sheldon et al., 1997; Petkov et al., 2012; 2014] have been shown to induce bladder smooth muscle relaxation in various mammalian species, but the density of some types of potassium channels may differ markedly between species. Some potassium channel openers have also been shown to suppress non-voiding detrusor contractions in vivo in animal models of DO [Howe et al., 1995; Martin et al., 1997; Tanaka et al., 2003] and this also includes activators of the KCNQ type of potassium channels [Streng et al., 2004]. Although potassium
channel openers are believed to mainly act directly on smooth muscle cells [Gopalakrishnan and Shieh, 2004; Petkov et al., 2012; 2014], they may also at least in part affect bladder function by modulating the activity of afferent neurones [Tanaka et al., 2003]. While the above data demonstrate the potential of potassium channel openers to inhibit non-voiding detrusor contractions, these channels are expressed not only in bladder, but also e.g. in vascular smooth muscle. Therefore, potassium channel openers may also affect cardiovascular function, and in effective doses may considerably lower blood pressure [Howe et al., 1995; Shieh et al., 2007]. While some compounds of this class have a certain degree of selectivity for the bladder as compared to the cardiovascular system, it remains unclear whether the degree of selectivity offers a sufficiently large therapeutic window for clinical use. This consideration has led to a considerable hesitancy to study potassium channel openers in OAB patients. Nevertheless, one randomized, placebo-controlled clinical study on the K\textsubscript{ATP} opener ZD0947 has been reported [Chapple et al., 2006]. While ZD0947 at the chosen dose did not lower blood pressure or cause adverse events typical for a vaso-dilating drug, it also failed to achieve superiority relative to placebo for the treatment of OAB symptoms. Therefore, despite promising preclinical efficacy data, potassium channel openers at present are not a therapeutic option and may never become one due to a lack of selectivity for bladder over cardiovascular tissues (Table 2).

Another way to use potassium channels to normalize bladder function was suggested by Christ et al. [2001] in a rat model of detrusor hyperactivity. They injected "naked" hSlo/pcDNA3 (maxiK channel) into the bladder and found a significant amelioration of the hyperactivity. As to whether this principle can be therapeutically useful in man is currently under investigation.

### 4. \(\alpha\)-ADRENOCEPTOR (AR) ANTAGONISTS

It is well documented that \(\alpha\)-AR antagonists can ameliorate lower urinary tract symptoms in men, and currently used \(\alpha\)-AR antagonists are considered effective for treatment of both storage and voiding symptoms in men with LUTS associated with or suggestive of BPH [Andersson, 2002; McVary et al., 2011; Oelke et al., 2011; Lepor et al., 2012; Fonseca and Martins da Silva., 2015]. However, in a study where tamsulosin was given alone, or together with tolterodine, to patients with male LUTS and OAB symptoms, monotherapy with the drug was not effective [Kaplan et al., 2006]. In an RCT from Korea, doxazosin monotherapy resulted in only minimal effects in IPSS storage subscore, urgency episodes and no improvement in the patient perception of bladder condition (PPBC) [Lee et al., 2011b]. Thus, there is no convincing evidence that \(\alpha\)-AR antagonists, given as monotherapy, are effective in patients with storage symptoms only.

A pivotal question is if better efficacy and/or tolerability can be obtained by highly subtype selective drugs than with the commonly used alternatives. \(\alpha\)-ARs include three receptor subtypes, \(\alpha\textsubscript{1A}, \alpha\textsubscript{1B},\) and \(\alpha\textsubscript{1D},\) that are structurally and pharmacologically distinct and have different tissue distributions [Andersson and Gratze, 2007]. \(\alpha\textsubscript{1A}-ARs\) are the predominant subtype in the human prostate, where they mediate smooth muscle contraction. A fourth subtype, \(\alpha\textsubscript{1L},\) also present in human prostate, is derived from the same gene as \(\alpha\textsubscript{1A},\) but \(\alpha\textsubscript{1L}\)- and \(\alpha\textsubscript{1A}\)-receptors have different pharmacologic properties and bind some \(\alpha\)-AR antagonists with different affinities. The precise structural relationship between the two subtypes remains to be elucidated.

Selectivity for \(\alpha\textsubscript{1D}-AR\) has been considered disadvantageous from a cardiovascular point of view [Schwinn and Roehrborn, 2008]. Kojima et al. [2008] studied the expression of \(\alpha\textsubscript{1A}-AR\) in the transitional zone of prostates from 55 patients with BPH, comparing patients treated with tamsulosin presumed to block \(\alpha\textsubscript{1A}-ARs\) and naftopidil presumed to block \(\alpha\textsubscript{1D}-ARs.\) However, the selectivity of naftopidil for \(\alpha\textsubscript{1D}\) vs \(\alpha\textsubscript{1A}\)-ARs is modest [Take et al., 1998] and its use as a tool to separate between \(\alpha\textsubscript{1A}\)-AR subtypes is questionable. Nevertheless, the tamsulosin and naftopidil groups were classified as \(\alpha\textsubscript{1A}\)-AR dominant (22 and 12 patients) and \(\alpha\textsubscript{1D}\)-AR dominant (11 and 16, respectively). The efficacy of tamsulosin and naftopidil differed depending on the dominant expression of the \(\alpha\textsubscript{1A}-AR\) subtype in the prostate. Tamsulosin was more effective in patients with dominant expression of the \(\alpha\textsubscript{1A}-AR\) subtype, whereas naftopidil was more effective in those with dominant expression of the \(\alpha\textsubscript{1D}-AR\) subtype. In another study, the same group assessed whether there was a direct correlation between the prostatic expression of \(\alpha\textsubscript{1A}-AR\) subtype mRNA and severity of LUTS or bladder outlet obstruction [Kojima et al., 2010]. They found no direct correlation between the expression of \(\alpha\textsubscript{1A}-AR\) subtype mRNA in the prostate and severity of LUTS or BOO, although there was a significant regression of this expression with patient age. Kojima et al. [2010] concluded that the expression level of \(\alpha\textsubscript{1A}-AR\) subtype mRNA in the prostate could be a predictor of the efficacy of subtype selective \(\alpha\)-AR antagonists in patients with BPH, and suggested that genetic differences were responsible for the diverse responses to the drugs.

Silodosin (KD-3213), which has a high selectivity for \(\alpha\textsubscript{1A}-ARs\) [Tatemichi et al., 2006a; b; Lepor and Hill, 2010; Yoshida et al., 2011], had clinically good effects on both voiding and storage symptoms in men with BPH [Kawabe et al., 2005; Yoshida et al., 2007; Marks et al., 2009a;b; Chapple et al., 2010; Morganroth et al., 2010; Yoshida et al., 2011; Novara et al., 2014; Montorsi et al., 2016]. Chapple et al. [2010] conducted a multicenter double-blind,
placebo- and active-controlled parallel group study comparing silodosin, tamsulosin, and placebo. A total of 1228 men ≥50 yr of age with an International Prostate Symptom Score (IPSS) ≥13 and a urine maximum flow rate (Qmax) >4 and ≤15 ml/s were selected at 72 sites in 11 European countries. The patients were entered into a 2-wk wash-out and a 4-wk placebo run-in period. A total of 955 patients were randomized (2:2:1) to silodosin 8 mg (n=381), tamsulosin 0.4 mg (n=384), or placebo (n=190) once daily for 12 wk. Its overall efficacy was not inferior to tamsulosin. Only silodosin showed a significant effect on nocturia over placebo. There was no significant difference between the two α1-AR antagonists and the placebo in terms of Qmax. There was also no difference between the two α1-AR antagonists for the QoL parameter, whereas both were better than the placebo. Active treatments were well tolerated, and discontinuation rates due to adverse events were low in all groups (2.1%, 1.0%, and 1.6% with silodosin, tamsulosin, and placebo, respectively). The most frequent adverse event with silodosin was a reduced or absent ejaculation during orgasm (14%), a reversible effect as a consequence of the potent and selective α1A-AR antagonism of the drug. The incidence was higher than that observed with tamsulosin (2%); however, only 1.3% of silodosin-treated patients discontinued treatment due to this adverse event. Silodosin treatment improved DO and obstruction grade by decreasing detrusor opening pressure, detrusor pressure at Qmax, bladder outlet obstruction index and Schafer’s obstruction class significantly [Yamanishi et al., 2009]. In a different open, nonblinded prospective study silodosin 8 mg lead to a significant increase in bladder capacity at first desire to void with no significant change in maximum cystometric capacity. In the voiding phase mean detrusor pressure at maximum flow significantly decreased, mean bladder outlet obstruction index decreased significantly and obstruction grade as assessed by the Schaefer nomogram improved significantly [Matsukawa et al., 2009].

It thus seems that selective blockade of α1A-ARs is a clinically effective approach (Table 2), and silodosin is an effective and well-tolerated treatment for the relief of both voiding and storage symptoms in male patients with LUTS, even if treatment is associated with a high incidence of ejaculatory dysfunction.

Interest has also been focussed on the α1-ARs (α1D), specifically in the bladder [Schwinn et al., 2004; Schwinn and Roehrborn, 2008], assuming that these receptors were responsible for storage symptoms. However, the inter-relationship between the α1D-ARs in the human detrusor smooth muscle and the pathophysiology of LUTS is unclear. Naftopidil was shown to significantly improve the OAB symptom score [Sakai et al., 2011] and urgency episodes [Yokoyama et al., 2009]. Ikemoto et al. [2003] gave tamsulosin and naftopidil to 96 patients with BPH for 8 weeks in a crossover study. Whereas naftopidil monotherapy decreased the I-PSS for storage symptoms, tamsulosin monotherapy decreased the I-PSS for voiding symptoms. However, this difference (which was suggested to depend on differences in affinity for α1A-AR subtypes between the drugs) could not be reproduced in a randomized head to head comparison between the drugs [Gotoh et al., 2005]. Based on available evidence, it therefore cannot be concluded that the α1D-ARs on the detrusor smooth muscle are the main therapeutic target. However, α1D-ARs may have effects on different locations in the bladder beside the detrusor smooth muscle: the detrusor vasculature, the urothelium, and the afferent and efferent nerve terminals and intramural ganglia [Andersson and Gratze, 2007]. The importance and functional role of this observation remain to be established.

In females, treatment with OAB, α1-AR antagonists seem to be ineffective. In an RCT, comprising 364 women with OAB, no effect of tamsulosin vs placebo could be demonstrated [Robinson et al., 2007]. On the other hand, voiding symptoms in women with functional outflow obstruction, or LUTS, were treated (with modest success) with an α1-AR antagonist [Kessler et al., 2006, Low et al., 2008]. It should be remembered that in women, these drugs may produce stress incontinence [Dwyer and Teele, 1992].

In patients with neurogenic DO, treatment with α1-AR antagonists was moderately successful [Abrams et al., 2003].

5. PHOSPHODIESTERASE (PDE) INHIBITORS

Drugs stimulating the generation of cAMP are known to relax smooth muscles, including the detrusor [Andersson, 1999; Andersson and Wein, 2004]. It is also well established that drugs acting through the NO/cGMP system can relax the smooth muscle of the bladder outflow region [Andersson and Arner, 2004]. Use of PDE inhibitors to enhance the presumed cAMP- and cGMP-mediated relaxation of LUT smooth muscles (detrusor prostate, urethra) should then be a logical approach (Andersson et al., 1997; 2007; 2011). There are presently 11 families of PDEs, some of which preferentially hydrolyse either cAMP or cGMP [Uckert et al., 2006].

As a basis for PDE inhibitor treatment of LUTS, Uckert et al. [2006] investigated human bladder tissue, revealing messenger RNA for PDEs 1A, 1B, 2A, 4A, 4B, 5A, 7A, 8A, and 9A; most of these PDEs preferably inhibit the breakdown of cAMP. In vitro, human detrusor muscle responded poorly to sodium nitroprusside, and to agents acting via the cGMP system [Truss et al., 2000]. However, significant relaxation of human detrusor muscle, paralleled by increases in cyclic nucleotide levels, was induced by papaverine, vinpocetine (a low affinity inhibitor of PDE 1), and forskolin (stimulating the generation of cAMP), suggest-
ing that the cAMP pathway and PDE 1 may be important in regulation of detrusor smooth muscle tone [Truss et al., 2001]. Significant dose-dependent relaxations were also induced by human cAMP analogs [Truss et al., 2001]. With these studies as a background, Truss et al. presented preliminary clinical data with vinpocetine in patients with urgency/urinary incontinence or low compliance bladders, and not responding to standard antimuscarinic therapy (Truss et al., 2000). This initial open pilot study suggested a possible role for vinpocetine in the treatment of OAB. However, the results of a larger RCT in patients with DO showed that vinpocetine only showed statistically significant results for one parameter [Truss et al., 2001]. Studies with other PDE 1 inhibitors than vinpocetine (which may not be an optimal drug for elucidation the principle) do not seem to have been performed.

PDE 4 (which also preferably hydrolyses cAMP) has been implicated in the control of bladder smooth muscle tone. PDE 4 inhibitors reduced the in vitro contractile response of guinea pig [Longhurst et al., 1997] and rat [Kaiho et al., 2008] bladder strips, and also suppressed rhythmic bladder contractions of the isolated guinea pig and rat bladder [Gillespie and Drake, 2004; Nishiguchi et al., 2007]. Xin et al. [2014] found that that selective pharmacological inhibition of PDE4 increases the frequency of Ca2+ sparks and their functionally coupled BK channels, which lead to the attenuation of DSM excitability and contractility and suggested that PDE4 isoforms might be valuable therapeutic targets for the treatment of overactive bladder. However, previous experiences with selective PDE 4 inhibitors showed emesis to be a dose-limiting effect [Giembycz, 2005]. If this side action can be avoided, PDE 4 inhibition seems to be a promising approach.

Oger and co-workers showed that PDE5-inhibitor sildenafil-induced relaxation of human detrusor smooth muscle involved cGMP-, cAMP- and K(+) channel-dependent signalling pathways, with a minor contribution from NO [Oger et al., 2010]. In combination with the alpha-blocker doxazosin, sildenafil reduced adrenergic tone of prostatic and cavernosal smooth muscle and their combination provided a significant benefit when targeting relaxation of both tissues [Oger et al., 2008].

In-vivo, several studies have indicated a role for PDE5-inhibitors in the regulation of micturition function. Systemic vardenafil reduced both nonvoiding contractions and bladder afferent nerve firing in unanesthetized, decerebrated, spinal cord injury rats, indicating potential mechanisms by which PDE5-Is improve storage symptoms in SCI patients [Behr-Roussel et al., 2010]. The effect of vardenafil on OAB-symptoms could be related to a cGMP-dependent RhoA/ROCK signaling inhibition, as shown in spontaneously hypertensive rats (SHR) [Morelli et al., 2009a; Morelli et al., 2009b]. Using the same animal model, bladder hypoxia was significantly reduced by acute vardenafil treatment [Morelli et al., 2009b]. Thus, besides relaxing muscular wall, PDE5 inhibition may positively affect urinary bladder blood perfusion. In the same respect, tadalfil was shown to increase prostate tissue oxygenation in SHR and human vesiculodigestive deferential artery is characterized by a high expression and activity of PDE5, which was inhibited by tadalfil in vitro; these results suggest another possible mechanism through which PDE5i exert beneficial effects on LUT symptoms [Morelli et al., 2011; Cellek et al., 2014].

NO has been demonstrated to be an important inhibitory neurotransmitter in the smooth muscle of the urethra and its relaxant effect is associated with increased levels of cyclic GMP [Andersson and Arner, 2004]. However, few investigations have addressed the cAMP- and cGMP-mediated signal transduction pathways and its key enzymes in the mammalian urethra. Morita et al. examined the effects of isoproterenol, prostaglandin E1 and E2, and SNP on the contractile force and tissue content of cAMP and cGMP in the rabbit urethra [Morita et al., 1994]. They concluded that both cyclic nucleotides can produce relaxation of the urethra. Werkström et al.[2006] characterized the distribution of PDE 5, cGMP and PKG1 in female pig and human urethra, and evaluated the effect of pharmacological inhibition of PDE-5 in isolated smooth muscle preparations. After stimulation with the NO donor, DETA NONO-ate, the cGMP-immunoreactivity (IR) in urethral and vascular smooth muscles increased. There was a wide distribution of cGMP- and vimentin-positive interstitial cells between pig urethral smooth muscle bundles. PDE-5 IR could be demonstrated within the urethral and vascular smooth muscle cells, but also in vascular endothelial cells that expressed cGMP-IR. Nerve-induced relaxations of urethral preparations were enhanced at low concentrations of sildenafil, vardenafil and tadalsafil, whereas there were direct smooth muscle relaxant actions of the PDE-5 inhibitors at high concentrations. Fibbi et al. [2009] confirmed that the highest expression and biological activity of PDE5 was found in bladder. However, a consistent PDE5 expression and activity was also found in prostatic urethra. In contrast, the prostate gland showed the lowest PDE5 abundance and cultures derived from this tissue were less sensitive to vardenafil. Using a different animal model associated with C-fibre afferent activation, it was shown that the NO/cGMP signalling pathway is involved in the regulation of the micturition reflex, with an action that seems more predominant on the sensory rather than on the motor component of the micturition reflex [Caremel et al., 2010].

The observation that patients treated for erectile dysfunction with PDE5 inhibitors had an improvement of their LUTS, has sparked a new interest in using these drugs also for treatment of LUTS and OAB. After the report in an open study that treatment with sildenafil appeared to improve urinary symptom scores in men with ED and LUTS [Sairam et al., 2002], this observation has been confirmed in several well designed and conducted RCTs.
A number of RCTs are available comparing the effect of PDE5 inhibitors alone to placebo and the combination of α-AR antagonists and PDE5 inhibitors vs α-AR antagonists alone [Bechara et al., 2008; Gacci et al., 2011; Kaplan et al., 2007; Ligouri et al., 2009; McVary et al., 2007a; b; Pors et al., 2009; 2011; Roehrborn et al., 2008; Stief et al., 2008; Tammi et al., 2010; Tuncel et al., 2010; see Gacci et al., 2016]. In these studies, different PDE5 inhibitors and different doses were administered. PDE5-inhibitors significantly improve IPSS and IIEF scores, but not Qmax when compared to placebo. According to a meta-analysis by Gacci and co-workers, differences in IPSS score were significantly lower in older and obese patients [Gacci et al., 2011]. The combination of PDE5-inhibitors and α-AR-blockers lead to significant improvements of the IPSS and IIEF score as well as Qmax when compared to the use of α-AR-blockers alone. Dmochowski showed that tadalafil once daily for LUTS had no significant effect on bladder function as measured by detrusor pressure at maximum urinary flow rate or such as maximum detrusor pressure and bladder outlet obstruction index while improving IPSS [Dmochowski et al., 2010b]. PDE5-inhibitors were generally shown to be safe and well tolerated.

The mechanism behind the beneficial effect of the PDE inhibitors on LUTS/OAB and their site(s) of action largely remain to be elucidated. There is in vitro evidence that PDE5 inhibition might relax the smooth muscle of the prostate, bladder, and urethra, dilate the pelvic vasculature (including the microvasculature), and modulate sensory bladder functions [Andersson et al., 2011; Giuliano et al., 2013; Cелек et al., 2014]. Improvement of bladder blood flow to the LUT has been suggested [Cелек et al., 2014], and this has been supported by studies in animals with chronic bladder ischemia [Nomity et al., 2013]. However, Pinggera et al. [2014], using transrectal ultrasonography, compared the effects of tadalafil 5 mg/day and placebo given for 8 weeks to men with moderate to severe LUTS/BPH. They found no differences between the treatments, but did not exclude that changes in blood flow may have occurred which for several reasons could not be detected. Previously, Pinggera et al. [2008], using the same methodology, quite convincingly showed that tamsulosin could increase perfusion to the LUT.

Currently, tadalafil is the only FDA approved PDE-5 inhibitor for treatment of male LUTS even of e.g, sildenafil and vardenafil have been shown to be effective. However, there are several other drugs belonging to the same class that are used for treating erectile dysfunction, including avanafil, udenafil, mirodenafil, gisadenafil [Gacci et al., 2014], and there are no reasons to believe that they should not be effective in relieving male LUTS. To what extent new molecules with ability to inhibit PDE-5 [Sawant et al., 2015] will be developed for future clinical application remains to be seen.

### 6. ANTIDEPRESSANTS

Several antidepressants have been reported to have beneficial effects in patients with DO [Lose et al., 1989; Martin and Schiff, 1984]. However, the use of antidepressants was shown to be an independent risk factor for LUTS suggestive of benign prostatic hyperplasia in a community based population of healthy aging men [Kringle Study] [Kok et al., 2009]. In a prospective trial, and in total, 205 consecutive female (113 patient taking antidepressants for various disorders and 92 healthy controls), Albayrak et al. [2015] found that the prevalence of OAB was significantly higher in antidepressant users (64 %) than in the control group (33 %) (p = 0.003). They suggested that since each SSRI and SNRI has a unique pharmacological profile, this could explain the opposing reports in the literature.

#### 6.1. Imipramine

Imipramine is the only drug that has been widely used clinically to treat this disorder. Imipramine has complex pharmacological effects, including marked systemic antimuscarinic actions [Baldessarini, 1985] and blockade of the reuptake of serotonin and noradrenaline [Maggi et al., 1989], but its mode of action in DO has not been established [Hunsballe and Djurhuus, 2001]. Even if it is generally considered that imipramine is a useful drug in the treatment of DO, no good quality RCTs that can document this have been retrieved. It has been known for a long time that imipramine can have favourable effects in the treatment of nocturnal enuresis in children with a success rate of 10-70 % in controlled trials [Glazener et al., 2003; Hunsballe and Djurhuus, 2001]. It is well established that therapeutic doses of tricyclic antidepressants, including imipramine, may cause serious toxic effects on the cardiovascular system (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine [Bigger et al., 1977; Giardina et al., 1979]. Children seem particularly sensitive to the cardiotoxic action of tricyclic antidepressants [Baldessarini, 1985]. The risks and benefits of imipramine in the treatment of voiding disorders do not seem to have been assessed. Very few studies have been performed during the last decade [Hunsballe and Djurhuus, 2001; Natalin et al., 2009]. No good quality RCTs have documented that the drug is effective in the treatment DO. However, a beneficial effect has been documented in the treatment of nocturnal enuresis.

A prospective (no controls) study the impact of the "three-drug therapy" (antimuscarinic, alpha-blocker and tricyclic antidepressants) on the treatment of refractory detrusor overactivity (DO) showed a significant increase on bladder capacity and decreases on urgency, urge-incontinence and frequency. Objective urodynamic data as well as symptom score improved significantly with triple therapy [Natalin et al., 2009].
Selective serotonin-reuptake-inhibitors (SSRIs) have been tested with regard to their effects on OAB symptoms. Milnacipran hydrochloride, a serotonin-norepinephrine reuptake inhibitor (SNRI), or paroxetine hydrochloride, a selective serotonin reuptake inhibitor, were analysed in a prospective open trial in neurogenic OAB-patients. Milnacipran reduced daytime urinary frequency, improved the quality of life index and increased bladder capacity as shown in urodynamic studies. No such changes were noted in the other categories of the lower urinary tract symptoms questionnaire or urodynamic studies, or in the paroxetine group [Sakakibara et al., 2008].

In a retrospectively Hillelsohn et al. [2014] evaluated 43 patients who were treated with desipramine for OAB refractory to antimuscarinic therapy. Twelve patients (28%) discontinued desipramine, 9 due to perceived lack of efficacy. Still, the authors concluded that desipramine is a potential useful treatment for patients with OAB symptoms, e.g., those with pain. To confirm any useful effect of desipramine, RCTs are needed.

6.2. Duloxetine

Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor, which has been shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function [Katofiasc et al., 2002; Thor and Katofiasc, 1995]. Bladder capacity was also increased in this model, both effects mediated centrally through both motor efferent and sensory afferent modulation (Fraser and Chancellor, 2003). In a placebo-controlled study, the drug showed efficacy in patients with OAB [Steers et al., 2007]. The number of micturition episodes, the primary outcome, was reduced by 2 in the duloxetine arm and by 0.5 in the placebo arm. Episodes of urgency incontinence were also significantly reduced by duloxetine. These data have not been reproduced so far in another trial. However, the high withdrawal rate observed across all studies in which the drug was evaluated due to SUI, affecting 20-40% of the patients at short-term and up to 90% in long-term studies, do not predict clinical utility of duloxetine in OAB.

7. CYCLOOXYGENASE (COX) INHIBITORS

Prostanoids (prostaglandins and thromboxanes) are synthesized by cyclooxygenase (COX) from a common precursor, arachidonic acid. Prostanoids may be involved in the control of bladder function under normal and pathological conditions, including DO and OAB. Human bladder mucosa has the ability to synthesize eicosanoids [Jeremy et al., 1987], and these agents can be liberated from bladder muscle and mucosa in response to different types of trauma [Downie and Karmazyn, 1984; Leslie et al., 1984]. Even if prostaglandins cause contraction of human bladder muscle, it is still unclear whether prostaglandins contribute to the pathogenesis of unstable detrusor contractions. More important than direct effects on the bladder muscle may be sensitization of sensory afferent nerves, increasing the afferent input produced by a given degree of bladder filling. Involuntary bladder contractions can then be triggered at a small bladder volume. If this is an important mechanism, treatment with prostaglandin synthesis inhibitors could be expected to be effective. However, clinical evidence for this is scarce.

Cardozo et al. performed a double-blind controlled study of 30 women with DO using the prostaglandin synthesis inhibitor flurbiprofen at a dosage of 50 mg 3 times daily [Cardozo et al., 1980a]. The drug was shown to have favourable effects, although it did not completely abolish DO. There was a high incidence of side effects (43%) including nausea, vomiting, headache and gastrointestinal symptoms. Palmer studied the effects of flurbiprofen 50 mg x 4 versus placebo in a double-blind, cross-over trial in 37 patients with idiopathic DO (27% of the patients did not complete the trial) [Palmer, 1983]. Active treatment significantly increased maximum contractile pressure, decreased the number of voids and decreased the number of urgent voids compared to baseline. Indomethacin 50 to 100 mg daily was reported to give symptomatic relief in patients with DO, compared with bromocriptine in a randomized, single-blind, cross-over study [Cardozo and Stanton, 1980b]. The incidence of side effects was high, occurring in 19 of 32 patients.

Although these early clinical studies with nonselective COX inhibitors showed some promise in the treatment of these disorders, the drugs were not further developed for this indication mainly due to side effects. The interest in the use of selective COX-2 inhibitors was hampered by concerns about long-term cardiovascular toxicity with these drugs.

No recent clinical studies on the use of COX-inhibitors for treatment of LUTS/OAB seem to have been published.

8. TOXINS

Intravesical pharmacological therapy for LUTS stems from the fact that circumventing systemic administration of active compounds offers two potential advantages. First, high concentrations of pharmacological agents can be given to the bladder tissue producing enhanced local effects. Second, drugs inappropriate for systemic administration due to off target effects can be safely used. Attractive as it may be, intravesical pharmacological therapy should still be considered as a second line treatment in patients refractory to oral therapy or that do not tolerate its systemic side effects. However, this statement is based on the assumption that intervention therapy should follow oral medication. Research aiming at defining if
patients subgroups will benefit of intravesical therapy as first line is clearly necessary.

8.1. Botulinum Toxin

Mechanism of action. Botulinum toxin (BoNT) is a neurotoxin produced by Clostridium botulinum. Of the seven subtypes of BoNT, sub-type A (BoNT/A) has the longest duration of action, making it the most relevant clinically. BoNT/A is available in different commercial forms, with the proprietary names of Botox®, Dysport®, Xeomin®, and Prosigne. Although the toxin is the same, it is wrapped by different proteins which modify the relative potency of each brand. This was the basis for the introduction of the non-proprietary names onabotulinum toxin A (onabotA), abobotulinum toxin A (abobotA) and incobotulinum toxin A (incobotA) for Botox®, Dysport® and Xeomin®, respectively. Prosigne is the proprietary name of a BoNT/A produced in China, which currently does not have a known non-proprietary name.

The current approved method to estimate the potency of a BoNT/A brand is the mouse LD50 (lethal dose 50%); that is, the mass of toxin (expressed in ng/kg of body weight) that kills 50% of mice. More recently, a cell-based potency assay was approved specifically for onabotulinum toxin assay which uses differentiated human neuroblastoma SiMa cells and replicates all steps in BoNT/A mechanism of action. The assay measures the BoNT/A-dependent intracellular increase of cleaved SNAP-25. The EC50, that is, the concentration of toxin required to provoke a response halfway between the baseline and maximum response for OnabotA, is about 1–0.4 U per well [Fernandez-Salas et al., 2012].

Although potency of each toxin brand is expressed in units (U) the doses are not inter-changeable and conversion ratios between the different brands do not exist. Estimates from studies carried in the skeletal muscle suggest that onabotA is roughly three times more potent than abobotA and equivalent to incobotA. Nevertheless, these equivalences should be approached with caution. Comprehensive reviews have been produced during the last few years. The interested reader is also invited to read [Chapple and Patel., 2006; Nitti, 2006; Patel et al., 2006; Karsenty et al., 2008; Apostolidis et al., 2009; Silva and Cruz, 2009b; Dowson et al., 2010; Duthie et al., 2011; Mangera et al., 2011].

In a recent experimental study in the mice the capacity of 1 U of onabotA and 1 U of abobotA to cleave SNAP25 were compared after one single injection in the bladder wall. The average number of cleaved SNAP-25 positive fibers was higher after onabotA, than after abobotA, the difference suggesting that when injected in the bladder wall, in the same unit amount and same volume, the conversion ratio between onabotA and abobotA should be around 1:1.6 [Oliveira et al., 2015].

Most of the information available about intravesical application of BoNT/A derives from the use of onabotA (Botox®). However, in addition to sub-type A, some studies have investigated the effect of detrusor injection sub-type B, rimabotulinumtoxinB (proprietary names being Miobloc™ or Neurobloc™ depending on country). For further details, see below.

8.1.1 BoNT/A

BoNT consists of a heavy and a light chain linked by a disulphide bond. As the BoNT/A gene may differ in nucleotides, four A subtypes have been classified based on up to 15% variation in the amino acid composition. The amino acid sequence of the BoNT/A light chain constitutes a catalytic Zn-dependent endopeptidase domain. The heavy chain is subdivided into three portions (HN, HCN, and HCC), but only two have clear functions. The HCC is associated both with the recognition of neuronal-specific areas and toxin internalization. The HN is responsible for translocation of the light chain from synaptic vesicles into the neuronal cytoplasm. In the synaptic cleft BoNT/A binds predominately to the isoform C of the synaptic vesicle protein or SV2 (SV2C) [Dong et al., 2006, Dolly et al., 2014], or to the FGF Receptor 3 [Jacky et al., 2013] by the heavy chain. The importance of the latter toxin acceptor is still unclear.

The most well studied process involves SV2 binding before being internalized by the nerve terminal during the recycling process of synaptic vesicles (Figure 16). The two chains are then cleaved and the light chain passes into the cytosol, where it cleaves the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmatic membrane necessary for neurotransmitter release. Attachment protein (SNARE or soluble N-ethylmaleimide-sensitive fusion attachment protein receptor) include synapticosome associated protein 25 kD (SNAP 25), synaptobrevin (vesicle associated membrane protein - VAMP) and syntaxin. BoNT/A cleaves SNAP 25 rendering the SNARE complex inactive (Figure 17) [Humeau et al., 2000; Chancellor et al., 2008b]. Sub-type B, acts preferentially through the inactivation of VAMP [Humeau et al., 2000]. Interestingly, BoNT/A cleaves SNAP 25 always in the same position, cutting the 9 terminal amino-acids of the C terminal of the protein [Dolly et al., 2014].

BoNT/A application was extensively evaluated in striated muscle. In this tissue paralysis occurs by prevention of acetylcholine (ACh) release from cholinergic motor nerve endings [Humeau et al., 2000]. Accumulation of neurotransmitter containing synaptic vesicles is followed by terminal axonal degeneration. Striate muscle paralysis recovers within 2 to 4 months time. During this time axons develop lateral
sprouts and eventually regenerate completely [de Paiva et al., 1999].

In the human bladder SV2 and SNAP-25 expression has been demonstrated in parasympathetic, sympathetic and sensory fibers [Coelho et al., 2010; 2012a; b]. Almost all parasympathetic nerves express the two proteins [Coelho et al., 2012b]. As these nerves play a fundamental role for detrusor contraction during voiding, the blockade of ACh release is believed to play an essential role in detrusor hypo- or acontractility that follows BoNT/A injection in the bladder. In accordance with this view it was shown that in normal or SCI animals BoNTA treatment decreased the bladder contractions evoked by electrical stimulation of spinal nerves without altering intrinsic contractions [Ikeda et al., 2012]. However cholinergic axon sprouting concomitant with clinical remission could not been documented in the detrusor [Haferkamp et al., 2004].

Bladder sensory impairment is also expected to play an important role in the final effect of BoNT/A bladder injection (Figure 18). About half of the peptidergic sensory fibers express SV2 and SNAP25 [Coelho et al., 2010]. BoNT/A inhibits the spinal cord release of glutamate, substance P (SP) and CGRP from sensory nerves [Purkiss et al., 2000; Aoki et al., 2005; Meng et al., 2007] as well as the release of neuropeptides at the peripheral extremities [Rapp et al., 2006; Lucioni et al., 2008]. BoNT/A has also been shown to reduce the suburothelium immunoreactivity for TRPV1 or P2X3 [Apostolidis et al., 2005]. BonT/A also impedes TRPV1 trafficking from intracellular vesicles to the neuronal membrane, as this process is also dependent on SNARE proteins [Morenilla Palao et al., 2004; Shimizu et al., 2012]. All these mechanisms may contribute to the recent observation that BoNT/A reduces afferent firing from bladder afferents and antidromic release of neuropeptides [Ikeda et al., 2012].

In the human bladder SV2 and SNAP-25 expression by immunohistochemistry could not be demonstrated [Coelho et al., 2010]. In another study using immunoblot analysis the existence of SV2 in isolated human urothelial cells also was not demonstrated although SV2 was present in the human bladder mucosa (which contains sub-urothelial connective layer). SNAP 25 was present in both isolated human urothelial cells and human bladder mucosa [Hanna-Mitchell et al., 2013]. Another SNARE protein, SNAP 23 was identified in the human urothelial cells and may contribute to the activity of BoNT/A in the urethelium [Hanna-Mitchell et al., 2013; Cruz, 2014]. As a matter of fact urethelial function seems also compromised after BoNT/A administration. BonT/A has been shown to inhibit ATP release from urothelium in animal models of spinal cord injury [Khera et al., 2004; Smith et
Therefore, it is not surprising that administration of BoNT/A to inflamed rat bladders reduces spinal c-fos counts at the L6 and S1 spinal cord segments [Vemulakonda et al., 2005].

Cleaved, inactive SNAP-25 appears rapidly after BoNT/A injection. In the guinea-pig a robust expression of cleaved SNAP 25 could be detected already at 12 hours and maximum intensity could be detected at 24 hours with little changes afterwards. In guinea-pigs cleaved SNAP-25 expression was restricted to nerve fibers. Almost all parasympathetic fibers, either preganglionic and postganglionic were affected while less than half of the sensory fibers express the cleaved protein [Coelho et al., 2012a; b]. In the human urinary bladder cleaved SNAP 25 could be detected in NDO patients up to 11 months after BoNT/A injection. [Schulte-Baukloh et al., 2007].

BoNT/A has a unique long lasting effect. The structural basis for this remarkable persistence remains poorly explained. The enzymatic capacity of the light chain is long lasting apparently due to presence of two leucines near the C terminus of the protease light chain of A toxin [Wang et al., 2011b]. The duration of effect of BoNT/A in the detrusor smooth muscle, longer than in striated muscles, has currently no firm explanation. However, the longer persistence of the inactive form of SNAP-25 plus the involvement of pre and post-ganglionic parasympathetic neurons may contribute to persistence of the BoNT/A effect in the bladder.

8.1.1.1 BoNT/A Effects on Bladder Histology

There is no evidence that repeated injections of BoNT/A into the detrusor muscle cause inflammatory infiltrates, fibrotic activity or apoptosis within the bladder wall [Comperat et al., 2006; Apostolidis et al., 2008; Kessler et al., 2010]. Rather the reverse, one study demonstrated that NDO patients treated with BoNT/A had less fibrosis than nontreated patients [Compérat et al., 2006]. The presence of eosinophilic infiltrate Myofibroblasts form a syncytium through extensive coupling via the gap-junction protein connexin 43 and have close contacts with sensory nerves. These facts led to the hypothesis that myofibroblasts act as modulators of bladder behaviour [Wiseman et al., 2003; Apostolidis et al., 2006]. However, the expression of connexin 43 is not altered by BoNT/A [Roosen et al., 2009]. Hence, currently a firm evidence for the action of BoNT/A on myofibroblasts is scant.

BoNT/A may decrease the levels of neurotrophic agents in the bladder tissue. Levels of Nerve Growth Factor (NGF) [Giannantoni et al., 2006; Liu et al., 2009] and Brain-derived Neurotrophic Factor (BDNF) [Pinto et al., 2010] have been shown to decrease in the bladder and/or urine following BoNT/A injections. As both neurotrophins have paramount roles for growth, maintenance and plasticity of peptidergic sensory nerves, these findings may point toward another mechanism whereby BoNT/A acts upon the bladder.

Figure 17: Onabotulinum toxin A inhibition of acetylcholine (ACh) release decreases detrusor smooth muscle contraction.
was shown to increase in specimens of patients receiving multiple treatments, a finding that could not be fully explained [Apostolidis et al., 2008].

**BoNT/A injection protocol in the bladder wall.**
When the treatment was first described in 1999 for NDO patients, onabotA was diluted in normal saline in order to obtain a concentration of 10 units/ml [Schurch et al., 2000a; b]. Under visual control through a rigid cystoscope and a flexible 6 Fr injection needle, 30 injections of 1 ml (10 units of botulinum-A toxin) were done in 30 different bladder wall locations above the trigone to prevent vesico-urethral reflux. Additional refinements have been added to this technique along the following years, including the use of a local anaesthetic agent (4% lidocaine) and a flexible cystoscope [Harper et al., 2003].

The pivotal studies [Cruz et al, 2011; Ginsberg et al., 2012] which included more than 700 NDO patients led to the approval of a dose of onabotA 200 U applied in 30 injections sites above the trigone (1ml saline each 6.66 U/ml). The studies showed that 300 U produced the same results and had the same duration of effect but caused more adverse events than the 200 U dose [Cruz et al., 2011; Ginsberg et al., 2012]. When considering OAB/IDO two large pivotal studies have been published after enrolling more than 1000 patients. The protocol was first investigated in a dose finding study which led to the conclusion that 100 U was the ideal dose [Dmochowski et al., 2010c]. The toxin was administered via cystoscopy as 20 intradetrusor injections of 0.5 ml, evenly spaced but avoiding the trigone [Chapple et al., 2013; Nitti et al., 2013]. Following the approval of 100 U of onabotA for the treatment of refractory incontinence in OAB patients, this protocol should be considered standard while those reviewed in previous systematic reviews for OAB/IDO should be considered off-label. This includes the use of 200 U or abobotA 500 U [see Mangera et al., 2011; Karsenty et al., 2014 for review of other protocols].

Despite the existence of an approved protocol for onabotA injection in the bladder wall, in NDO and OAB/IDO, several variations have been investigated. One variable at stake is the trigone injection, the rationale for the injection being the dense sensory innervation of this part of the bladder. The suggested risks of ureteral reflux after injecting bladder trigone were never demonstrated, whether onabotA or abobotA was used [Karsenty et al., 2007; Citeri et al., 2008; Mascarenhas et al., 2008; Pinto et al., 2010]. A few studies have, therefore, compared trigonal versus trigonal sparing protocols in IDO patients. A recent trial randomised 22 IDO patients to receive abobotA 500 U administration in 20 injections (1ml each) sparing the trigone against 15 off the trigone plus 5 injections in the trigone [Manecksha et al., 2012]. Mean

**Figure 18: Onabotulinum toxin A inhibition of the release of adenosin triphosphate (ATP) from the urothelium decreases bladder afferent activity.**
postvoid residual volumes and clean intermittent self-catheterisation rates between the two groups were similar. However, the change from baseline of the OABSSS score was greater in the trigone injected group.

One study compared 10 trigonal injections versus 40 injections into the detrusor or suburothelium of 100 U of OnabotA in IDO patients [Kuo, 2007a]. The most effective protocol was the 40 detrusor injections because it brought more robust symptomatic improvement which lasted longer. The trigone injection only protocol was the less effective and durable of the three, although the risk of urinary retention was null [Kuo, 2007a]. The suburothelial protocol brought intermediate results, worse than the detrusor but better than the trigone only technique [Kuo, 2007a]. Pinto et al. [2010] injected 100 U distributed by 10 sites only in the trigone in 26 women with BPS/IC. No cases of voiding dysfunction were observed. PVR remained normal and bladder contractility index was not changed by OnabotA.

In patients with BPS/IC, pilot studies used onabotA 100 U injected in 10 sites in the trigone to treat bladder pain in patients with and without Hunner’s lesions. This protocol was not associated with urinary retention or clinically relevant increase of PVR (Pinto et al., 2010; Pinto et al., 2013).

Another variable under investigation is the reduction of injection sites while increasing the dose in each site. One study randomized NDO patients to receive 300 U either in 10 or 30 sites [Karsenty et al., 2005]. The authors reported that 10 site injection was quicker and less painful and that no differences in efficacy between the two procedures could be detected up to 24 weeks. In another study, it was found that patients receiving 300 U of onabotA distributed over 30 injection sites (30 ml of fluid in total) or the same dose of toxin distributed over 10 injection sites (10 ml of fluid in total) had a similar distribution of the fluid, as determined by MRI. About 1/3 to 1/4 of the total detrusor volume was covered by the two protocols, respectively [Mehnert et al., 2009].

More recently forty-five patients (22 IDO, 23 NDO) were treated with 100–300U of onabotA injected on 1 or 3 injection sites in the posterior bladder wall. ICQ-SF score improvement of >5 points was achieved in 73% of them (IDO 55%, NDO 91%) and the subjective success rate was 69% (50% IDO, 87%NDO). Full continence was achieved in 52% of NDO patients. Increase of PVR was modest and urinary retentions were not reported. Urinary tract infection occurred in 11.1%. Mean duration of effect was 31 weeks. It is unclear if this protocol has already been applied in other centers.

Another variable in the injection protocol is the volume of the saline used to reconstitute the toxin. Most studies used 1.0 mL per injection, although a few used 0.5 mL [Grosse et al., 2005; Schulte-Baukloh et al., 2005], 0.2 mL [Kuo et al., 2004], 0.25 ml [Grise et al., 2010] or even 0.1 mL per injection site [Rapp et al., 2004]. In a recent experimental study, the amount of cleaved SNAP-25 induced by a fixed amount of OnabotA was directly related with the volume of the injection [Coelho et al., 2012a]. Thus, more controlled studies designed to compare different number and locals of injection and the volume of each injection are necessary.

BoNT/A does not cross the rat urothelium if instilled in the bladder [Coelho et al., 2012a]. OnabotA instillation in the bladder encapsulated in liposomes may however overcome the urothelial barrier and induced distinctive bladder effects [Chuang et al., 2009].

Recently the liposome encapsulation technology to deliver onabotA was tested in humans. The study used the change of total urinary frequency per 3-day bladder diary at 1 mo after treatment as the primary end-point. A small group of 24 patients were randomized to intravesical instillation of Lipotoxin containing 80 mg liposomes and 200 U BoNT-A or normal saline. Patients were retreated with Lipotoxin 1 month later if they failed the first treatment. At 1 month after treatment, the change of urinary frequency per 3d was significantly improved in the Lipotoxin group. Urgency episodes also showed a significant decrease in the Lipotoxin group. Although no adverse events were reported, the duration of the effect was unfortunately short lasting [Kuo et al., 2014].

Electromotive administration may also help to carry the large botulinum toxin molecule across the urothelium. In 15 children with NDO due to myelomeningocele, a 10F indwelling catheter containing a silver spiral electrode was placed in the bladder, after providing a local transurethral anaesthesia with 2% lidocaine. The bladder was filled with saline and 10 U/kg of abobotA was added. A maximal current of 10 mA (100 mA increment/s) for 15 minutes was applied using abdominal pads [Kajbafzadeh et al., 2010]. The urodynamic and symptomatic results were excellent. Skin erythema and burning sensation were de only side effects reported with this method. If this technique can be applied to adults it is not known. However, it would certainly simplify BoNT/A administration.

AbobotA administration remains off-label. Nevertheless, in larger cohorts coming from several institutions aboboatA was applied in the bladder wall by similar technique albeit the number of injections was only 20 [del Popolo et al., 2008; Grise et al., 2010]. A total of 500-1000 U of abobotA are injected [del Popolo et al., 2008]. The volume of saline at each injection site is commonly 1 ml but volumes so low as 0.25 ml per site were also used [Grise et al., 2010].

In the pivotal RCT with NDO some type of antibiotic prophylaxis was allowed for onabotulinum toxin injection in the bladder wall on the presumption that bacteriuria reduced the efficacy of the toxin [Cruz et al., 2011; Ginsberg et al., 2012]. However, many of injected SCI patients relied on some type of bladder catheterisation and presented therefore chronic bacteriuria. Thus, the relevance of antibiotic prophylaxis

DRUGS USED FOR TREATMENT OF OVERACTIVE BLADDER SYMPTOMS/DETRUSOR OVERACTIVITY | 855
before botulinum toxin injection in SCI patients was investigated in 154 SCI patients undergoing a total of 273 treatments with onabotA for refractory NDO. Patients with no clinical signs of UTI underwent injections without antibiotic prophylaxis. Bacteriuria was found in 73% (200/273) of all patients pre-treatment. Following treatment, symptomatic UTI occurred in 7% (5/73) of cases with sterile urine culture and in 5% (9/200) with bacteriuria. These results suggest that routine antibiotic prophylaxis is not required prior to botulinum toxin injection in asymptomatic SCI patients [Leitner et al., 2016]. Is patients non-catheterizing at treatment, however, the high risk of UTI recommends that antibiotic prophylaxis should be maintained together with a careful exclusion of active UTI at the moment of injection. TI screening after each BoNT/A bladder treatment remains justifiable until further study.

Effect of BoNT/A on NDO adult patients. OnabotA 200 U is the only dose approved by FDA and by European Authorities to treat NDO in SCI and MS patients. This was in part the consequence of the findings of two large pivotal phase 3 studies where efficacy and safety of onabot A in about 700 patients with NDO was compared against placebo in patients with NDO and incontinence caused by multiple sclerosis (EDSS ≤ 6.5) or spinal cord injury below T1 [Cruz et al., 2011; Ginsberg et al., 2012]. Thesestudies were preceded by small exploratory RCT (Schurch et al., 2005; Schurch et al., 2007). Two doses, 200 and 300 U of onabotA were compared against placebo. Primary outcome measure was the change from baseline in week episodes of urinary incontinence at week 6 after treatment. Secondary outcome measures included the change from baseline in maximum cystometric capacity, maximum detrusor pressure during first involuntary detrusor contraction and quality of life using the I-QOL total score. Both studies yielded similar findings, and indicated that 200 and 300 U provided the same effect and had the same duration of action. In the first study [Cruz et al., 2011] onabotA significantly reduced UI and improved QOL in both MS and SCI patients, with no clinically relevant differences between the two doses. At week 6 mean change from baseline in weekly incontinence episodes was -21.8 in onabotA 200U, -19.4 with 300U and -13.2 with placebo (p < 0.01). At the same time point 7.6%, 38.0%, and 39.6% of patients in the placebo, 200U, and 300U onabotA groups, respectively, were fully continent. The proportion of patients without IDC was around 60% after onabotA 200 and 300 groups but only 17.4% after placebo. In the second study [Ginsberg et al., 2012], onabotA resulted in a 23.0%, 26.7% and 27.4% change from baseline in the incontinence episodes in the placebo, and 200 and 300 groups, respectively. Furthermore, 36% and 41% of patients in the 200 and 300 U groups, respectively, achieved dry status, contrasting with 10% in the placebo arm. In both studies, detrusor pressure and cystometric capacity increased significantly with the two onabotA doses, without clinically relevant differences between them [Cruz et al., 2011; Ginsberg et al., 2012]. Patients could request a retreatment 12 weeks after initial treatment. Median time for saline treated patients was about 90 days days and 250 to 300 days for those treated with 200 or 300 onabotA, without differences between the two doses [Cruz et al., 2011; Ginsberg et al., 2012]. No differences were found between patients with SCI or MS in terms of clinical response to onabotA [Cruz et al., 2011; Ginsberg et al., 2012].

When pooled data were analysed by etiology, both MS and SCI patients treated with the toxin exhibited decreases from baseline in urinary incontinence episodes that were significantly larger than in those treated with placebo. A significantly higher percentage of MS and SCI patients were dry during week 6 after treatment than in the placebo group [Ginsberg et al., 2013]. The change in the number of voluntary voids per week was examined only in MS patients, the majority of whom did not use intermittent self-catheterization at study entrance. Following onabotA 200 U treatment, a decrease from baseline of 2 mic turities per day at week 6 and around 3 micturitions per day at week 12 was detected [Ginsberg et al., 2013]. There was no difference in terms of continence between patients on or off anticholinergic medication [Ginsberg et al., 2013]. Antibody formation against onabotA were not detected in the pivotal RCT during the first treatent cycle [Cruz et al, 2011; Ginsberg et al., 2012].

As a consequence of the symptomatic improvement detected after onabotA injection, NDO patients of both MS and SCI etiologies found a significant improvement in quality of life whether analysed by the I-Qol Questionnaire (Ginsberg et al., 2012; 2013), the 3 domain scores of the I-Qol Questionnaire (avoidance and limiting behavior, psychosocial, and social embarrassment), the modified Overactive Bladder Patient Satisfaction with Treatment Questionnaire (OAB-PSTQ), or the Patient Global Assessment [Chancellor et al., 2013]. The change from baseline in I-QOL score was analysed in patients who did not perform CIC at baseline. Surprisingly, the magnitude of the I-Qol improvement was similar whether they did or did not require this maneuver after toxin administration [Ginsberg et al., 2012].

The symptomatic improvement brought by BoNT/A injection in the bladder does not coincide with the moment of injection. The onset of BoNT/A effect was evaluated in a small open-label prospective study that specifically investigated the chronology of the symptomatic changes. Some improvement in urgency, nocturia and frequency could already be demonstrated as soon as 2 days after neurotoxin injection in NDO patients [Kalsi et al., 2008]. In a large RCT with SCI and MS patients treated with OnabotA, 200 or 300U, significant decrease in the number of incontinence episodes over placebo were first detected at week 2 after injection [Cruz et al., 2011; Ginsberg et al, 2012].
About 60% of the patients were taking antimuscarinics and maintained the same dose throughout the pivotal studies. A recent subanalysis of the pooled data of the 2 pivotal studies showed that similar reductions in urinary incontinence episodes and proportion of patients fully dry were achieved, regardless of anti-cholinergic use. Moreover, increment of maximal cystometric, decrease in detrusor pressure, improvement in quality of and median time to patient request for re-treatment were similar in anticholinergic users and non-users [Ginsberg et al., 2013; Sievert et al., 2012] These observations go along with previously made suggestions by Reitz et al. [2004a; b] and Grosse et al. [2005] that a substantial proportion of SCI patients could reduce or interrupt anti-muscarinic medication after BoNT/A injection.

Doses of onabotA below 200 U were tested in patients with SCI below T1. Patients (n= 73) with NDO and UI (C14 UI episodes/week) received 30 intradetrusor injections of onabotA (50 U [n = 19], 100 U [n = 21], or 200 U [n = 17]) or placebo (n = 16) via cystoscopy, avoiding the trigone for the treatment of NDO. Linear dose response for UI episodes/week was identified with a maximal effect detected with 200 U and no effect observed in patients treated with 50U [Apostolidis et al., 2013].

A consequence of BoNT/A treatment in NDO patients is the decrease in the incidence of severe urinary tract infections. In 30 SCI patients Gamé et al. [2008] observed that the number of pyelonephritis, orchitis and prostatitis in the 6 month before onabotA 300U, 1.75±1.87 per patient, decreased to 0.2±0.41 in the first 6 month after treatment. In 17 SCI patients that received onabotA injections for a period of 6 years, the number of urinary tract infection at the sixth year was 1.8±0.5 per year, significantly lower than at baseline, 6.7±2.1 [Giannantoni et al., 2008]. In a multicentre, cross-sectional retrospective cohort study, data from 214 NDO patients treated in 7 German centers were collected. The rate of urinary tract infections in 12 months preceding and in the 12 months following onabotA was 68% and 28%, respectively [Boy et al., 2008]. The reason for these findings is unclear but may lie in a decreased maximum detrusor pressure resulting in less bladder wall ischemia and vesicoureteral reflux [Wefer et al., 2009].

Multiple Sclerosis patients represent a particular subgroup of patients in whom a careful analysis of the efficacy and safety of BoNT/A requires additional attention if voluntary voiding is present before treatment. The first cohort studies used onabotA 300 U and while this dose was effective in improving or curing urinary incontinence most patients non-catheterizing at baseline had to initiate CIC [Kalsi et al., 2007; Khan et al., 2011]. Despite this drawback, improvements in quality of life were quite remarkable indicating that patients may prefer CIC to incontinence [Kalsi et al., 2007; Khan et al., 2011]. The large pivotal phase 3 studies [Cruz et al., 2011; Ginsberg et al., 2012] showed that 200 and 300 U of onabotA had exactly the same efficacy in terms of continence and duration of effect but 200 U had a much lower risk of urinary retention and de novo CIC.

The efficacy and safety of 100 U of onabotA in MS patients non-catheterising before onabotA injection was recently compared against placebo. Injections of 1ml each were carried out in 30 places above the trigone containing onabotA (n=66) or saline (n=78). OnabotA 100U significantly improved UI episodes/day compared with placebo (-3.3 vs -1.1; P<.001), and improved all the key urodynamic parameters like maximal cystometric capacity and maximal detrusor pressure. Improvements in I-QOL total score with onabotA were 4 times higher than placebo (40.4 vs 9.9; P<.001). Median duration of effect was 11.9 for onabotA and 2.9 months for placebo (P<.001). The risk of UTI (25.8%) and de novo CIC (15.2%) after 100 U onabotA was half of that observed with 200 U of toxin injections [Chartier Kastler et al., 2016]. This RCT confirmed therefore the small pilot studies that investigated onabotA 100 U in non-catheterising MS patients [Mehnert et al., 2010] and points out to such dose as the ideal to start treatment of in MS patients with NDO resistant to oral pharmacotherapy but not requiring any form of bladder catheterization. From the initial pivotal trials, it was possible to conclude that there is no risk of MS exacerbation after onabotA administration. The annualized event rate was 0.36 and 0.19 in the onabotA and placebo populations, respectively, therefore in the lower range of the annualized rate known for the general MS population, that varies between 0.2 and 1.2 in general MS population [da Silva et al., 2015].

Although not officially approved for NDO, abobotA has been the object of investigation in a few comparative clinical trials. A small study randomized a total of 31 NDO patients due to spinal cord injury, myelomeningocele, trauma at birth, multiple sclerosis and myelitis to intravesical injections of abobotA 500 U or placebo [Ehren et al., 2007]. Patients in the abobotA arm had a significantly higher cystometric capacity at 6 and 12 weeks, lower maximum detrusor pressure and episodes of urinary incontinence and less consumption of antimuscarinic drugs. Efficacy and safety of abobotA were, additionally, investigated in NDO patients that had abandoned anticholinergic therapy. Two doses, 500 U (n = 39) or 750 U (n = 38) were compared. Complete continence at day 30 was observed in 22 patients (56.4%) and 28 patients (73.7%) receiving 500Uor 750U. The median delay in the reappearance of leakages was 168 days. Although there was a trend towards a greater improvement with 750 U, no statistically significant differences in terms of clinical and urodynamic variables and QoL were found between the treatment groups. Excellent tolerability was reported for both doses. A single-center retrospective study investigated 750 U intradetrusor injection of abobotA in 81 consecutive patients performing CIC. Six weeks after the first injection, the success rate, defined as a combination of no incontinence episode, a number of catheterization <8 reported in a 3-day bladder diary and the lack of
detrusor overactivity, was reported in 64.2%. Mean reinjection number was 3.9 and mean interval between reinjection was 8.8 ± 3 months. The clinical efficacy rate after each reinjection (up to fourteen) was at least 86.7% [Peyronnet et al., 2016].

Recently a phase IIa, randomised, placebo-controlled, pilot study enrolled 47 patients with NDO and urinary incontinence resulting from spinal cord injury (SCI) or multiple sclerosis (MS). Patients were treated with 15 intra-detrusor injections of abobotA 750 U or the equivalent placebo (n = 16) [n = 7) or 30 injections of AbobotA 750 U or the equivalent placebo (n = 17 and 7). Primary endpoint was change from baseline in mean number of daily incontinence episode frequency at day 84. Adjusted mean changes from baseline were -3.2 and -1.7 in the 15 injections group for abobotA and placebo respectively. In the 30 injections group the change was -3.2 and -2.6, respectively for the toxin and placebo. Statistically significant improvements in maximum cystometric capacity, maximum detrusor pressure and volume at first contraction were reported in the toxin groups compared with placebo. Three muscle weakness episodes were reported as serious adverse events in two tetraplegic and one paraplegic patient, all in the 15 injections group [Denys et al., 2016].

8.1.1.2 BoNT/A in IDO Patients

The enthusiasm of investigators rapidly produced a reasonable number of pilot studies investigating BoNT/A in patients with IDO refractory to antimuscarics. Although proper dose-escalating studies capable of defining ideal doses were lacking, investigators opted for the administration of BoNT/A in doses smaller than those initially used in NDO. That is the reason why most pilot studies used either onabot 200 U or abobot 500 U ([see list at the end, see also Mangera et al., 2011] and 4 RCT trials compared onabotA 200 U against placebo [Kuo, 2005b; Sahai et al., 2007; Brubaker et al., 2008; Flynn et al., 2009; Tincello et al., 2012]. Due to high incidence of voiding dysfunction associated with the use of onabotA 200 U in IDO patients one large cohort, 100 patients, investigated the effect of onabot 100 U.

Two large well designed dose escalating placebo controlled studies investigated the ideal dose of onabotA. Dmochowski et al. [2010d; see also Rovner, 2011] enrolled 313 OAB wet and experiencing 8 or more urinary urgency incontinence episodes a week and 8 or more micturitions daily at baseline. They received 50, 100, 150, 200 or 300 U intradetrusor onabotA, or placebo. Durable efficacy was observed for all groups treated with 100 U dose or higher but in dose response curve doses greater than 150 U contributed minimally to the symptomatic improvement. As the use of OIC was also dose dependent, 100 U offered the best balance between efficacy and safety. Denys et al. [2012] randomised 99 OAB patients to receive a single injection of either placebo or onabotA 50 U, 100 U or 150 U. A >50% improvement versus baseline in urgency and urge urinary incontinence (UUI) in 65% and 56% of patients who respectively received 100 and 150 U. Complete continence was observed in 55% and 50% patients after 100 U and 150 U. The dose of 100 U seemed to offer the best balance between efficacy and increase of PVR.

A few additional studies contributed to defined 100 U as the ideal dose for refractory OAB treatment. Cohen et al. [2009] randomized 44 OAB-dry and wet patients to receive 100 U or 150 U. No significant differences in clinical or urodynamic outcome measures were noted between the two doses. QOL was significantly improved in both groups with no difference between 100 U or 150 U. Altaweel et al. [2011] randomized 11 patients for onabotA 100U and 11 patients to onabotA 200 U. No clinical or urodynamic differences were detected between the 2 groups at 3-months follow-up. Urinary retention occurred in 2 patients in the 200 U and in 1 patient in the 100 U arm. The same conclusion was withdrawn by Schmid et al. [2006] who injected onabotA 100 U in 100 IDO patients refractory to antimuscarinic therapy. Treatment remained highly effective, incontinence and urgency sensation disappearing in 86% and 82% of patients, respectively, during an average period of 6 months. Temporary urinary retention only occurred in 4% of the cases, with additional 15% reporting moderate voiding difficulties.

Data from two large pivotal phase 3 studies in which patients were randomized to receive 20 injections of 0.5 mL each above the trigone, containing 5 U per injection with a total of 100 U or only saline are now available [Chapple et al., 2013; Nitti et al., 2013]. These studies enrolled mostly female patients with idiopathic OAB with ≥3 urgency urinary incontinence (UUI) episodes over 3 days and ≥ 8 micturitions per day and a postvoid residual less than 100 mL who were inadequately managed by anticholinergics. The co-primary efficacy endpoints were change from baseline in the number of UI episodes and the proportion of patients with a positive treatment response on the treatment benefit scale (TBS) at week 12.

The Chapple et al. [2013] study randomized 277 patients to onabotA and 271 for saline injection. At baseline the average number of daily UI episodes was above 5 per day. OnabotA significantly decreased UI episodes per day at (-2.95 for onabotA versus -1.03 for placebo; p < 0.001). Significant reductions in frequency, urgency episodes per day and nocturia were also observed. Changes in TBS indicate that patients perceived a significant improvement in their condition (62.8% for onabotA versus 26.8% for placebo; p < 0.001). Clinically meaningful improvements from baseline in all I-QOL and KHQ multi-item domains indicated positive impact on quality of life.

The Nitti et al. [2013] study randomised 280 for onabotA and 277 for saline. In average patients experienced more than 5 episodes of UI per day. At week 12 there were greater decreases from baseline in the
mean daily UI in the active group (−2.65 for onabotA and −0.87 for saline, p < 0.001). The percentage of fully dry patients at week 12, was 22.9% after onabotA and 6.5% with saline. The other key OAB symptoms, frequency, urgency and nocturia also improved after onabotA. Of interest, all changes in OAB symptoms detected at week 12 were already present at week 2. A higher proportion of onabotA treated patients reported a positive treatment response on the TBS vs those on placebo. Large, clinically significant improvements in all I-QOL and KHQ multi-item domain scores were noted after onabotA.

A pooled analysis of the two pivotal phase 3 studies [Sievert et al., 2014] included a population of 1,105 patients randomized to onabotulinumtoxinA 100 U (n = 557) or placebo (n = 548) confirmed the results of the 2 RCT and allowed additional insights into the effect of onabotA 100 U in OAB patients. Patients treated with onabotA 100 U had an average decline of 2.8 episodes of urinary incontinence per day whereas the reduction in the placebo group was only 0.95 episodes per day (p < 0.001). In the group submitted to onabotA the rate of dry patients at week 12 was 27.1%, significantly higher than the rate of 8.4% in the placebo group (p=0.001). Moreover, 60.5% of onabotA treated patients reported a reduction ≥50% from baseline in urinary incontinence episodes compared to 31% in the placebo group (p < 0.001). Other key OAB symptoms were also substantially improved by toxin treatment. The decrease from baseline in the number of episodes of urinary urgency per day was 3.0 and 3.8, respectively. The percentages of patients with 13 weeks with placebo. Median leakage episodes were already significantly reduced by week 6 and at 6 months were 1.67 in onabotA vs 6.0 in the placebo group. Continence was more common after onabotA (31% vs 12%). Significant decreases also occurred in voiding frequency (8.3 vs 9.67) and in daily urgency episodes (3.83 vs 6.33). Quality of life scores were better in the toxin group.

Further breakdown of the pooled data [Sievert et al., 2014] showed that the number of previous anticholinergic drugs does not seem to influence the outcome of onabotA treatment. The number of prior anticholinergics also did not affect the improvement caused by onabotA in urinary urgency episodes per day and in the number of micturitions per day. The rate of satisfaction was also independent from the number of previously used anticholinergic drugs. When analysing the efficacy of onabotA by the reasons why the anticholinergic treatment was stopped, insufficient efficacy or intolerable side effects, the symptomatic improvement and patient satisfaction after onabotA was similar in the two subgroups and comparable with the results achieved by the overall pooled population [Sievert et al., 2014]. However, the latter data should be compared with those of a retrospective analysis of a single center cohort that evaluated the efficacy of 100-150 U of onabotA injections in 85 patients. Results were superior in patients who did not tolerate anticholinergics than in those who abandoned the medication due to poor efficacy (86% vs. 60%, respectively) [Makoey et al., 2011].

Drake et al. [2015] conducted another post hoc analysis of the two pivotal phase 3 studies where the effect of the treatment was examined according to the severity of the incontinence at study entry. Patients with < 2, between 2 and 5 or > 5 UII episodes per day had decreases in incontinence episodes of 2.7, 3.0 and 3.8, respectively. The percentages of patients with a reduction of more than 50% in the urinary incontinence episodes in each subgroup were 56.6%, 66.5% and 56.7%, respectively. All these numbers were significantly better than in the placebo groups, indicating that OnabotA is effective regardless of the grade of urinary incontinence at baseline.

A large placebo controlled RCT was conducted in 8 centers in UK (the RELAX study) and randomised a total of 240 women with refractory DO to receive onabotA 200 U or placebo distributed by 20 bladder wall sites above the trigone (10 U/1ml) [Tincello et al., 2012]. Primary outcome was voiding frequency per 24 h at 6 months. Secondary outcomes included urgency and incontinence episodes and quality-of-life data. A total of 122 women received onabotA and 118 received placebo. Median leakage episodes were already significantly reduced by week 6 and at 6 months were 1.67 in onabotA vs 6.0 in the placebo group. Continence was more common after onabotA (31% vs 12%). Significant decreases also occurred in voiding frequency (8.3 vs 9.67) and in daily urgency episodes (3.83 vs 6.33). Quality of life scores were better in the toxin group.

Other small RCTs have been conducted on IDO using onabotA 200 U [Sahai et al., 2007, Brubaker et al. 2008] or a combination onabotA 200 or 300 U [Flynn et al., 2009]. These studies were extensively reviewed in the 2013 edition of this book, but their relevance after the large RCTs of Chapple et al. and Nitti et al. make their detailed analysis today superfluous. Only safety data of these small studies will be mentioned below. A small open-label prospective study specifically investigated the chronology of the effect of onabot 200 U in IDO patients. Urgency, nocturia and frequency improved as soon as 4 days in IDO patients, a time-period slightly longer than that reported in NDO cases [Kalsi et al., 2008].

Successful OAB treatment with onabotA does not appear to be related to the existence of DO. In a sub-analysis of the dose finding study for onabotA, no differences in outcomes were found between those with and those without baseline DO [Rovner et al., 2011]. Likewise, in a cohort of 5 male and 27 female patients with OAB and without DO, improvement in frequency and urinary incontinence was observed after treatment with onabotA [Kanagarajah et al., 2012]. Two doses were tested, 100 and 150 U, without any clinically relevant differences between them [Kanagarajah et al., 2012]. Thus, in clinical practice there is little justification to indicate routinely urodynamic testing in subjects with OAB symptoms refractory to oral medication to decide onabotA administration.
8.1.1.3 Adverse events in OAB and NDO Patients After BoNT/A Injection

In NDO the most common adverse events were UTI and de novo CIC [Cruz et al., 2011; Ginsberg et al., 2012; 2013].

In the SCI population, the majority of which was performing CIC at baseline, the incidence of UTI was similar across all treatment groups (around 50%). In the MS population, the rate of UTI was highest in the onabotA 300 U arm (saline 32%, 200U: 58.5%, 300U: 70%) in the study by Cruz et al. [2011] whereas the incidence of UTI was similar, around 50%, after 200 and 300 onabotA doses in the study by Ginsberg et al., [2012]. The high incidence of UTI among MS patients in the pivotal studies was related with dose dependent increase in PVR and necessity of de novo CIC. The latter was considered necessary in 12.2% of the patients after after saline, 29.5 after 200 U, and 42.2 after 300U in the study by Cruz et al. [2011].

Ginsberg et al. [2012] observed that the incidence of de novo CIC in patients not catheterizing at baseline was dose 10% on placebo, 35% on 200 U and 42% on 300 U, and also mainly affected MS patients. The pooled data of the two pivotal studies showed that the incidence of UTIs was similar among all treatment groups for SCI patients (P = 0.534), but was higher in the onabotA-treated MS patients compared with placebo (P<0.001). However, very few complicated UTIs were reported; pyelonephritis was reported in one MS patient (onabotA 300U group) and in two SCI patients (both in the placebo group), and urosepsis was reported in two SCI patients (both in the placebo group). Among patients non-catheterizing at baseline that received 200 U of onabotA about 1/3 required CIC. The period of time in which CIC was required was long lasting (>36 weeks) in about half of them [Ginsberg et al., 2013]. The risk of urinary retention and de novo CIC in MS patients non-catheterizing before treatment may be substantially decreased by using a lower dose of the toxin. Using 100U of OnabotA in non-catheterizing MS patients de novo CIC (15.2%) and the rate of UTI (25.8%) was half of that observed with 200 U of toxin injections [Chartier Kastler et al., 2016]

Paralysis of the striated musculature due to systemic leakage of the toxin has never been reported with the doses tested in the several studies reviewed here. Transient muscle weakness was, nevertheless, reported with AbobotA application in several studies [Wyndaele and Van Dromme, 2002; Akbar et al., 2007; Del Popolo et al., 2008]. Among 199 NDO patients followed during 8 years, 5 developed hypostenia when injected with after abobotA 1000 U [Del Popolo et al., 2008]. In another study with 44 patients, 3 adults also treated with 1000 U developed muscular weakness which subsided after 5 to 7 weeks [Akbar et al., 2007]. In a recent phase IIa RCT with abobotA 750 U, 3 cases of muscle weakness episodes were reported in two tetraplegic and one paraplegic patient among 15 NDO patients who received the toxin in 15 injection sites [Denys et al., 2016]. No such cases were reported with onabotA by Karsenty et al. [2008]. The reason for the less frequent transient muscle weakness among onabotA-treated patients is unclear but might be related with the larger size of its molecule which limits diffusion into the blood stream or a dose of abobotA which is more powerful that the doses used with onabotA. Anyway, the risk of hypostenia associated with abobotA might be avoided by using lower doses of the toxin, no more that 750 U for adults and 20 units/kg for children [Akbar et al., 2007, Del Popolo et al., 2008] or by avoiding high amounts of toxin per injection site. In addition, caution should be used in selecting high risk patients for botulism including children, patients with low pulmonary reserve or patients with myasthenia gravis. Aminoglycosides should be avoided during BoNT-A treatment since they might blockade motor plates and therefore enhance BoNT/A effect.

Episodes autonomic dysreflexia in SCI patients during injection were rare. Ginsberg et al. [2012] in 167 injected patients reported 7 events of autonomic dysreflexia.

Data from long-term studies that followed the large RCT are now available. In NDO, most common adverse events during 4-year follow-up were urinary tract infections and urinary retention. De novo CIC rates were 29.5%, 3.4%, and 6.0% (200U), and 43.0, 15.0, and 4.8% (300U) for treatments 1–3, respectively; de novo CIC rates were 0% for treatments 4–6 [Kennelly et al., 2015]. UTI ranged between 20% and 30% along the follow-up without relevant differences between patients treated with 200 U or 300 U [Kennelly et al., 2015]. In OAB studies UTI was the most common adverse event and ranged between 17.0% after treatment cycle 1 and 14.4% after treatment 6. CIC was necessary in 4.0% after the first treatment but this incidence decreased in all subsequent treatment cycles and was below 1% after treatment cycle 5 and 6. The median duration of CIC ranged from 3.1 to 8.3 weeks [Nitti et al., 2016].

Although it is a concerned frequently rose by caregivers, at this moment there is no evidence that repeated BoNT/A injections cause detrusor atrophy or bladder wall fibrosis. Whether onabotA or abobotA were used, repeated injections in NDO patients in the short to medium term did not decrease bladder compliance which would presumably be the case if fibrosis were to develop [Reitz et al., 2007; Del Popolo et al., 2008]. Histological inspection of injected bladders did not show inflammatory changes, fibrosis, or dysplasia after repeated treatments and independently of the neurogenic or non-neurogenic origin of the detrusor overactivity [Haferkamp et al., 2004; Compérat et al., 2006; Apostolidis et al., 2008]. Rather the reverse, one study demonstrated that NDO patients treated with BoNT/A had less fibrosis than nontreated patients [Compérat et al., 2006]. Curiously, the presence of eosinophilic infiltrate was shown to increase in specimens of patients receiving multiple treatments, a finding that could not be fully explained [Apostolidis et al., 2008].
In OAB, the dose finding study conducted by Dmochowski et al. [2010] the proportion of patients with posttreatment PVR of 200 ml or greater was dose dependent and patients requiring CIC were 0%, 3.6%, 9.1%, 12.7%, 18.2% and 16.4 after placebo or 50, 100, 150, 200 and 300 U onabotA injections. In what concerned UTI this complication occurred in 16.3%, 33.9%, 44%, 48.1% and 34.5% patients after placebo, and 50, 100, 150, 200 and 300 U onabotA injections, respectively.

In the pivotal studies the most common adverse event was uncomplicated UTI followed by urinary retention. In the Chapple et al. [2013] study, UTI occurred in 24.1% of the onabotA patients and 9.6% in the placebo group. The majority of patients treated with onabotA (75.8%) did not have an increase from baseline in PVR exceeding 100 ml and only 8.8% had PVR increases exceeding 200 ml. The proportion of patients who initiated CIC in the first 12 weeks after treatment was 6.9% following onabotA and 0.7% after placebo injection. In the Nitti et al. study [2013] UTI, again the most frequently reported AE occurred in 15.5% for onabotA and 5.9% for placebo in the first 12 weeks after treatment. All UTIs were uncomplicated, coursing without pyelonephritis. Other notable adverse events that occurred in the first 12 weeks at a higher incidence in patients treated with onabotA were dysuria (12.2%) asymptomatic bacteriuria (5.0%) and urinary retention (5.4%). PVR significantly increased in patients treated with the toxin, with the highest increase being detected at week 2 (49.5 ml). A total of 8.7% had a 200 ml or greater increase from baseline in PVR. CIC was necessary in 6.1% of patients treated with onabotA and in none in the placebo group. For more than half the patients who initiated CIC the duration was 6 weeks or less.

In the RELAX study, as mentioned before, the dose of onabotA used was 200 U. UTI occurred in 31% vs 11% in the onabotA and placebo groups, respectively. Voiding difficulty requiring CIC occurred in 16% of cases that received the toxin and in 4% of patients that received placebo [Tincello et al., 2012].

In a small RCT, CIC was required in 37.5% of patients treated with 200 U of onabotA [Sahai et al., 2007]. In another small RCT comparing onabotA 200U vs placebo, PVR increased above 200 ml in 43% of the women in the BONT/A group and UTI developed in 75% of these women [Brubaker et al., 2008].

Currently it is not possible to identify beforehand patients who will develop voiding difficulties after BoNT/A injection. The positive or negative status of the ice water test does not correlate with the risk of urinary retention after onabotA injection in NDO patients [Huwyler et al., 2007]. A retrospective analysis of 217 patients receiving their first intravesical BoNT/A injection for refractory IDO in a tertiary center concluded that risk factors for dysfunctional voiding and urinary retention included male gender (p = 0.013), baseline postvoid residual (PVR) > 100 ml (p = 0.003) and onabotA > 100 U (p = 0.029) [Kuo et al., 2010]. Also in a retrospective analysis of a cohort of 67 patients with IDO treated with onabotA 200 U CIC was necessary in 19 (28%). When compared to those not requiring CIC, those that started CIC had lower pretreatment maximum flow rate (15 vs 22 mL/s, P=0.003), lower projected isovolumetric pressure (43 vs 58, P=0.02) and lower bladder contractility index (113 vs 180, P=0.001) [Sahai et al., 2009].

Hematuria may occur after toxin injection in the bladder wall of OAB or NDO patients but in most of the times is mild in nature and does not require any active treatment.

8.1.1.4 BONT/A in Children and Elderly Patients

In children, the dose of BoNT/A should be calculated according to body weight. Doses of between 12 U/kg of weight up to a maximum dose of 300 U [Schulte-Baukloh et al., 2002] and 4 U/Kg [Corcos et al., 2002] have been used for onabotA. The maximum suggested for abobotA is 20 U/kg up to a maximum of 400 U [Altaweel et al., 2006; Akbar et al., 2007]. OnabotA has been essentially assayed in children with myelomeningocele [Schulte-Baukloh et al., 2002; 2003; Corcos et al., 2002; Riccabona et al., 2004; Kajbafzadeh et al., 2006; Altaweel et al., 2006]. In 12 children with a mean age of 6.9 years, 19 of them (73%) became completely dry between clean intermittent catheterizations while 88% reported a global improvement in urine incontinence. Interestingly, in 11 (73%) out of the 15 children who had vesicoureteral reflux before injection, reflux either disappeared or decreased in grade. BONT/A also improved bowel function in 66% of the children with intestinal problems [Kajbafzadeh et al., 2006]. The success rate in terms of continence and cessation of anticholinergic medication may, however, be substantially inferior to that seen in adults, potentially due to irreversible bladder wall changes associated with longstanding detrusor overactivity [Altaweel et al., 2006]. In a group of 20 children with myelomenigocele continence was achieved in only 13 children. At a second injection, this number also did not change appreciably [Altaweel et al., 2006].

A recent systematic review found a total of 13 studies reported on 368 children receiving BoNTA for NDO, none with a placebo comparator arm. The only parameters reported with consistency between studies were the MCC and MDP, which changed by between 42 to 59% [Mangera et al., 2014].

To date, two case series have looked at the use of BoNT/A in children with non-neurogenic OAB refractory the anti-cholinergics. Both studies have shown an excellent response to treatment [Hoebeke et al., 2006; Marte et al., 2010]. Data have been updated recently [McDowell et al., 2011]. A total of 57 children of both gender received abobotA 12 U/kg up to a maximum dose of 480 U in multiple bladder sites. A total disappearance of OAB symptoms occurred in
66% and a partial improvement in 19% of the patients. About half of the cases had repeated injections after a mean time slightly exceeding 6 months. No cases of voiding dysfunction or UTI were reported [McDowell et al., 2011].

Electromotive administration of BoNT/A may represent a substantial breakthrough among children. In 15 children with NDO due to myelomeningocele, electromotive administration of abobotA instilled in the bladder in a dose of 10 U/kg, proved very effective and safe. The mean reflex volume (99 ± 35 ml to 216 ± 35 ml) and maximal bladder capacity (121 ±39 ml to 262 ± 41 ml) increased substantially while maximal detrusor pressure decreased from 75 ± 16 cm H2O to 39 ± 10 cm H2O. Urinary incontinence improved in 12 patients (80%) [Kajbafzadeh et al., 2011].

Elderly patients represent, as well, a very special population where urgency and incontinence are not only very distressful but also particularly prevalent. Nevertheless, only one study specifically addressed efficacy and safety of BoNT/A in elderly patients. Twenty-one patients with refractory IDO (18 females and 3 males) with a mean age of 81.2 years (range 75 to 92) received onabotA 200 U in 20 bladder sites [White et al., 2008]. A significant decrease in the number of daily voids, from 11.4 ± 1.67 to 5.19 ± 0.83 and incontinence pads per day, from 4.0 ± 0.89 to 1.3 ± 0.60, occurred. One month after treatment 16 of the 21 patients (76%) reported greater than 50% improvement in symptoms after 1 injection while only 3 did not show improvement after 2 injections [White et al., 2008]. Mean time to deterioration was 7.12 months. There were no treatment related complications.

8.1.1.5 Effect of BoNT/A on Quality of Life

Firm evidence that BoNT/A bladder injection in NDO and IDO patients increases quality of life can be extracted from several RCT in which QoL changes were in most cases a secondary outcome parameter.

One pivotal phase 3 study in NDO patients used the I-QOL questionnaire to evaluate quality of life changes in SCI and MS patients randomized to 200 and 300 U of onabotA or placebo. Change from baseline was 24 points for both onabotA doses at 6 and 12 weeks but only 11 points at week 6 and 8 points at week 12 in the placebo group. The I-Qol questionnaires requires that a minimum change of 11 point occur in order to QoL to be detectable by patients, a barrier that was overcome by both OnabotA doses [Cruz et al., 2011]. Improvements were present both in SCI and MS patients. In another large phase 3 trial these data were totally confirmed [Ginsberg et al., 2012]. Interestingly, a comparison in QoL in patients performing and non-performing CIC in the placebo, 200U and 300U arms did not show differences in patient perception, indicating that improvement in the continence condition was a more relevant outcome [Ginsberg et al., 2012]. Improvements from baseline in the avoidance, limiting behavior, psychosocial and social embarrassment domains of the I-QoL Questionnaire were greater after onabotA treatment. Responses to the OAB-PSTQ and to the Patient Global Assessment also demonstrated superior mean improvements from baseline in 200 U onabotA than in placebo treated group [Chancellor et al., 2013]. The Canadian multicenter double-blind study [Herschorn et al., 2011a] that randomised to onabotA 300 U or placebo 57 incontinent patients with NDO secondary to spinal cord injury or multiple sclerosis also found significant advantage of onabotA in terms of I-Qol score. A small exploratory, multicenter, randomized, double blind placebo controlled trial by Schurch et al. (2007) which randomized 59 NDO patients with urinary incontinence for onabotA 200U or 300U or placebo found that. I-QOL scores improved significantly over placebo, at all time points whether 300U or 200U were used.

The importance of continence for patients’ quality of life is also confirmed by the study of 43 MS patients treated with onabotA 300 U [Kalsi et al., 2007]. Although 98% of patients had to perform CIC after treatment, there were sustained improvements in all quality-of-life scores with a mean duration of effect was 9.7 months. Results were maintained with repeat treatments for 11.7 months. These results were confirmed in a larger MS cohort by Khan et al. (2011). Urogenital Distress Inventory and Incontinence Impact Questionnaire 7 scores showed considerable improvement 4 weeks after onabotA 300 U treatment even when repeated 6 times. Again, the fact that 76% of the patients were dry seemed more relevant for QoL score than the necessity of CIC that was required by almost all patients [Khan et al., 2011].

Improvement in QoL was also found in a study that compared abobot 500 U versus /750 in a NDO population predominantly suffering from SCI. A disease- and organ-specific Qualiveen questionnaire with four domains (limitations, constraints, fears, and feelings) was used to assess the Specific Impact of Urinary Problems on QoL. The initial evaluation was repeated at days 30, 90, 180, and 360. Identical improvements were detected for the two doses [Grise et al., 2010]. A single center, double blind, placebo controlled study performed by Ehren et al. [2007] randomised 37 NDO patients with incontinence to abobotA 500 U or placebo. Patients in the AbobotA group showed greater improvement in quality-of-life parameters compared to the placebo group. A more recent study that compared 750 U of abobotA injected in 15 or 30 sites showed increases in I-QOL scores were observed in both groups and to a lesser extent the placebo groups at day 14 and 84 after injection which were statistically significant differences only for the 15 injection sites group [Denys et al., 2016].

In IDO/OAB, the dose finding study by Dmochowski et al. [2010] in which placebo and onabotA 50, 100, 150, 200 and 300 U were compared showed a sustained improvement in the King’s Health Questionnaire score only in patients that received doses of 100
U or higher. In contrast, patients randomized to onabotA 50 U had changes similar to those observed after placebo [Dmochowski et al., 2010]. The dose finding study by Denys et al. [2012] showed an I-QoL improvement in patients receiving onabotA 100 U and 150 U, though at some time points scores were only numerically higher than in placebo or 50 U groups. The general health status, as measured by the EQ-5D visual analogue scale also improved in patients that received 100 or 150 U [Denys et al., 2012].

In the pivotal study conducted by Chapple et al. [2013] in OAB patients there were significant improvements in the I-QOL total summary score and all three domain scores in the onabotA group vs placebo. The improvement far exceeded the predefined minimal important difference (MID) of a 10-point increase. Improvements from baseline in all seven multi-item domains of the KHQ were also greater in the onabotA group. The same was observed by Nitti et al. [2013]. Large, clinically significant improvements in all I-QOL and KHQ multi-item domain scores were noted after onabotA vs placebo treatment in OAB patients. Improvements from baseline for onabotA, in contrast to placebo, were considerably greater than the predefined minimally important differences.

The RELAX study [Tincello et al., 2012] showed significant improvement in ICIQ-SF and I-QOL scores. However, none of the questionnaires were restored to the normal score (0 for ICIQ; 100 for IQOL) [Tincello et al., 2012].

Two small RCT with OAB/IDO patients [Sahai et al., 2009] used the King's Health Questionnaire (KHQ) at baseline and at 4 and 12 weeks, after injection of onabotA 200 U or saline in 16 and 18 patients of both genders. Overall QoL was significantly improved in the onabotA treated patients compared with placebo in the KHQ subdomains, ‘Incontinence Impact’, ‘Emotions’, ‘Physical imitations’, ‘Social Limitations’ and ‘Severity Measures’ at the two time-points.

8.1.1.6 Repeated Injections in NDO Patients

Median time for NDO patients due to SCI or MS to request a retreatment was around 300 days after onabotA 200 or 300 U but only 92 days after placebo [Cruz et al., 2011]. Therefore, for patients that respond to BoNT/A a programme of rejections is inevitable.

With the objective of evaluating the long-term efficacy and safety of repeated onabotA injections, patients who completed the two pivotal phase III studies were invited to participate in a long-term study. At the start of the extension study, patients that had received onabotA 200 U or 300 U continued with the same dose while dose on placebo were randomized to receive the active compound in one of the two doses. Later, with the license of 200 U, all patients were converted to this dose. The primary assessment was the change from baseline in urinary incontinence episodes during the week 6 after each injection. The first analysis was carried out after 5 treatment cycles [Kennelly et al., 2013]. Update of the long-term study in patients that were treated up to 4 years was reported recently [Kennelly et al., 2015]. OnabotA 200 U consistently reduced UI episodes/day, ranging from −3.2 to −4.1 across six treatments (variations from baseline). Volume/void consistently increased, nearly doubling after treatment. I-QOL improvements were consistently greater than twice the minimally important difference. Overall median duration of effect was 9.0 months for patients treated with 200 U. In the reduced number of cases treated with 300 U results were similar [Kennelly et al., 2015]. However, patients did not request the same number of treatments along the 4 yeras follow-up. While some patients required 8 re-injections, others asked only for 2. Patients with fewer treatments had a slightly fewer baseline episodes of incontinence per day than those that required 7 or 8 treatments. Nonetheless, the daily episodes that were observed in week 6 after each treatment indicated a similar efficacy of onabotA, regardless of the number of injections requested. This suggests that patient preference for retreatment was not motivated by a different degree of toxin efficacy.

Rovner et al. [2016] reanalysed this large cohort looking only to the 227 patients who did not abandon the study and therefore completed the 4-year period of analysis. Patients reported 4.3 urinary incontinence episodes per day at baseline and received 1.4 to 1.5 onabotA treatments per year. The decrease in urinary incontinence following onabotA consistently ranged from −3.4 to −3.9 episodes per day across 4 years. A high proportion of patients achieved 50% or greater and 100% urinary incontinence reductions in each year (range 86.6% to 94.1% and 43.6% to 57.4%, respectively). Consistent and clinically relevant improvements in I-QOL scores were observed in each treatment year. The overall median duration of effect of onabotA range beween 3.0 to 49.2 months and 26.0% or more of patients experienced a duration of effect of 12 months or greater. The most common adverse event was urinary tract infection with no increased incidence with time the proportion of UTI in the years 1 to 4 were 21.5%, 20.9%, 17.3% and 18.9%, respectively [Rovner et al., 2016].

Toxin-neutralizing antibody formation (i.e., seroconversion), occurred in three patients who received onabotA 200U (one in each of cycles 2, 8, and 9) and five patients who received 300U [Kennelly et al, 2015].

It may be interesting to compare this study with data extracted from real-life practice, in a population of NDO subjects mainly composed by SCI and MS patients. The number of patients requesting retreatments substantially decrease during follow-up and 5 years after the initial injection only 10% of the original cohort remained on treatment. The explanation for such decrease includes the progression of the neurological disease, which can be particularly expected in MS patients. The worsening of the motor capacities will restrain a significant number of these patients to a bed-ridden condition in which the advantages of
onabotA injections may no longer be perceived. One should remember that the regulatory studies excluded patients wheelchair bound or bed-ridden. In addition, a significant number of SCI patients had bladder augmentation or urinary diversion during the period of analysis.

Three studies were identified that assessed the effect of repeated injections of onabotA and abobotA in NDO patients. A cohort of 199 patients with spinal cord lesions treated with abobotA 500 U to 1000 U was analysed retrospectively, after 8 years of repeated injections. The intervals of between injections remained constant. Urodynamic improvements, patients' satisfaction with treatment and number of pads or other protective devices was also constant after treatments [Del Popolo et al., 2008]. Intervals exceeded 12 months in 19.5% of the patients, ranged between 10 and 12 months in 40.2%, was < 10 months in 30.5% and < 6 months in only 10% of the patients [Del Popolo et al., 2008].

In another study, 20 consecutive NDO (SCI 18, MS 2) patients received at least five intradetrusor injections of onabotA 300 U in 30 sites above the trigone. Intervals between injections remained constant, between 193 and 199 days. Clinical continence improved significantly after the first injection and then remained constant after repeat injections. The median reflex volume increased from a 200 ml at baseline to values between 440 and 500 ml at follow-up studies. The presence of NDO decreased by 60–75%. Maximum cystometric capacity increased more than 2 folds and maximum detrusor pressure from a median of 70 cm H2O to values of about 20 cmH2O [Reitz et al., 2007].

In a MS cohort with 137 patients who underwent detrusor onabot 300 U, 99 (72%) returned for a second treatment, and 47, 25, 14 and 5 returned for re-treatments 3 to 6, respectively. The median interval for 1st, 2nd, 3rd, 4th, and 5th re-injections ranged between 12 and 13 months. The outcome in terms of continence did not differ among treatments [Khan et al., 2011].

8.1.1.7 Repeated Injections in IDO/OAB

The median time to request a retreatment in the Chapple et al. [2013] and Nitti et al. [2013] RCTs was 24 weeks following treatment with onabotA implies that repeated injections are necessary if treatment is required.

Patients participating in the two phase 3 studies were invited to participate in a long-term, 3-year extension study to determine the efficacy and safety of repeated onabotA 100 U injections for the management of OAB. This is the largest cohort with the longest follow-up available until now. Treatments were requested by participants upon reappearance of OAB symptoms and once eligible, patients were re-injected with a similar 100 U dose of onabotA. An interim analysis after 5 treatment cycles showed that the decrease from baseline of UUI episodes remained stable, around 3 episodes per day and the proportion of patients reporting a high satisfaction rate remained high, ranging from 70% to 90%. The duration of the effect remained stable or even increased in subsequent treatments. However, for reasons that are unclear patients that received up to 5 treatments were a minority when compared with those that requested only 1 or 2 injections. These results were up-dated recently by Nitti et al. [2016]. From the initial 839 patients enrolled, a total of 829 received one or more treatments and 430 (51.3%) completed the 3.5-year study period. At baseline the mean episodes of UI per day was 5.6 and the I-QOL total score was low. The decrease of UI episodes ranged between -3.1 and -3.8 episodes per day whether patients received 1 to 6 treatments. The median duration of effect, calculated as the time to requalify to a retreatment was 7.6 months. The median duration of effect was 6 months or less in 34.2% of the participants, between 6 to 12 months in 37.2% and greater than 12 months in 28.5% [Nitti et al., 2016]. The overall incidence of toxin neutralizing antibody formation was 0.4% [Nitti et al., 2016].

Real-life studies offer contradictory results concerning persistence on an onabotA program. Malde et al. [2014] reported that in a group of 100 patients with refractory OAB 90% would return to the program in the future and 93% would recommend the treatment to a friend. Moreover, 81% accepted the treatment as life-long. On the other hand, Mohee et al. [2013] found that 66.3% of patients discontinued therapy at 36 months. The main reasons for abandonment were UTIs and the need for CIC. In a single-centre retrospective study [Marcelissen et al., 2016] the persistence on treatment of a total of 128 women with at least 5-year follow-up after their first injection and a mean follow-up 97 (60-125) months was investigated. Of all patients, 30% were still on BoNT-A treatment at the last follow-up visit. Of the 70% that discontinued treatment, 27% had insufficient effect and 43% had tolerability issues. Most patients discontinued treatment after the first (79%) and second (19%) injections. Only 2% of patients discontinued treatment after more than two injections during follow-up. In these last two studies [Mohee et al., 2013; Marcelissen et al., 2016] the majority of patients were treated with onabotA 200 U. A high rate of adverse events related with the high dose used may have, therefore, contributed to the low persistence in treatment.

Other 4 studies were identified that analysed repeated injections in IDO patients. In general, longer duration of BoNT/A effect and a relatively higher rate of treatment drop out is seen among IDO patients. A cohort of 34 IDO patients treated with onabotA 200 U [Sahai et al., 2010] was updated with 100 patients [Dowson et al., 2012]. A statistically significant reduction in frequency, urgency, and urge urinary incontinence were seen following onabotA 200 U injection compared to baseline. Such improvement was again
maintained after repeated injections. The mean inter-injection interval was 322 days. Interestingly, 37% of the patients stopped treatment after the first two injections, dropouts being rare thereafter. The most common reason for discontinuing treatment was poor efficacy (13%). CIC related issues was pointed out by 11% of patients despite the incidence of CIC after the first injection being 35% [Dowson et al., 2012].

In a prospective, observational study after 1 single onabotA 100 U injection, 26 patients were followed up for 2 years. One patients did not respond (primary failure), 3 were lost to follow-up, and 11 patients had a repeated injection at 5–26 months. At 2 years 7 of the remaining 11 patients were recommended repeated injection or another treatment, and four required no other treatment.

Schmid et al. [2008] reported on 25 women and 5 men that received repeated (2) injections of onabotA for treatment of IDO. The interval between two subsequent treatments ranged between 4 and 26 months (mean 12 months). Improvement of OAB symptoms, quality of life and urodynamic parameters were observed after reinjection.

8.1.1.8 Cost-effectiveness of BoNT/A

Economic aspects of BonT/A are a concern due to the price of the drug and the need for repeated cystoscopies, very often performed under general anaesthesia and under close monitoring to detect and treat eventual episodes of autonomic dysreflexia. Nevertheless, In UK, in a cohort of 101 patients with detrusor overactivity, 63 of whom of neurogenic origin, BonT/A treatment was shown to be cost-effective in both NDO and IDO cases [Kalsi et al., 2006]. Costs were based on the resources used by typical patients in UK and in the cost-effectiveness of 200-300 U BoNT/A (Botox) compared with standard care [Kalsi et al., 2006]. In Germany, a multicenter cost analysis showed that BonT/A (onabotA) treatment halved costs for incontinence aids and for urinary tract infection treatment in 214 NDO patients. In patients using incontinence aids, mean costs per patient decreased from €2 to €1 per day, whereas the mean cost of drugs to treat UTIs per patient decreased from €163 to €8 per year [Wefer et al., 2009].

Also in NDO patients, break-even point for BoNT/A and augmentation cystoplasty costs may be reached at five years. However, BoNT/A may be substantially more cost-effective if the duration of effect of each injection is superior to 5 months or if the complications associated with augmentation cystoplasty overtake 40% of the patients [Padmanabhan et al., 2011].

For OAB/IDO, an assessment of costs, from a US payer perspective, extending up to 3 years, was made for 3 interventions, sacral neuromodulation, BoNTA, and augmentation cystoplasty in patients refractory to antimuscarinics. The initial treatment cost was $22,226, $1,313, and $10,252 for sacral neuromodulation, BoNTA, and augmentation cystoplasty respectively. Three years after initiating treatment, the cumulative cost was $26,269, $7651, and $14,337 respectively. Sensitivity analyses revealed that sacral neuromodulation persisted as the most costly intervention [Watanabe et al., 2010].

Visco et al. [2016] analysed cost and effectiveness data from participants in the Anticholinergic versus Botox Comparison randomized trial of daily anticholinergic medication versus 100 U of intradetrusor Botox injection. They concluded that Botox and anticholinergic medications have similar costs and effectiveness in the first 6 months of UI/U treatment. If costs and outcomes are considered through 9 months, Botox may have significantly lower costs but similar symptom control as anticholinergics.

8.1.1.9 Clinical Comparisons and Switch Between Different BoNT/A Brands

Different brands of botulinum toxin type A cannot be used interchangeably. The molecular weights are different. OnabotA is a 900 kDa molecule, abobotulinumtoxinA is approximately 500 kDa and incobotA, is a 150 kDa molecule [Cruz, 2014]. In addition, potency of these brands is impossible to compare due to the distinct tests used to evaluate it. While onabotA’s potency is determined by the EC50 (amount of toxin required to provoke a response halfway between the baseline and the maximum response) of cleaved synaptosomal associated protein of 25 kDa (cSNAP-25) in differentiated neuroblastoma cells, abobotA potency is determined by the mouse LD50 (amount of toxin that kills 50% of the mice) [Cruz, 2014]. Despite the fact that they are not licenced both abobotA and incobotA are however being used in real-life clinical practice to treat NDO and OAB. As doses for these brands were never established by appropriate dose finding studies in the lower urinary tract, empiric conversion ratios are applied with unknown consequences for the comparison of the outcomes. Mangera et al. [2011] in a systematic review identified good-quality studies that evaluated onabotA for all the indications in adults. However, that was not the case with abobotA. Although this does not imply that onabotA is more effective than abobotA, it should be a consideration when counselling patients on the use of botulinum toxin in urologic applications, either in terms of predicting outcomes or in determining doses to be used.

A study compared two different brands of BonT/A, onabot A 200 or 300 U against the Chinese BoNT/A Presigne in the same dosage. Improvement in MCC was significantly greater with onabotA Botox versus Prosigne (+103.3% vs. +42.2%; P = 0.019). Continence was achieved by week 12 in 16 onabotA recipients (76.2%) and in 10 Presigne recipients (47.6%; P = 0.057) [Gomes et al., 2010]. Future studies seems, therefore, justified to assess the relative potencies of the different brands of BonT/A.

A few studies have examined the consequences of changing botulinum toxin type A brands to treat bladder dysfunction. Ravindra et al. [2013] initially treated OAB patients with onabotA with a standard dose of
200 U. Then, they switched to abobotA with a standard dose of 500 U based on an empiric conversion ratio of 1:2.5 between the two toxins. The onabotA (n = 101) and the abobotA cohorts (n = 106) had similar reductions in frequency, nocturia and daily incontinence episodes. No difference in the duration of the effect was observed. However, the abobotA group had almost twice the rate of symptomatic urinary retention requiring CIC (42% versus 23%).

Peyronnet et al. [2016] assessed the results of onabotA detrusor injections when abobotA detrusor injection failed. Twenty-six patients with SCI (n=14), MS (n=9), myelomeningocele (n=2) and myelitis (n=1) in whom a first injection of 750 U abobotA in 20 sites failed in treating NDO received onabotA 300 U in 30 sites. The reasons for the failure of first treatment were not clear and in no case a second injection of abobotA was attempted. OnabotA injections brought were not clear and in no case a second injection of abobotA was attempted.

In another study Peyronnet et al. [2015] reviewed the charts of 58 NDO patients who received either onabotA or abobotA for the management of NDO. A toxin switch was carried out in 29 patients, whereas the other 29 patients received a reinjection of the same toxin at the same dose. The success rate was higher in patients who switched toxin (51.7% vs 24.1%, P = 0.03). Patients treated with a switch from abobotA to onabotA and those treated with a switch from onabotA to abobotA had similar success rates (52.9% vs 50%).

Switch between brands is currently clearly being made on empiric grounds. In particular the lack of effect of a treatment with a particular brand should not be seen as a compulsory reason for switching to another brand. In a recent sub-analysis of the NDO patients included in the onabotA pivotal studies whom experienced <50% reduction in urinary incontinence episodes following the first onabotA treatment, about 1/3 had a positive response in subsequent injections [Denys et al., 2015]. Even in patients with an initial response below 25%, marked improvements were found in subsequent treatments. As a matter of fact, in 10 of the 23 patients with <25% reduction at the first treatment, mean urinary incontinence reduction was ≥50% in all subsequent injections. Thus, an initial low response does not necessarily predict a permanent low response to subsequent treatments.

Reasons for the lack of response to botulinium toxin A injection in the bladder wall cannot be attributed neither to the lack of SNAP-25, an indispensable membrane protein nor to the formation of antibodies against the toxin which is a rare event. Rather, inappropriate storage the vials, incorrect toxin reconstitution, or incorrect technique of administration, including the type of needle used, should be more obvious reasons for treatment failure [Karsenty et al., 2014]. A large variation of the number of bladder neurons expressing cleaved SNAP-25, the end-product of botulinum toxin A activity, after 1 injection of a fixed dose of onabotA was recently shown in experiments conducted in rodent bladder. The amount of cleaved protein after onabotA injection reached a 5-fold variation between experiments [Oliveira et al., 2015].

8.1.1.10 Comparison Between BoNT/A and Other Treatments

BoNT/A has been compared to other OAB treatments only rarely as it is assumed that its introduction should follow the failure of first line oral pharmacotherapy, antimuscarinics and the beta3 agonist mirabegron. However, given the frequently suboptimal efficacy and long-term compliance of anticholinergic medications, researchers must assess whether BoNT/A has a role as first line therapy for women with OAB. The Anticholinergic Versus Botulinum Toxin A Comparison Trial (ABC trial) [Visco et al., 2012] randomization of 249 women with OAB who had 5 or more episodes of urgency urinary incontinence in a 3-day bladder diary. For a 6-month participants were randomly assigned to one intradetrusor injection of 100 U of onabotA plus daily oral placebo daily or oral anticholinergic medication (solifenacin, 5 mg initially, with possible escalation to 10 mg and, if necessary, subsequent switch to trospium XR, 60 mg) plus one intradetrusor injection of saline. The primary outcome was the reduction from baseline in mean episodes of urgency urinary incontinence per day recorded in 3-day diaries over the 6-month [Visco et al., 2012]. The mean reduction in episodes of urgency urinary incontinence per day, from a baseline average of 5.0 per day, was 3.3 in the onabotA group and 3.4 in the anticholinergic group (P = 0.81). Complete continence was reported by more commonly in the onabotA than in the anticholinergic group, 27% vs 13% (P = 0.003), respectively. The toxin group had higher rates of catheter use at 2 months (5% vs. 0%, P = 0.01) and UTI (33% vs. 13%, P<0.001) than the anticholinergic group. The latter on the other hand had a higher rate of dry mouth (46% vs. 31%, P =0.02) [Visco et al., 2012].

In a similar study researchers randomised patients with OAB and urinary incontinence to receive double placebo (n = 60), onabotA 100 U injection plus placebo (n = 145), or oral solifenacin plus placebo injection (n = 151) for 12 weeks. Co-primary endpoints were change from baseline in urinary incontinence episodes/day and the proportion of patients with 100% reduction in urinary episodes at week 12 after injection. Overall, patients had 4.9 urinary incontinence episodes per day. At week 12, mean reduction from baseline in urinary incontinence episodes/day was significantly greater with either onabotA (-3.2) or solifenacin (-2.6) versus placebo (-1.3; P < .001 for both). Reduction in urinary incontinence episodes/day was significantly greater with onabotA than solifenacin (post-hoc analysis; P = .022). The proportion of patients with 100% reduction in urinary incontinence episodes at week 12 was significantly better for onabotA (33.8%) and solifenacin (24.5%) compared with placebo (11.7%) [Everaert et al., 2016].
The Rosetta study compared onabotA 200 U bladder injections against SNM (interStim) in refractory OAB patients [Amundsen et al., 2014]. The proportion of randomised patients suitable for SNM implant was identical in the two arms. At baseline the onabotA group (n=190) had 5.4 and the SNM (n=174) had 5.2 episodes of urinary incontinence per day. OnabotA 200 U resulted in a significantly greater mean daily reduction in UIUI episodes over 6 months, which averaged one episode/day. A significantly greater number of patients experienced a complete resolution (20% vs 4%) or 75% reduction of UIUI episodes (46% vs 26%) with OnabotA 200 U treatment than with SNM InterStim.

In addition, a survey in 50 OAB patients, with a mean age of 61 years, 74% prefer onabotA and only 26% chose SNM as first treatment option. In those who preferred onabotA, 54% disliked the thought of a foreign body in the back, 45.9% made the option due to a short waiting list and 43.24% made the choice based on the quicker onset of benefit. In the SNM group 61.5% were averse to the potential need for repeated injections and 46.1% chose SNM to avoid the risk of urinary retention associated with the toxin [Balchandra and Rogerson, 2014].

Although the outcomes of SNM (interStim) seem worse than those of onabotA it should be noticed that SNM may be useful in non-responders to onabotA. In a small cohort with 20 patients 17 (85%) had discontinued onabotA because of lack of efficacy and 3 had been treated successfully with BoNT/A but requested a more permanent solution. In 14 patients (70%) the test stimulation was successful and they received a definitive implant. Of the 14 patients 5 even showed a decrease of greater than 90% in leakage episodes. One year after implantation 11 patients (79%) were satisfied with SNM [Smits et al., 2013]. This study suggests therefore that half of patients non-responders to onabotA may still have a chance of long term improvement with SNM.

8.1.1.11 BONT/A in IC/PBS

BoNT/A significantly inhibits the noxious sensory input from the bladder [Vemulakonda et al., 2005; Rapp et al., 2006; Lucioni et al., 2008]. Moreover, BoNT/A decreases the urinary levels of NGF and BDNF which may contribute to decrease the bladder alldynia observed in these patients [Pinto et al., 2010; 2014]. Therefore, several pilot studies were carried out in the last few years. None is placebo controlled, a fact that limits the scientific value of the observations. On the other hand, different techniques of administration have been assessed. These two facts may explain some heterogeneity of results.

The first pilot study with 13 females observed that, 9 (69%) had subjective improvement after onabotA 100 or 200 U injected in the trigone and above the trigone. Mean scores in the Interstitial Cystitis Symptom Index and the Interstitial Cystitis Problem Index improved by 71% and 69%, respectively. Daytime frequency, nocturia, and pain measured by a Visual Analogue Scale (VAS) decreased by 44%, 45%, and 79%, respectively. Symptom improvement lasted a mean of 3.7 months (range 1 to 8) [Smith and Chancellor, 2004]. In another pilot study with 15 patients, Gian­nantoni et al. [2006; 2008] reported similar observations after bladder injection of onabotA 200 U (150 U above the trigone, 50 U in the trigone). Subjective improvement at 1- and 3-month follow-up occurred in 86% of the patients but at 5-month only persisted in 26.6%. Importantly, 9 patients experienced moderate to severe voiding difficulties [Gian­nantoni et al., 2006; 2008] A third study could not demonstrate any effect of onabotA in 13 IC/PBS patients treated with onabotA 100–300 U in the bladder [Davies et al., 2006].

Three other studies, which added substantial modifications to the above protocol, reported, on the contrary, considerable improvement in clinical and urodynamic outcomes after BoNT/A administration.

A prospective, randomized study enrolled 67 patients with refractory IC/PBS. Of these, 44 patients received suburothelial injection of onabotA 200 U (15) or 100 U (29) followed by cystoscopic hydrodistention 2 weeks later. The control group (23 patients) only received hydrodistention. The IC/PBS symptom score significantly decreased in all three groups, but VAS pain reduction and urodynamic improvement were only observed at 3 months in the arms that received onabotA, without any relevant differences between the two doses. A successful result at 12 and 24 months was reported in 55% and 30% of onabotA treated patients, respectively, compared with only 26% and 17% in the control group. The validity of these positive long-term results should however be interpreted with caution since all patients remained on baseline pentosan polysulphate throughout the study [Kuo and Chancellor, 2009].

Taking in consideration that most of the bladder nociceptors course in the trigone, Pinto et al. [2010] restricted 100 U onabotA injections to the trigone, in 10 sites (10 U/1 ml each. Twenty-six women with positive findings at cystoscopy and biopsy were enrolled. All patients reported subjective improvement at 1- and 3-month follow-up in pain, daytime and nighttime voiding frequency, O’Leary-Sant score and QoL. Bladder volume to first pain and maximal cystometric capacity more than doubled. Treatment remained effective in >50% of the patients for 9 months. Retreatment was equally effective in all cases, with similar duration of the effect up to four consecutive treatments (Pinto et al., 2013). No cases of dysfunctional voiding were reported after trigonal injections of onabotA 100 U. Also, PVR at urodynamics and bladder contractility index were not impaired [Pinto et al., 2010; Pinto et al., 2013]. Interestingly trigonal injections of onabotA 100 U were equally effective in patients with and without Hunner’s lesions [Pinto et al., 2014].

The third was a small placebo controlled trial comparing periurethral injections of onabotA 50U (n=9) versus saline (n=11). The rationale was to investigate
the participation of periurethral somatic afferents to pain. The solution, 2 ml, was injected in the region of the bladder neck, at the 3 o’clock and 9 o’clock positions. Unfortunately, there was no differences between the onabotA and the at 3-month follow-up in terms of symptoms.

8.1.2 BoNT/B

Some humans repeatedly injected with BoNT/A may develop resistance to the toxin, possibly due to antibody formation. Although this event seems very rare in the case of bladder injections, a minimum interval of 3 months between two BoNT/A injections is generally recommended to decrease its occurrence. If resistance appears, recent reports [Dykstra et al., 2003; Pistolesi et al., 2004; Reitz et al., 2004] investigated the replacement of BoNT/A serotype by BoNT/B. At this moment empiric doses of BoNT/B are being used as there is no clear potency equivalents for the two serotypes and between BoNT/B brands.

In 3 patients with spinal NDO, bladder injection of 5000 U [Pistolesi et al., 2004] or 7500 U [Reitz and Schurch, 2004] of BoNT/B (Neurobloc ®) restored bladder function for 6 months [Reitz and Schurch, 2004]. Interestingly, one patient experienced dry mouth and dry eyes that resolved within 20 days. As this side effect was not reported after bladder BoNT/A application, it is possible that different toxin serotypes have some different degrees of organ affinity. Dykstra et al. [2003] carried on a dose escalation study with BoNT/B (rimabotB) in 15 female patients with OAB. They used doses of 2500, 3750, 5000, 10,000, and 15,000 U injected at 10 sites. Only one patient failed to respond and a clear dose-dependent effect, was observed, with the longest response seen in those injected with 15,000 U. Two patients, both injected with 15,000 U, experienced dry mouth and general malaise. In another study involving IDO and NDO patients, in which rimabotB 5000 U were used, Hirst and coworkers [2007] observed a limited duration of action, with most of the symptomatic beneficial effects wearing off by 10 weeks in most of the patients. The short duration of action for BoNT/B at safe doses may, therefore, limit the clinic usefulness of this serotype.

BoNT is effective for treatment of both NDO and IDO and has an acceptable adverse effect profile (Table 2).

8.2. Capsaicin and Resiniferatoxin (RTX)

8.2.1 Rationale for Intravesical Vanilloids

The rationale for intravesical vanilloid application in patients with detrusor overactivity (DO) was offered by the demonstration that capsaicin, following bladder C-fiber desensitization, suppresses involuntary detrusor contractions dependent upon a sacral micturition reflex [de Groat, 1997]. The C-fiber micturition reflex is usually inactive but it was shown that it is enhanced in patients with chronic spinal-cord lesions above sacral segments [de Groat, 1997] in those with chronic bladder outlet obstruction [Chai et al., 1998] and in those with IDO [Silva et al., 2002]. In the bladders of NDO patients, the enhancement of the micturition reflex is accompanied by an increase in the number of sub-urothelial C-fibers expressing TRPV1 [Brady et al., 2004]. Curiously, NDO patients who responded better to intravesical RTX exhibited a significant decrease in the density of TRPV1 immunoreactive fibers, whereas non-responders experience a non-significant variation [Brady et al., 2004]. A decrease in TRPV1 expression in urothelial cells of NDO patients was also demonstrated after intravesical application of RTX [Apostolidis et al., 2005; 2006].

Changes in sub-urothelial C-fiber innervation expressing neuropeptides [Smet et al. 1997] or TRPV1 [Liu and Kuo, 2007] were also reported in patients with and sensory urgency. In IDO patients, responders to intravesical RTX are closely associated with the over-expression of the receptor in the bladder mucosa [Liu and Kuo, 2007]. In women with sensory urgency, TRPV1 mRNA expressed in trigonal mucosa was not only increased but also inversely correlated with the bladder volume at first sensation of filling during cystometry further indicating that TRPV1 play a role in premature bladder sensation [Liu et al., 2007].

8.2.2 Intravesical Capsaicin

Intravesical capsaicin for NDO was studied in 6 non-controlled [Fowler et al., 1992; Fowler et al., 1994; Geirsson et al., 1995; Das et al.,1996; Cruz et al., 1997; De Ridder et al., 1997] and one controlled clinical trial [de Seze et al., 1998]. Capsaicin was dissolved in 30% alcohol and 100-125 ml (or half of the bladder capacity if lower than that volume) of 1-2 mM solutions were instilled into the bladder and left in contact with the mucosa for 30 minutes. Best clinical results were found among patients with incomplete spinal cord lesions, in whom clinical improvement could be observed in up to 70-90% the patients [Fowler et al., 1994; Cruz et al., 1997; De Ridder et al., 1997]. In patients with complete spinal cord lesions the success rate was much lower [Geirsson et al., 1995].

Only one small randomized controlled study compared capsaicin against 30% ethanol, the vehicle solution. Ten patients received capsaicin and found a significant regression of the incontinence and urge sensations. In contrast, only 1 among the 10 patients that received ethanol had clinical improvement [de Seze et al., 1998].

The pungency of alcoholic capsaicin solutions has prevented the widespread use of this compound. The possibility of triggering autonomic dysreflexia with capsaicin, especially in patients with higher spinal cord lesions has progressively restrained its use. The relevance of capsaicin might however be back with a recent observation by de Sèze et al. [2006] with a new capsaicin formulation. They conducted a double-blind placebo controlled study with a glucidic solution of capsaicin in 33 NDO patients. The glucidic-capsaicin
treated group showed improvement both in symptoms and urodynamic parameters above the comparator arm. The global tolerance of this new capsaicin formulation was excellent [de Sèze et al., 2006].

### 8.2.3 RTX in NDO

Resiniferatoxin (RTX) has the advantage over capsaicin in being much less pungent [Cruz et al., 1997]. Intravesical RTX application in NDO patients was evaluated in five small open-label studies (Cruz et al., 1997; Lazzeri et al., 1997; 1998; Silva et al., 2000; Kuo, 2003). Different RTX concentrations, 10 nM, 50 nM, 100 nM and 10 μM were tested. RTX brought a rapid improvement or disappearance of urinary incontinence in up to 80% of the selected patients and a 30% decrease in their daily urinary frequency. Furthermore, RTX also increased the volume to first detrusor contraction and maximal cystometric capacity. In general, in patients receiving 50-100 nM RTX the effect was long-lasting, with a duration of more than 6 month being reported. In patients treated with 10 μM doses, transient urinary retention may occur [Lazzeri et al., 1998].

In a recent placebo-controlled study, the urodynamic effects of RTX in NDO patients was specifically evaluated. Only in the RTX arm a significant increase in first detrusor contraction and maximal cystometric capacity was found [Silva et al., 2005]. RTX also caused a significant improvement in urinary frequency and incontinence [Silva et al., 2005].

RTX, 600 nM was compared against BONT/A (Botox, 300U) in a study involving 25 patients with NDO due to chronic spinal cord injury [Giannantoni et al., 2004]. Both neurotoxins were capable of significantly reducing the number of daily incontinence episodes and improving maximum bladder capacity, although BONT/A turned out to be more effective.

### 8.2.4 RTX in IDO

The first study with intravesical RTX in IDO patients was designed as a proof-of-concept study and involved 13 patients. Intravesical RTX 50 nmol/L was associated with an improvement in volume to FDC from 170 ± 109 mL to 440 ± 153 mL at 30 days, and to 391 ± 165 mL at 90 days. An increase in mean MCC from 291 ± 60 mL to 472 ± 139 mL at 30 days and to 413 ± 165 mL at 90 days was also observed. These improvements were accompanied by a decrease in episodes of urgent incontinence and of daily frequency [Silva et al., 2002]. Subsequent small open label studies confirmed these observations using either a single high (50-100 nM) or multiple low (10 nM) dose approaches [Kuo, 2003; Dinis et al., 2004b; Kuo et al., 2005a].

The effect of RTX on refractory IDO was evaluated in two randomized clinical trials [Kuo et al., 2006; Rios et al., 2007]. Kuo et al. [2006] randomised 54 patients to receive 4 weekly instillations of a low concentration RTX solutions (10 nmol/L) or the vehicle solution, 10% ethanol in saline [Kuo et al., 2006]. Three months after completing the 4 intravesical treatments, the RTX treated group had 42.3% and 19.2% of patients feeling much better or improved, respectively. This was significantly more than in the placebo group, 14.2% and 7.1% respectively. At 6 months, treatment remained effective in 50% patients in the RTX group but only in 11% in the placebo group [Kuo et al., 2006]. Such clinical and urodynamic findings could not be reproduced in another study in which patients were randomly assigned to receive a single intravesical dose of 100 ml of either RTX 50 nM or placebo. Patients were followed-up only for 4 weeks. During this period a single 50 nM intravesical dose of RTX was not better than placebo for the treatment of women with IDO and urgency incontinence [Rios et al., 2007].

### 8.2.5 RTX and Urgency

The involvement of bladder C-fibers in IDO has led some investigators to explore the role of these sensory afferents to the genesis of urgency. In a non-controlled study involving 12 male patients with LUTS associated with BPH, mean IPSS halved following intravesical administration of RTX (50 nmoL/L). The decrease in IPSS was largely due to improvements in scores related to urgency, in addition to improvement in nocturia and frequency [Dinis et al., 2005]. In another open-label study 15 patients with intractable urgency and frequency, with or without urgency incontinence or bladder pain/discomfort, and without urodynamic evidence of DO received one single 50 nM RTX solution. A trend towards an improvement of urgency was noticed [Apostolidis et al., 2006].

In a quasi-randomised study, 23 OAB patients with refractory urgency entered a 30-day run-in period in which medications influencing the bladder function were interrupted. At the end of this period patients filled a 7-day bladder diary. Then, patients were instilled with 100 ml of 10% ethanol in saline (vehicle solution) and 3 days later a second 7-day diary was collected. Finally, patients were instilled with 100 ml of 50 nM RTX in 10% ethanol in saline and additional bladder diaries were collected at 1 and 3 months. After vehicle instillation, the mean number of episodes of urgency per week was 56 ± 11. At 1 and 3 months after RTX instillation the number of episodes of urgency decreased to 39 ± 9 (p = 0.002) and 37 ± 6 (p = 0.02), respectively [Silva et al., 2007].

### 8.2.6 Intravesical RTX and IC/PBS

TRPV1 involvement in pain has stimulated the investigation of RTX as a treatment for bladder pain in IC/PBS. After desensitization of bladder C-fibers, RTX reduces the spinal expression of c-fos, a pain evoked gene, in animal models of cystitis [Dinis et al., 2004a]. TRPV1 knock-out mice, which do not express the receptor in the bladder, do not experience an increase in the frequency of bladder reflex contractions or in the expression of c-fos in the spinal cord during cystitis [Charrua et al., 2007]. Patients with IC/PBS have more TRPV1 expressing sensory fibers in their
bladder mucosa than normal individuals [Mukerji et al., 2006].

In a placebo-controlled study of 18 patients with IC/PBS, Lazzeri et al. [2000] reported an improvement in pain and urinary frequency after administration of intravesical RTX in 10 nmol/L concentration. This effect was short-lasting, eventually due to the use of a low dose of RTX. Chen and co-workers conducted a dose-escalating study and concluded that the most commonly reported adverse event with RTX was pain during instillation. However, at 10 or 5 nM RTX was safe and could improve bladder pain [Chen et al., 2005]. Additionally, 3 non-controlled studies have also reported bladder pain improvement after intravesical RTX [Lazzeri et al., 2004; Apostolidis et al., 2006; Peng and Kuo, 2007]. A randomized, double-blind study in 163 patients with IC/PBS, in which several doses of intravesical RTX (10 nmol/L, 50 nmol/L, and 100 nmol/L) were compared with placebo, failed, however, to show any advantage for the neurotoxin over placebo in terms of overall symptoms, pain, urgency, frequency, nocturia, or average voided volume during 12 weeks of follow up [Payne et al., 2005].

9. OTHER DRUGS

9.1. Baclofen

Gamma-amino-butyric acid (GABA) is a ubiquitous inhibitory neurotransmitter in the CNS that can inhibit the micturition reflex in several points along its central pathway [de Groat, 1997; Pehrson et al., 2002]. Experimental data suggest the GABAergic system as an interesting target for bladder dysfunction therapy. Baclofen intrathecally attenuated oxyhemoglobin induced detrusor overactivity, suggesting that the inhibitory actions of GABA(B) receptor agonists in the spinal cord may be useful for controlling micturition disorders caused by C-fiber activation in the urothelium and/or suburothelium [Pehrson et al., 2002]. In spinal intact rats, intrathecal application of bicuculline induced detrusor-sphincter dysynergia (DDY)-like changes whereas intrathecal application of baclofen induced urethral relaxation during isovolumetric bladder contractions [Miyazato et al., 2009]. After spinal cord injury (SCI), Miyazato et al. [2009] found signs of hypofunction of the GABAergic system (glutamate decarboxylase 67 mRNA levels in the spinal cord and dorsal root ganglia were decreased), and showed that activation of GABA(A) and GABA(B) receptors in the spinal cord inhibited DO as evidenced by a reduction in non-voiding contractions. GABA(B) receptor activation preferentially reduced DO prior to inhibiting voiding contractions while GABA(A) receptor activation inhibited DO and voiding contraction at the same concentration.

As a GABA agonist on GABA(B) receptors, baclofen was used orally in IDO patients. However, its efficacy was poor, eventually dictated by the fact that baclofen does not cross the blood-brain barrier [Taylor and Bates, 1979]. ADX71441 is a selective positive allosteric modulator of the GABA_9 receptor (GABA_9 PAM), which is orally available and showed promising effects in animal models of micturition disturbances [Kalnichev et al., 2014]. Further studies of this agent would be of interest.

Baclofen is one of the most effective drugs for the treatment of spasticity following spinal cord injury, traumatic or hypoxic brain injury, and cerebral palsy [Ochs, 1993], and intrathecal baclofen was shown to be useful in some patients with spasticity and bladder dysfunction [Bushman et al., 1993]. Baldo et al. [2000] found a rapid (24 hours) and persistent increment in the volume to first detrusor contraction and of the maximal cystometric whereas maximal detrusor pressure decreased. At ten days, the volume to first detrusor contraction had increased from 143 ml to 486 ml. In selected patients with spasticity and bladder dysfunction, intrathecal baclofen seems to be an effective therapy.

10. COMBINATIONS

10.1. α1-AR Antagonists with Antimuscarinics or β3-AR Agonists

Traditionally, male lower urinary tract symptoms (LUTS) were thought to result from benign prostatic obstruction (BPO) secondary to benign prostatic enlargement (BPE). However, male LUTS may arise from prostatic pathology, bladder dysfunction, or both. Thus, diagnosis and appropriate treatment of men with overactive bladder (OAB) symptoms are complex and difficult. α1-AR antagonists remain the most widely used pharmacologic agents for relief of bladder outflow resistance as they relax prostatic and urethral smooth muscle tone, which is the dynamic component of BPO. In contrast, antimuscarinics, which function by competitively blocking muscarinic receptors, are the first-line pharmacologic treatment for OAB. Given the prevalence of combined voiding and OAB symptoms, as well as the finding that the quality of life (QoL) of these patients is affected primarily by the symptoms of OAB, it is logical for this category of patients to be given antimuscarinic drugs.

A number of studies have demonstrated the superior efficacy of combination treatment with an α1-AR antagonist and an antimuscarinic for alleviating symptoms of benign prostatic hyperplasia (BPH) and concomitant OAB compared to either monotherapy [Saito, et al., 1999; Athanasopoulos et al., 2003; Lee et al., 2005; Ruggieri et al., 2005; Kaplan et al., 2006, MacDiarmid et al., 2006; Kaplan et al., 2013a; van Kerrebroeck et al., 2013a; b Van Kerrebroeck et al., 2013]. The combination treatment is now recommended treatment for men with moderate-to-severe LUTS in those with predominant storage symptoms by AUA, EAU, and NICE.

The therapeutic benefits of combining an antimuscarinic agent (propiverine) with α1-AR antagonists
(tamsulosin) compared to \(\alpha_1\)-AR antagonists alone were reported by Saito and colleagues [Saito et al., 1999]. The rates of improvement in daytime frequency, incontinence, and urgency were greater in the combination group than the \(\alpha_1\)-AR antagonist-alone group. The post-void residual (PVR) was unchanged in both groups, and there was one case (1.5%) of acute urinary retention (AUR) with the combined treatment. Subsequently, Lee et al. [2005] compared the efficacy and safety of combination therapy using propiverine and doxazosin in 21 men with uro-dynamically confirmed bladder outlet obstruction (BOO) and OAB symptoms for 8 weeks. Compared with doxazosin monotherapy, patients in the combination therapy group showed greater improvement in urinary frequency, average micturition volume, and storage and urgency scores of international prostate symptom score (IPSS). Patient satisfaction was significantly higher in the combination group. There was also a significant increase in PVR (+20.7 mL) in the combination group, but no case of urinary retention was reported.

A large-scale, multicenter, randomized, double-blind, placebo-controlled trial (TIMES study) demonstrated the efficacy and safety of tolterodine extended release (ER) alone, tamsulosin alone, and the combination of both in 879 men with OAB and BPO [Kaplan et al. 2006]. In their primary efficacy analysis, 172 men (80%) receiving tolterodine ER plus tamsulosin reported treatment benefits by week 12 (\(p<0.001\) vs. placebo; \(p=0.001\) vs. tolterodine ER; \(p=0.03\) vs. tamsulosin). In their secondary efficacy analysis, patients receiving tolterodine ER plus tamsulosin compared with placebo experienced small but significant reductions in urgency incontinence, urgency episodes, daytime frequency, and nocturia. However, there were no significant differences between tamsulosin monotherapy and placebo for any dietary variables at week 12. Patients receiving tolterodine ER plus tamsulosin demonstrated significant improvements in total IPSS (\(-8.02\) vs. placebo, \(-6.19, p=0.003\)) and QoL (\(-1.61\) vs. \(-1.17, p=0.003\)). Although there were significant improvements in total IPSS among patients who received tamsulosin alone, the differences in total IPSS among patients that received tolterodine ER versus placebo were not significant. A subanalysis [Rovner et al., 2008] of data from the TIMES study focused on the urgency perception scale and concluded that the group of 217 men who received tolterodine plus tamsulosin showed significantly improved urgency variables and patient-reported outcomes. Moreover, this group of patients reported increased satisfaction with the treatment as well as a greater willingness to continue the treatment. Another subanalysis [Kaplan et al., 2008b] of data from the TIMES study examined the effects of the drugs on urinary symptoms as assessed by the IPSS. Based on this subanalysis, the authors concluded that tolterodine ER plus tamsulosin was significantly more effective than placebo in treating storage LUTS, including OAB symptoms.

Maruyama et al. [2006] reported different results in their prospective, randomized, controlled study in which naftopidil (25-75 mg/day), an \(\alpha_1\)-AR antagonist, was administered alone or in combination with propiverine hydrochloride (10-20 mg/day) or oxybutynin hydrochloride (2-6 mg/day) for 12 weeks to 101 BPH patients. In their study, the IPSS and QoL indexes improved significantly in both groups, with no marked differences between groups. Maximum flow rate (Qmax) and PVR showed an improvement trend in both groups, again with no differences between groups. However, the median post-therapeutic PVR was significantly higher in the combination group (45.0 mL) than in the monotherapy group (13.5 mL, \(p = 0.021\)). There were significantly more patients with increased residual urine volume relative to unchanged residuals in the combination therapy (22.9%) group versus the monotherapy group (5.0%, \(p = 0.038\)). The authors concluded that combination therapy with a low-dose antimuscarinic agent was not more effective than monotherapy. Moreover, although they did not encounter any cases of urinary retention, the percentage of patients with increased residual urine volume was significantly greater in the combination therapy group than in the monotherapy group.

In a large-scale, multicenter, randomized, double-blind, placebo-controlled study assessing solifenacin 5 mg as an add-on therapy to \(\alpha_1\)-AR antagonists treatment in men with residual OAB symptoms. Significant reductions in daytime frequency, the primary outcome of the study, were achieved in both solifenacin (and tamsulosin) and placebo (and tamsulosin) trials. The VICTOR trial [Kaplan et al., 2013] was a randomized, placebo-controlled study assessing solifenacin 5 mg as an add-on therapy to \(\alpha_1\)-AR antagonists treatment in men with residual OAB symptoms. Significant reductions in daytime frequency, the primary outcome of the study, were achieved in both solifenacin (and tamsulosin) and placebo (and tamsulosin) trials compared to baseline, but the difference between the two drug groups was not significant. Solifenacin add-on significantly reduced daily urgency episodes compared to placebo, but this was the only significant efficacy difference between solifenacin and placebo. Seven patients (3%) in the solifenacin group developed retention problems, with three requiring catheterisation, versus none in the placebo group. The SATURN study was a randomized, placebo-controlled trial evaluating the combination of different doses of solifenacin (3, 6, and 9 mg/day) with tamsulosin versus tamsulosin alone in men with voiding and storage LUTS [Van Kerrebroeck et al., 2013].
Decreases in micturition frequency and total urgency and frequency scores and increases in void volume per micturition were significantly greater with increasing solifenacin dosage in the combination groups versus with tamsulosin monotherapy. In a post-hoc analysis, patients with at least two urgency episodes and at least eight micturitions per 24 h at baseline showed clear improvements in storage and QoL parameters with combination treatment over tamsulosin alone. The subgroup of patients with fewer storage symptoms experienced little or no additional benefit from combination therapy compared with tamsulosin monotherapy. Combination therapy was well tolerated, and adverse events were consistent with the safety profiles of each individual compound. Mean PVR volume increased with increasing solifenacin dose, but the changes were not clinically relevant and were not accompanied by an increase in the incidence of retention.

A meta-analysis compared the efficacy and safety of treatment with α-blockers and anticholinergics to α-blocker monotherapy among men with storage urinary symptoms related to benign prostatic hyperplasia (BPH) [Filson et al., 2013]. Combination therapy produced a significantly greater reduction in IPSS storage subscore (Δ -0.73, 95% CI -1.09 - -0.37) and voiding frequency (Δ -0.69 voids, 95% CI -0.97 - -0.41) than monotherapy. There was also a greater reduction in Qmax (Δ -0.59 ml/sec, 95% CI -1.04 - -0.14) and an increase in PVR (Δ 11.60 ml, 95% CI 8.50-14.70) with combination therapy. The number of patients needed to be treated with combination therapy to cause 1 acute urinary retention episode was 101.

More recently, the efficacy and safety of a fixed-dose combination (FDC) tablet containing solifenacin 6 mg plus an oral controlled absorption system (OCAS™) formulation of tamsulosin (TOCAS) 0.4 mg has been studied in a phase III trial (NEPTUNE). NEPTUNE, which included 1,334 men with LUTS/BPH who had moderate-to-severe storage symptoms and voiding symptoms, showed that an FDC of solifenacin 6 mg plus TOCAS improved storage symptoms and QoL compared with TOCAS alone [van Kerrebroeck et al., 2013]. FDC treatment was also well tolerated and exhibited an adverse event profile similar to those reported for the individual monotherapies. Consequently, a once-daily FDC tablet of solifenacin 6 mg plus TOCAS 0.4 mg aimed at treating both storage and voiding symptoms in men with LUTS/BPH is licensed and available in several countries, including the UK. NEPTUNE and NEPTUNE II open-label extension studies further evaluated long-term (up to 52 wk) safety and efficacy of flexible dosing of two FDC of solifenacin plus TOCAS (Soli 6 mg plus TOCAS 0.4 mg or Soli 9 mg plus TOCAS 0.4mg) in men with moderate to severe storage and voiding symptoms [Drake et al., 2015]. Reductions in total IPSS and total urgency and frequency score (TUFS) during NEPTUNE were maintained for up to 52 wk of FDC treatment, with mean reductions of 9.0 (standard deviation [SD]: 5.7) and 10.1 (SD: 9.2), respectively. Ichihara et al. [2015] evaluated the efficacy and safety of add-on treatment with mirabegron for overactive bladder symptoms remaining after α1-blocker (tamsulosin) treatment in men with benign prostatic obstruction. The change in post-void residual urine volume was significantly greater in the combination group. Six patients (out of 76) experienced adverse events in the combination group, and urinary retention was observed in 1 patient. Nevertheless, the authors concluded that combination was effective and safe in these patients.

10.2. Combined Antimuscarinics

Although antimuscarinic agents are the first choice of treatment for patients with OAB symptoms, these drugs do not always lead to the desired effects of detrusor stability and continence, especially for patients with spinal cord injury or neurologic diseases such as multiple sclerosis or meningomyelecele. When antimuscarinic treatments fail, invasive procedures such as the injection of botulinum toxin, electrical nerve stimulation, or augmentation cystoplasty are necessary. In patients who failed to respond or showed suboptimal response to antimuscarinic drugs but tolerated the treatment well, it was shown that increasing the daily dose may lead to significant improvements of OAB symptoms. A significant decrease of incontinence episodes was observed after doubling the recommended daily doses of tropium chloride and tolterodine to 90 and 8 mg, respectively, in patients with persistent neurogenic detrusor overactivity (NDO) [Horstmann et al., 2006]. Another non-invasive approach in patients with refractory NDO or OAB is the combination of two different antimuscarinic drugs; this has been demonstrated as effective and safe in several clinical studies including patients with either NDO [Amend et al., 2008; Nardulli et al., 2012] or OAB [Bolduc et al., 2009; Kosilov et al., 2014a; b] (Table 3).

Positive results were speculated to be due to 1) synergistic activation of different muscarinic receptors or
interactions of receptors on different parts of the bladder wall, 2) undiscovered faster metabolism of antimuscarinics requiring an increased dosage of different antimuscarinic drugs, 3) down-regulation of subdivisions of antimuscarinic receptors under monotherapy that may lead to better susceptibility of other subdivisions when treated by the second drug.

Table 3. Clinical studies of combined antimuscarinic treatments

A combined antimuscarinic regimen using tolterodine, oxybutynin, and trosplum was evaluated as a non-invasive alternative by Amend and colleagues [Amend et al., 2008] for patients who had neurogenic bladder dysfunction with incontinence, reduced bladder capacity, and increased intravesical pressure. They added secondary antimuscarinics to the existing double-dosed antimuscarinics for patients who previously demonstrated unsatisfactory outcomes with double-dosed antimuscarinic monotherapy. After a 4-week combined regimen, incontinence episodes decreased, and reflex volume, maximal bladder capacity, and detrusor compliance increased. Side-effects were comparable to those seen with normal-dose antimuscarinics.

Kosilov and colleagues evaluated the effectiveness of cyclic therapy of combined high-dosed trosplum and solifenacin depending on severity of OAB symptoms in elderly men and women. They found that cyclic therapy of high-dose solifenacin and trosplum in elderly patients with moderate or severe symptoms of OAB enabled patients to maintain a longer therapeutic effect with an acceptable level of side effects [Kosilov et al., 2014a]. They conducted another study to evaluate the efficiency of treatment for severe symptoms of OAB with cyclic therapy of combined antimuscarinic drugs in elderly men and women and determined that cyclic therapy with combined antimuscarinics appeared to be effective for controlling severe OAB in elderly patients, increasing the compliance level (76–84%). However, continuous therapy with standard doses of trosplum and solifenacin results in low adherence and high rates of treatment withdrawal (≥ 66%) despite satisfactory clinical and urodynamic results.

The effectiveness of combination therapy with two different antimuscarinics was also evaluated in patients with severe symptoms of OAB and BPH [Kosilov et al., 2015b; Kosilov et al., 2016]. Patients in the experimental group for 2 months received treatment with a daily combination of solifenacin 5 mg and trosplum 5
mg simultaneous with tamsulosin 0.4 mg. Patients in the control group were treated only with tamsulosin. In the experimental group, the number of episodes of incontinence reduced from a moderate level of 3.4 (0.8) per day to 0.9 (0.7) per day, and most urodynamic indices normalized significantly.

In the control group, changes in urodynamic indices were not significant. The quantity of side effects did not exceed the level that is commonly found in patients receiving antimuscarinic monotherapy. The authors concluded that combination of trosuspium and solifenacin in standard doses is an efficient and safe method for managing severe symptoms of OAB over the course of treatment with tamsulosin in patients with OAB/BPH [Kosilov et al., 2016]. However, in patients with OAB/BPH, the efficacy and side effects of combination therapy using different antimuscarinics should be further evaluated.

10.3. Antimuscarinics and 5α-Reductase Inhibitors

The standard first-line medical therapy for men with moderate-to-severe LUTS is an α1-AR antagonist, a 5α-reductase inhibitor, or combination therapy with both drugs. Both α1-AR antagonist and 5α-reductase inhibitors alleviate LUTS in men by reducing bladder outlet resistance. α1-AR antagonists decrease smooth muscle tone in the prostate and bladder neck, while 5α-reductase inhibitors reduce prostate volume. Several trials have demonstrated the efficacy and safety of combination therapy with antimuscarinics and α1-AR antagonist for patients with OAB and coexisting BPO. However, post hoc analyses of the TIMES study [Kaplan et al., 2006] suggested that men with smaller prostates benefit more from antimuscarinic therapy than those with larger prostates [Roehrborn et al., 2008; Roehrborn et al., 2009]. Chung and co-workers conducted an open-label, fixed-dose study to assess the efficacy and safety of tolterodine ER in combination with dutasteride in men with large prostates (≥30 g) and persistent OAB symptoms after α1-AR antagonist before the start of the study. At the start of the study, all patients had been on dutasteride 0.5 mg daily for at least 6 months, and α1-AR antagonist therapy had failed. All patients were given 4 mg tolterodine ER daily for 12 weeks and had discontinued α1-AR antagonist before the start of the study. At 12 weeks, the frequency (-3.2/24hrs, p < 0.02), urgency (19.2%, p < 0.03), number of severe OAB episodes (71.4%, p < 0.05), and incidence of nighttime voiding (-0.9, p < 0.003) were found to have decreased significantly from baseline. IPSS decreased with dutasteride treatment (from 19.3 to 14.3) and further decreased with the addition of tolterodine to 7.1 (p < 0.001). Storage symptoms decreased from 9.8 to 4.5 (p < 0.001). Dry mouth occurred in four (7.5%) subjects, constipation in one (2%), and decreased sexual function in two (3.9%). PVR increased by 4.2 mL, Qmax decreased by 0.2 mL/s, and no patients went into retention. The authors concluded that the combination of tolterodine and dutasteride was effective, safe, and well-tolerated in men with large prostates with persistent OAB symptoms and LUTS secondary to BPO. Their results indicate that antimuscarinics are safe and effective in select patients with OAB and BPO when used in combination with 5α-reductase inhibitors. Further studies are required to verify the efficacy of antimuscarinics combined with 5α-reductase inhibitors in patients with persistent OAB symptoms and LUTS secondary to BPO.

Dutasteride was evaluated in terms of OAB symptoms and bladder ischemia in men with BPE [Wada et al., 2015]. Twenty-four weeks after dutasteride treatment, bladder vascular resistive index (RI) significantly decreased, and urgency score of IPSS was significantly improved from 2.3±1.9 to 1.4±1.4 (P < 0.01). In 20 patients with persistent urgency after dutasteride, RI was less improved than in an additional 10 patients without urgency. Post-treatment bladder outlet obstruction index (BOOI) and PdetQmax in patients with persistent urgency were significantly higher than in those without urgency after dutasteride. The authors suggested that reduction of obstruction and improvement of bladder ischemia might play important roles in the beneficial impact of dutasteride on OAB symptoms.

10.4. α1-AR Antagonists with 5α-Reductase Inhibitors

The Medical Therapy of Prostatic Symptoms Study (MTOPS) and Combination of Avodart® and Tamsulosin study (ComBAT) have demonstrated that superiority of combinations of α1-AR antagonists with 5α-reductase inhibitors over monotherapy for improving clinical outcomes and preventing symptomatic progression, risk of AUR, and BPH-related surgery [McConnell et al., 2003; Roehrborn et al., 2010]. Currently, a combination of α1-AR antagonist with a 5α-reductase inhibitor is recommended by the American Urological Association (AUA) and European Association of Urology (EAU) for men with bothersome moderate to severe LUTS, high risk of disease progression-enlarged prostate (prostate volume > 40 mL), and higher PSA [McVary et al., 2011; Oelke et al., 2013]. The possible disadvantage of combinations of α1-AR antagonists with 5α-reductase inhibitors is the increased incidence of adverse events, since there are concomitant effects of both classes of drugs [Fullhase et al., 2013; La Torre et al., 2016]. Potential side effects (e.g., ejaculation dysfunction with α1-AR antagonists or loss of libido with 5α-reductase inhibitors) might be additive and may negatively affect patient quality of life and, especially, sexual function.

10.5. Antimuscarinic with β3-Adrenoceptor Agonists

Since the mechanism of action of β3-adrenoceptor agonists is different from that of antimuscarinics, it might prove to be a useful treatment in patients experiencing adverse events to antimuscarinics or insufficient symptom improvement. In addition, combining
β3-AR agonist with an antimuscarinic may potentially improve efficacy in the treatment of OAB. Several clinical trials have demonstrated the efficacy and safety of the combination therapy of antimuscarinics and β3-AR agonists. Abrams et al. reported results of a phase II trial (Symphony) of combination treatment with mirabegron and solifenacin in patients with OAB [Abrams et al., 2015]. A total of 1306 patients were randomly assigned to 12 groups: placebo, 6 combination groups (solifenacin 2.5, 5, or 10 mg plus mirabegron 25 or 50 mg), and 5 monotherapy groups (solifenacin 2.5, 5, or 10 mg, or mirabegron 25 or 50 mg) for a 12-week treatment period. The primary endpoint was change from baseline to end of treatment in mean volume voided per micturition (MVV). All combinations with solifenacin 5 or 10 mg improved MVV significantly comparing to solifenacin 5 mg monotherapy, and a decreasing trend in the mean number of micturitions per 24 hours was observed with increasing solifenacin and mirabegron doses. The three drug combinations (solifenacin 5 mg plus mirabegron 50 mg, solifenacin 10 mg plus mirabegron 25 mg, and solifenacin 10 mg plus mirabegron 50 mg) demonstrated significant improvements compared to both solifenacin 5 mg and placebo.

No severe adverse events were reported, and treatment was generally well tolerated. In Japan, Yamaguchi et al. conducted a multicenter, open-label, phase IV study (MILAI study) to assess the safety and efficacy of mirabegron in combination with solifenacin in OAB patients who were being treated with solifenacin 2.5 mg or 5 mg once daily for at least 4 weeks [Yamaguchi et al., 2015]. A total of 223 patients were randomly assigned to one of 4 groups: solifenacin 2.5 mg plus mirabegron 25 mg (n=35), solifenacin 2.5 mg plus mirabegron 50 mg (n=37), solifenacin 5 mg plus mirabegron 25 mg (n=58), or solifenacin 5 mg plus mirabegron 50 mg (n=93) for a 16-week treatment period.

The overall incidence of drug-related TEAEs was 23.3%, and all TEAEs were mild or moderate. All treatments showed significant improvements in OABSS total score, overactive bladder questionnaire short form (OAB-q SF) score (symptom bother and total HRQL score), mean number of micturitions/24 h, mean number of urgency episodes/24 h, mean number of UI episodes/24 h, mean number of urgency UI episodes/24 h, mean volume voided/micturition, and mean number of nocturia episodes/night.

Recently, a phase IIIb trial (BESIDE) in incontinent OAB patients was carried out in Europe [Drake et al., 2016]. A total of 2174 patients with OAB who remained incontinent despite solifenacin 5 mg once daily during 4-wk single-blind run-in were randomized 1:1:1 to a double-blind daily combination (n=727), solifenacin 5 mg (n=728), or 10 mg (n=719) for 12 wk. The primary efficacy end-point was change in mean number of incontinence episodes per 24 h. Key secondary efficacy end points were change in mean number of micturitions per 24 h and the number of incontinence episodes noted in the 3-d voiding diary. All combinations significantly improved daily incontinence episodes (p<0.001), daily micturitions (p<0.001), and incontinence noted in a 3-d voiding diary (p=0.014) compared to solifenacin 5 mg monotherapy. The combination of drugs was not inferior to solifenacin 10 mg for key secondary end points and was superior to solifenacin 10 mg for improving daily
micturitions. All treatments were well tolerated. These results suggest that combination therapy of mirabegron 50 mg with solifenacin 5 mg may be an alternative to dose escalation of solifenacin in patients with insufficient response to solifenacin 5 mg monotherapy.

11. FUTURE POSSIBILITIES

Much nonclinical and clinical research is ongoing, both involving modifications of existing options and directed at identifying novel pharmacological principles involved in LUTS/OAB pathophysiology, and this has been extensively discussed in several reviews [Yeo et al., 2013; Zacche et al. 2014; Sacco and Bientinesi, 2015; Bechis et al. 2015; Andersson, 2015; 2016]. Details on some of the drugs under discussion are given below as is a critical summary of the current situation (Table 4).

11.1. Peripherally Acting Drugs

11.1.1 P2X3-Receptors and P2X3 Receptor Antagonists

During bladder filling the urothelium is stretched and ATP is released from the umbrella cells, thereby activating mechanotransduction pathways via stimulation of purinergic receptors on suburothelial sensory nerves to initiate the voiding reflex and to mediate the sensation of bladder filling and urgency [Burnstock, 2013; 2014]. P2X receptors are ligand-gated ion channels (Figure 19), and seven P2X receptor subunits have been identified from molecular studies and characterized functionally and pharmacologically [North and Surprenant, 2000; Gever et al., 2006; Ford and Cockayne, 2011]. Sensory nerve fibers expressing P2X3 immunoreactivity have been found projecting into the lamina propria, urothelium and detrusor smooth muscle (Ford and Cockayne, 2011), where this and several other P2X receptors are functionally expressed (Ford and Cockayne 2011; Shabir et al., 2013). As mentioned, ATP is released from the urothelium in response to bladder filling [Ferguson et al., 2007; Vlaskovska et al., 2001; Wang et al., 2005a], and studies using an isolated rodent bladder-pelvic nerve preparation have shown that bladder distension leads to increased afferent nerve activity that is mimicked by ATP and/or α,β-meATP [Namavariyam et al., 2009; Vlaskovska et al., 2001; Rong et al., 2002]. Intravesical infusion of ATP or α,β-meATP can directly stimulate bladder overactivity in conscious rats, in a manner that is concentration-dependent and sensitive to the ATP receptor antagonist, TNP-ATP [Pandita and Andersson, 2002]. Thus, P2X3 and P2X2/3 receptors may be important in sensing volume changes during normal bladder filling, and may participate in lowering the threshold for C-fiber activation under pathophysiological conditions.

Purinergic signaling in the bladder may be changed in different LUT disorders [Burnstock, 2014]. Thus, bladder inflammation can sensitize and enhance P2X receptor function on pelvic visceral and hypogastric splanchnic afferents in the lumbosacral and thoracolumbar DRG [Dang et al., 2005]. In bladder urothelial cells from patients with bladder pain syndrome/interstitial cystitis (BPS/IC), P2X3 receptor expression appears to be abnormally up-regulated in response to stretch [Sun and Chai, 2004; Sun et al., 2009]. An increased density of P2X3 and TRPV1-expressing nerve fibers has been observed in the bladders of patients with neurogenic detrusor overactivity, and following treatment with resiniferatoxin, patients responding to treatment showed diminished levels of both TRPV1 and P2X3 immunoactivity [Brady et al., 2004].

P2X receptors, and in particular P2X3 receptors, have been of interest for treatment of LUT disorders for a long time [Ford et al., 2006; Ford and Cockayne, 2011; Ford, 2012; North and Jarvis, 2013]. Selective P2X3 antagonists, such as A-317491, were shown to effectively reduce the signs of cyclophosphamide-induced cystitis [Ito et al., 2008], and to improve bladder function in a rat spinal cord injury (SCI) model [Lu et al., 2007]. A-317491 produced a dose-dependent inhibition of non-micturition contractions, increased
inter-micturition intervals, and bladder capacity, without influencing the amplitude of voiding contractions. Munoz et al. [2012] showed that SCI rats had significantly higher frequencies for field potentials and non-voiding contractions than normal rats. Intravesical ATP increased field potential frequency in control but not SCI rats, while systemic administration of the P2X3/P2X2/3 antagonist, AF-353 [Gever et al., 2010], significantly reduced this parameter in both groups. AF-353 also reduced the inter-contractile interval in control but not in SCI rats; however, the frequency of non-voiding contractions in SCI rats was significantly reduced. AF-353 was also studied in a closed cystometric model (“refill VIBC”) in a urethane anesthetized rat model. A dose-dependent increase in volume threshold by up to 50–70%, with slightly reduced frequency, but no appreciable change in amplitude was demonstrated [Ford and Cockayne, 2011]. As AF-353 penetrates the blood–brain barrier [Gever et al., 2010], it was not clear whether these effects resulted from P2X3 antagonism at peripheral terminals within the bladder wall, or alternatively at central terminals in the spinal cord dorsal horn. It has been suggested that ATP can be released and act on spinal P2X3 and P2X2/3 receptors to affect afferent signals originating from the bladder [Ford, 2012]. Spinal ATP may then constitute an endogenous central presynaptic purinergic mechanism to regulate visceral sensory transmission. Further characterization of this spinal purinergic control in visceral activities may help the development of P2X3 and P2X2/3 antagonists to treat urological dysfunction, such as overactive bladder [Ford, 2012].

11.1.2 TRP Channel Antagonists

The transient receptor potential (TRP) channel superfamily has been shown to be involved in nociception and mechanosensory transduction in various organ systems, and studies of the LUT have indicated that several TRP channels, including TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1, are expressed in the bladder, and may act as sensors of stretch and/or chemical irritation [Araki et al., 2008; Everaerts et al., 2008; Andersson et al., 2010; Skryma et al., 2011; Avelino et al., 2013; Deruyver et al., 2014; Franken et al., 2014]. TRPV1 and TRPV4 channels have been found to be expressed in the urinary bladder [Tominaga et al., 1998; Birder et al., 2001; Gevaert et al., 2007]. TRPV1 is present and active both in the urothelium and in the nerve fibers of several species including humans [Ji et al., 2002; Charrua et al., 2009]. TRPV4 was initially described in the urothelium of rodents and humans [Janssen et al., 2011]. Co-expression of the two receptors was observed in 20% of rat urothelial cells [Kullmann et al., 2009]. Recent observations indicate, however, that TRPV4 may also be expressed in bladder afferents. In fact, about 30% of L6 dorsal root ganglia neurons that project to the urinary bladder co-express TRPV1 and TRPV4 [Cao et al., 2009; Charrua et al., 2012]. The physiological meaning of this observation is unclear.

TRPV1 KO mice have a normal or quasi-normal phenotype. In awake animals, the only change detected in TRPV1 KO mice was a smaller volume per void when compared with wild type (WT) controls [Birder et al., 2001]. In cystometries performed under anaesthesia, the TRPV1 KO mice phenotype seems also

Figure 19: During bladder filling the urothelium is stretched and ATP is released from the umbrella cells, thereby activating mechanotransduction pathways via stimulation of purinergic receptors on suburothelial sensory nerves to initiate the voiding reflex and to mediate the sensation of bladder filling and urgency. Selective P2X3 antagonists have been shown to decrease signs of bladder overactivity in different animal models without affecting bladder contraction amplitude.
very benign. Some studies reported that this animals have totally normal cystometric traces [Charrua et al., 2007]. However, other studies showed that TRPV1 KO mice develop a few non-voiding contractions preceding the voiding contraction [Birder et al., 2001; Frias et al., 2012]. Accordingly, TRPV1 antagonists (GRC 6211) did not show any relevant effect on bladder activity of intact rodents [Charrua et al., 2009b]. In contrast with TRPV1 KO mice, the micturition phenotype of TRPV4 KO animals is clearly abnormal. TRPV4 KO mice are incontinent, most probably due to incomplete bladder emptying [Gevaert et al., 2007] Cystometric studies carried out under physiological conditions revealed that TRPV4 KO mice have an marked increase in the inter-contraction interval when compared to wild-type (WT) littermates. [Gevaert et al., 2007; Birder et al. 2002]. Likewise, TRPV4 antagonists (HC-067047) decreased the frequency of bladder contractions and increased the inter-contraction interval [Everaerts et al., 2010]. These observations indicated that TRPV4 has a role in the control of normal micturition reflex.

Indisputably, TRPV1 or TRPV4 have a role in the increase of micturition frequency associated with cystitis [Charrua et al., 2007; Everaerts et al., 2010]. While inflamed WT mice exhibit bladder hyperactivity and intense spinal Fos expression after different forms of bladder inflammation, including acetic acid or bacterial extracts, TRPV1 KO mice have normal cystometries and normal spinal c-fos expression [Charrua et al., 2007]. The same holds true for TRPV4. In fact, TRPV4 KO mice exhibit significantly lower voiding frequencies and larger voided volumes than WT after inflammation with cyclophosphamide [Everaerts et al., 2010].

The blockade of TRPV1 and TRPV4 with specific antagonist confirm the observations carried out in knock-out animals. As a matter of fact, the TRPV1 antagonist GRC 6211 or the TRPV4 antagonist HC-067047 both abolish the increase of micturition frequency associated with chemical cystitis [Everaerts et al., 2010; Charrua et al., 2009b]. Recently, it was shown that the systemic co-administration of TRPV1 and TRPV4 antagonist was more effective in treating the cystitis-induced increase of micturition frequency than the individual application of each antagonist [Charrua et al., 2012b]. The effect could be observed at very low doses of the TRPV1 and TRPV4 antagonists, which had no effect when given isolated. This observed effect might be the answer to overcome the eventual adverse events related with the application of some of these antagonists [Planells-Cases et al., 2011]. Just to mention a few, TRPV1 antagonists are associated with hyperthermia and increased risk of cardiac ischemia [Avelino et al., 2012] while TRPV4 antagonists may eventually precipitate urinary retention and overflow incontinence [Gevaert et al., 2007].

It is known for long that TRPV1 is involved in the emergence of neurogenic detrusor overactivity following spinal cord transaction [Avelino & Cruz, 2006]. A TRPV1 antagonist GRC 6211 has been shown to decrease reflex detrusor overactivity in rats after chronic spinal cord transaction. With increasing doses, it was possible to obtain a total suppression of bladder activity [Santos-Silva et al., 2012]. Kitagawa et al. [2013] evaluated the effects of the selective TRPV1 antagonist JTS-653 evaluated the effects of JTS-653 on the increased pelvic nerve discharge and intravesical pressure induced by intravesical infusion of capsaicin, in anesthetized rats. The drug significantly suppressed both parameters (Figure 20). The clinical relevance of this finding will be certainly further investigated in the future. Interestingly, Uvin et al. [2015] found evidence for involvement of TRPM8 in rat and mouse models of acute cold-induced urinary urgency.

There seem to be several links between activation of different members of the TRP superfAMILY and LUTS/DO/OAB, and further exploration of the involvement these channels in LUT function, normally and in dysfunction, may be rewarding. However, proof of concept studies in humans are still lacking.

11.1.3 Vitamin D3 Receptor Analogues

It is well known that vitamin D affects skeletal muscle strength and functional efficiency, and vitamin D insufficiency has been associated with notable muscle weakness. The levator ani and coccygeus skeletal muscles are critical components of the pelvic floor and may be affected by vitamin D nutritional status. Weakened pelvic floor musculature is thought to be associated with the development of urinary incontinence and fecal incontinence symptoms. Aging women are at increased risk for both pelvic floor dysfunction as well as vitamin D insufficiency [Kilic et al., 2016], and to date only case reports and observational studies have shown an association between insufficient vitamin D and pelvic floor dysfunction symptom severity (Parker-Autry et al., 2012). Rat and human bladders were shown to express receptors for vitamin D [Crescioli et al., 2005], which makes it conceivable that the bladder may also be a target for vitamin D. Analogues of vitamin D3 have also been shown to inhibit benign prostatic hyperplasia (BPH) cell proliferation and to counteract the mitogenic activity of potent growth factors for BPH cells [Crescioli et al., 2002; 2003; 2004]. Experiments in rats with bladder outflow obstruction, Schröder et al. [2006] showed that a vitamin D analogue, BXL-628 (elocalcitol), at non-hypercalcemic doses, did not prevent bladder hypertrophy, but reduced the decrease in contractility of the bladder smooth muscle which occurred with increasing bladder weight [Schröder et al., 2006]. The mechanism of action for the effects has not been clarified. However, elocalcitol was shown to have an inhibitory effect on the RhoA/Rho kinase pathway [Morelli et al., 2007]. Upregulation of its pathway has been associated with bladder changes associated with diabetes, outflow obstruction, and DO [Peters et al., 2006; Christ and Anderson, 2007]. In rats with outflow obstruction, previous elocalcitol-treatment improved the effects of tolerodine on bladder compliance [Streng et al., 2012]. It
was suggested that in rats elocalcitol exerted additional beneficial actions on outflow obstruction-induced functional changes during the filling phase of micturition, which may support combined therapy in BPH-related LUTS. If valid in humans, combined therapy with the drug would be of value.

The effect of elocalcitol on prostate volume was evaluated in patients with BPH, and it was found that the drug was able to arrest prostate growth within 12 weeks in men aged ≥50 years with prostatic volume > 40 ml [Colli et al., 2006]. In an RCT enrolling 120 female patients with OAB, where the primary endpoint was an increase in the mean volume voided, a significant increase vs placebo (22% vs 11%) was demonstrated [Colli et al., 2007]. Whether or not vitamin D receptor agonism (monotherapy or in combination) will be a useful alternative for the treatment of LUTS/OAB, requires further RCTs. However, currently, the development of the drug seems to be stopped [Tiwari, 2009].

11.1.4 Prostanoid Receptor Agonists/Antagonists

Recent developments in the field of prostanoid receptors may open new possibilities to use selective prostanoid receptor antagonists for DO/OAB treatment [Aoki et al., 2009; Jones et al., 2009; Rahnama’i et al., 2012; Dobrek and Thor, 2015]. There is evidence suggesting that PGE2 contributes to the pathophysiology of DO/OAB: PGE2 infused into the bladder induces DO in humans and animals, increases PGE2 production in DO models and there are high concentrations of PGE2 in the urine of patients with OAB [McCafferty et al., 2008]. PGE2 is an agonist at EP receptors 1 to 4, all G-protein coupled, which mediate its physiological effects. Based on studies using knockout (KO) mice and EP1 receptor antagonists, it was suggested that the effects of PGE2 on bladder function were mediated through EP1 receptors (Schroder et al., 2004). EP receptors can be found on urothelium/urothelium, in detrusor smooth muscle and in intramural ganglia [Rahnama’i et al., 2010; Rahnama’i et al., 2011]. Functionally, it has been proposed that modulation of bladder activity exerted via EP1 receptors occurs via an afferent mechanism. Schröder et al. [2004] found no difference in urodynamic parameters between unobstructed EP1 receptor KO and WT mice. However, EP1 receptor KO mice did not respond to intravesical PGE2 instillation, while WT mice developed DO. The lack of EP1 receptor did not prevent bladder hypertrophy due to partial bladder outflow obstruction but after obstruction WT mice had pronounced DO, while this was negligible in EP1 receptor KO mice.

Lee et al. [2008] found that in normal rats, a selective EP receptor antagonist significantly increased bladder capacity, micturition volume and micturition intervals. The antagonist significantly decreased the stimulatory effects of PGE2, and decreased the frequency and amplitude of nonvoiding contractions in animals with BOO. More recently it has been shown that also EP3 receptor KO mice have a diminished response to bladder infusion of PGE2, and demonstrate an enhanced bladder capacity

![Figure 20: Effect of the selective TRPV1 antagonist JTS-653 given intravenously on capsaicin induced increase in pelvic nerve firing frequency (A) and IVP (B) in anesthetized rats. Modified from Kitagawa et al., J Urol. 2013 Mar;189(3):1137-46.](image-url)
under basal conditions [Jones et al., 2009]. This findings suggest an important contribution for EP3 receptors in the modulation of bladder function under physiological conditions as well as under conditions of enhanced PGE2 production evoking DO. Thus, EP1 and EP3 receptors may have a role in PGE2 mediated DO.

Interestingly, activation of EP3 receptors evoked diuresis and EP3 receptor antagonism was found to induce an anti-diuretic effect [Jugus et al., 2009]. Thus, to modulate bladder activity, it appears that the EP3 receptor has a role in regulating urine production. Both effects may be useful for treatment of DO/OAB. It cannot be denied that EP1/EP3 receptors constitute interesting and promising targets for drugs aimed at DO/OAB treatment. However, a randomised, double-blind, placebo-controlled phase II study to investigate the efficacy and safety of the EP-1 receptor antagonist, ONO-8539, in patients with the overactive bladder syndrome suggests that the role of EP1 receptor antagonism in the management of OAB syndrome is minimal [Chapple et al., 2011].

11.1.5 Cannabinoids

There is increasing evidence that cannabinoids can influence micturition in animals as well as in humans, both normally and in bladder dysfunction [Ruggieri, 2011; Hedlund, 2014: Hedlund and Gratzke, 2016]. The effects of the cannabinoids are exerted via two types of well defined receptors, CB1 and CB2, distributed widely in the body. However, additional receptor subtypes cannot be excluded [Pertwee et al., 2010; Ruggieri, 2011]. Both in the CNS and in peripheral tissues, CB1 and CB2 receptors have been identified; centrally CB1 and peripherally CB2 receptors seem to be predominant [Pertwee et al., 2010; Ruggieri, 2011] CB1 as well as CB2 receptors have been identified in all layers of the human bladder [Merriam et al., 2008; Gratzke et al., 2009; Tyagi et al., 2009; Walczak et al., 2009]; their expression in the urothelium was found to be significantly higher than in the detrusor, and the expression of CB1 was higher than that of CB2 [Tyagi et al., 2009; Gratzke et al. [2009] found higher expression of CB2 receptors, but not CB1 receptors, in the mucosa than in the detrusor. Compared to the detrusor, larger amounts of CB2 receptors containing nerves that also expressed TRPV1 or CGRP were observed in the suburothelium. Nerve fibers containing CB2 receptors and VACHT (cholinergic neurons) were located in the detrusor. In general, activation of CB1 peripherally has been associated with vasodilation and motility changes via suppression of release of neurotransmitters, whereas activation of CB2 appears to induce anti-inflammatory, antinoceptive, and immunosuppressive actions [Pertwee et al., 2010; Ruggieri, 2011]. Several animal studies have suggested a modulatory role of CB2 receptors in both afferent signalling and cholinergic nerve activity [Gratzke et al., 2009; 2010; 2011]. Thus, in vivo the selective CB2 receptor agonist, cannabinor, increased micturition intervals and volumes, and increased threshold and flow pressures, suggesting that peripheral CB2 receptors may be involved in sensory functions. In rats with partial urethral obstruction treated daily for 14 days with cannabinor, bladder weight was lower, the ability to empty the bladder was preserved and nonvoiding contraction frequency was low compared to those in controls.

The key enzyme for the degradation of anandamide and other endogenous cannabinoids, is fatty acid amide hydrolase (FAAH). FAAH was found to be expressed in rat and human urothelium and was coexpressed with CB2 receptors. In rats, a FAAH inhibitor altered urodynamic parameters that reflect sensory functions, suggesting a role for the endocannabinoid system in bladder mechnoafferent functions [Strittmatter et al., 2011]. Aizawa et al. [2016] found that URB937, a peripherally restricted FAAH inhibitor, reduced BO and C-fibre hyperactivity in the rat bladder provoked by PGE2, suggesting an important role of the peripheral endocannabinoid system in bladder overactivity and hypersensitivity. Charrua et al. [2016] showed that URB937 in LPS induced cystitis decreased voiding contactions on a dose dependent manner in low to moderate doses. In high doses the FAAH inhibitor did the opposite effect, increasing voiding frequency. Moreover, in the same model of cystitis URB937 in the doses that decreased bladder overactivity decreased the levels of anandamide and increase the levels of palmitoylethanolamide in the bladder tissue. Therefore, more studies are necessary in this field to clearly understand the dynamic of endocannabinoids in peripheral tissues. In addition, there seem to be no clinical studies assessing the effects of FAAH inhibitors on LUTS or on LUT visceral functions in humans [Hedlund and Gratzke, 2016].

It has not been established whether the effects of the cannabinoids are exerted in the CNS (brain, spinal cord) or peripherally. In a preliminary report Blywert et al. [2003] demonstrated an effect of combined CB1/CB2 receptor activation on detrusor overactivity in rats with spinal cord transection, which seemed to exclude the brain as a main site of action.

The clinical experiences the cannabinoid treatment of micturition disturbances incluing LUTS are limited [Ruggieri, 2011], but both open-label and placebo-controlled studies have demonstrated that orally administered cannabinoid modulators may alleviate neurogenic overactive bladder (OAB) symptoms refractory to first-line treatment [Brady et al., 2004b; Freeman et al., 2006; Kavia et al., 2010]. Brady et al. [2004b] evaluated the efficacy of 2 whole plant extracts (δ9-tetrahydrocannabinol and cannabidiol) of Cannabis sativa in patients with advanced MS and refractory LUTS. Urinary urgency, the number and volume of incontinence episodes, frequency and nocturia decreased significantly following treatment. Freeman et al. [2006] tested in a subanalysis of a multicenter trial (the CAMS study) whether cannabinoids could decrease urge incontinence episodes without affecting voiding in patients with MS. The CAMS study randomized 630 patients to receive oral
administration of the cannabis extract δ9-tetrahydrocannabinol or matched placebo. Based on incontinence diaries a significant decrease in incontinence episodes was demonstrated.

Kavia et al. [2010] assessed the efficacy, tolerability and safety of Sativex® (nabiximols) as an add-on therapy in alleviating bladder symptoms in patients with MS. They performed a 10-week, double-blind, randomized, placebo-controlled, parallel-group trial on 135 randomized subjects with MS and overactive bladder (OAB). The primary endpoint, reduction in daily number of urinary incontinence episodes from baseline to end of treatment (8 weeks), showed little difference between Sativex and placebo. However, four out of seven secondary endpoints were significantly in favour of Sativex, including number of episodes of nocturia, number of voids/day, and number of daytime voids. The improvement in I-QOL was in favour of Sativex, but did not reach statistical significance.

Systemic cannabinoids have effects on the lower urinary tract that may have a therapeutic potential; local delivery (intravesical, spinal) may be possible, but more information is needed. The mechanisms of cannabinoid receptors in control of the human LUT is incompletely known, and further research is necessary for the development of novel cannabinoid drugs for treatment of LUT disorders. In a recent review, Hedlund and Gratzke [2016] concluded that currently “the endocannabinoid system can be considered as a potential drug target for pharmacological management of LUTS, with a more favourable adverse event profile than antimuscarinic agents”.

11.1.6 Intraprostatic Injections of Drugs.

Intraprostatic injection therapy is probably the oldest minimally invasive surgical therapy for BPH and has been investigated for over 100 years with renewed interest recently. There are different injectables and various routes of administration, transperineal, transrectal and transurethral (Andersson, 2015).

11.1.7 Ethanol

Ethanol injection is one of the most investigated intraprostatic therapies and have been investigated for more than a decade [Goya et al., 1999]. However, the mechanism of action, patient selection and application of ethanol (the number of injection sites and the injection volume) have not been well investigated and long-term results are scarce. It seems that ethanol causes inflammation, coagulative necrosis with protein denaturation and cell membrane lysis, and, finally, sloughing of prostatic tissue resulting in cavity formation [Plante et al., 2003]. The majority of trials demonstrated a significant reduction in symptoms and post-void residual volume as well as a significant improvement in Qmax and QoL and prostate volume also decreased significantly in the majority of studies [Goya et al., 2004; Grise et al., 2004; Plante et al., 2007; Sakr et al., 2009]. The durability of clinical effects beyond 1 year seems poor. One trial with a mean follow-up of 3 years showed a retreatment rate of 41% [Goya et al., 2004].

11.1.8 BoNT/A

BoNT-A investigation for the treatment of benign prostatic enlargement (BPE) due to benign prostatic hyperplasia (BPH) started in 2003 [Maria et al., 2003] after the experimental study by Doggweiler et al. [1998] demonstrating prostatic atrophy in the rat after intraprostatic injection of the neurotoxin. In an exploratory study, which involved injection of 200 U of onabotA in moderate to large prostate glands, a rapid prostate volume decrease was induced and still present at 12 months [Maria et al., 2003]. Following this study, Kuo [2005] reported similar findings when injecting prostate glands of 50 ml or larger. BoNT/A injection in smaller prostate glands caused a much lesser reduction in prostate volume, but a 15% reduction was still observed [Chuang et al., 2005; Chuang et al., 2006c]. Independent of the extent of prostate volume reduction, improvement of LUTS and flow were consistently reported [Maria et al., 2003; Kuo, 2005; Chuang et al., 2005; Chuang et al., 2006c], while a decrease in total serum PSA were observed only in some studies [Maria et al., 2003; Guercini et al., 2005]. In a multicenter, double-blind, randomized phase II clinical trial of 100 and 300 unit doses of onabotA to treat the lower urinary tract symptoms of BPH, Crawford and coworkers concluded that intraprostatic injection of 100 or 300 units of onabotA passed predetermined criteria for treatment efficacy and safety (30% improvement from baseline to 3 months in American Urological Association symptom index and/or maximum urinary flow rate and safety). The ideal dose was not found, but it seemed that the 100 U dose may be preferable due to similar efficacy with reduced costs and adverse effects [Crawford et al., 2011]. Some serious adverse events were reported, including 3 cases of urosepsis related to the onabotA injection. Other minor adverse events reported were urinary tract infection, pelvic pain, urinary retention, macroscopic hematuria and hemat-osphemia [Crawford et al., 2011].

Silva et al. [2008], selected a particular group of patients with high co-morbidity in which more invasive treatments were contraindicated. Intraprostatic BoNT/A injection was carried out transrectally, under ultrasound guidance. Twenty-one men with large BPE, 70±10 ml, on chronic indwelling catheter for at least 3 mo who were not candidates for surgery because of poor general condition received 200 U BoNT/A in the transition zone. Baseline prostate volume of decreased to 57±10 ml at 1mo and to 47±7ml at 3 months. At 1 month, 16 patients (76%) could resume voiding with a mean Qmax of 9.0±1.2 ml/s. At 3 months, 17 patients (81%) voided with a mean Qmax of 10.3±1.4 ml/s. Residual urine was not significant and mean serum total PSA showed a slight decrease [Silva et al. 2008]. The analysis of 11 patients
of the initial cohort showed that the duration of prostate atrophy after the single injection of 200U of BoNT/A was found to be about 18 months [Silva et al., 2009b].

Intraprostatic injection of BoNT/A seems devoid of sexual adverse events. Sixteen sexually active men aged > 60 years with BPH/benign prostatic enlargement (BPE) refractory to standard medical therapy received 200U of BoNT/A by transrectal route. Erectile function was evaluated using the International Index of Erectile Function – Short Form (IIEF-5) questionnaire. Orgasmic/ejaculatory function and libido were evaluated using questions 9, 10, 11 and 12 of the IIEF – Long Form. Intraprostatic injection of BoNT/A did not cause deterioration of any domain of sexual function [Silva et al., 2011].

Although necrosis of the gland at the places of BoNT/A injection could explain the rapid volume reduction, transrectal ultrasound examination of the glands, performed in those or in previous studies [María et al., 2003; Kuo 2005; Chuang et al., 2005; Silva et al., 2008, was unable to detect signs of cavitation that indirectly could suggest the presence of necrosis. Therefore, the reason for the decreased prostate volume should be more appropriately related to the widespread apoptosis detected in the gland after BoNT/A administration. Apoptosis was reported in rats, dogs, and humans, and affected both the epithelial and stromal components [Dogweiler et al., 1998; Chuang et al., 2005; Chuang et al., 2006b; Chuang et al., 2006d, Silva et al., 2009a].

Although until now, no important side-effects have been reported after intraprostatic injection of the neurotoxin in doses ranging between 100 and 300 U, a multicenter, double-blind, randomized phase II clinical trial of 100 and 300 unit doses of onabotA to treat the lower urinary tract symptoms of benign prostatic hyperplasia, was recently published [Crawford et al., 2011]. OnabotA prostate injection met the two safety criteria proposed, (a dose failed if: 1- a life threatening, disabling or fatal event was determined to be related to the onabotA injection, or 2- 40% or more of the participants reported a moderate or severe side effect related to the botulinum toxin injection). Nonetheless, some serious AEs were reported, including 3 cases of urosepsis related to the onabotA injection and the remaining events were judged not related to the injection. Other minor AEs reported were urinary tract infection, pelvic pain, urinary retention, macroscopic hematuria and hematospermia [Crawford et al., 2011].

These findings were not reproduced however, in two recent, large RCTs. One enrolled patients with IPSS > 12 and a peak flow rate (Qmax) between 5-15 ml/s [Marberger et al., 2012]. A total of 380 men met the inclusion/exclusion criteria, were randomized (ITT population), and received treatment via the transperineal (n = 63) or transrectal (n = 311) routes with either placebo (n = 94) or onabotA 100 U (n = 95), 200 U (n = 94), or 300 U (n = 97). The other [McVary et al., 2014] enrolled 427 men with IPSS score > 14 and Q max between 4 to 15 ml/s. All received initially a sham procedure to exclude cases with a high placebo response during the run-in phase. Then a total of 315 patients were randomized 1:1 to receive a single intraprostatic treatment of onabotA 200U or placebo. Although in both studies a substantial decrease in IPSS score and increase in Qmax occurred in the onabotA 200 U groups, the changes were not significantly different from those observed in the saline arm, indicating that they arose from a considerable placebo effect associated with the injection procedure.

The population enrolled in the Marberger and McVary trials may vary from those usually referred to minimal invasive BPH procedures. As a matter of fact, 51% of the men enrolled in the Marberger study, although having moderate to severe LUTS had never received treatment with licensed drugs for BPH/LUTS. In the McVary study [2014], 78.3% of the patients were not on α-AR antagonists or 5ARI when they were enrolled in the study. From a total of 313 patients only 68 (21.7%) were on treatment, while all the others had meanwhile abandoned oral pharmacotherapy. Interestingly, patients unsatisfied with medical treatment for their BPH/LUTS seem to respond more positively to onabotA injection in the prostate. In the Marberger trial, an exploratory post hoc analysis of the subgroup of patients who had received α-AR antagonists showed a significant reduction from baseline in IPSS in the onabotA 200-U group versus placebo. A sub analysis of the population on concurrent BPH therapy in the McVary study showed an improvement in Qmax that was significantly greater in the onabotA than in the placebo arm.

Recently, a non-inferiority randomized clinical trial compared in BPH patients dissatisfied with oral pharmacotherapy prostate injection of onabotA 200 U against optimized medical therapy [Robert et al., 2015]. Patients on optimized drug therapy received any possible drug combination for treatment of BPH/LUTS. The group submitted to toxin injection stopped oral medication 30 days after the procedure. Total IPSS at the end of treatment was similar in the two arms, allowing the conclusion that onabotA is not inferior to optimized medical therapy, in men with BPH/LUTS refractory to initial oral pharmacotherapy. Interestingly, in the onabotA group only 1 episode of acute urinary retention occurred. In contrast, 6 cases were observed in the optimized medical treatment group.

11.1.9 NX-1207

NX-1207 is a new drug under investigation for the treatment of LUTS associated with BPH [Kunit and Lusuardi, 2014]. It is a new therapeutic protein of proprietary composition with selective pro-apoptotic properties [Shore, 2011]. The drug is injected directly into the directly into the transitional zone of the prostate as a single administration to induce focal cell loss in prostate tissue through apoptosis, leading to non-regressive prostate shrinkage and both short- and
long-term symptomatic improvement. Information about the drugs is scarce and mostly published in abstract form and not yet in the peer-reviewed literature. Two US Phase II trials have been performed [Shore, 2011]. One of them was a multicenter, randomized, non-inferiority study involving 32 clinical sites with 85 subjects and two dose ranges (2.5 and 0.125 mg) and an active open-label comparator (finasteride). Subjects and investigators on NX-1207 were double-blind as to dosage. The primary endpoint was change in AUASI at 90 and 180 days for a single injection of NX-1207 as compared to finasteride on a non-inferiority basis. Inclusion criteria included an AU Symptom Score ≥15, diminished peak urine flow (<15 ml/s) and a prostate size of >30 and <70 mg. The mean AU Symptom Score improvement after 90 days in the intent-to-treat group was 9.71 points for 2.5 mg NX-1207 (n = 48) versus 4.13 points for finasteride (n = 24) (p = 0.001) and 4.29 for 0.125 mg NX-1207 (n = 7) (p = 0.034). The 180-day results also were positive (NX-1207 2.5 mg non-inferior to open-label finasteride).

No significant changes in serum testosterone or serum PSA levels in the NX-1207 cohorts. There were no reported adverse effects on sexual function. Two US multicenter, double-blind, placebo-controlled Phase III studies are currently underway. The results of such studies are needed to assess whether or not this therapeutic principle is a useful addition to the current treatment alternatives.

Recently, the clinical development of this drug was suspended and clinical trials going on in Europe suspended due to the release of negative data coming from a phase III trial run in the US.

**11.1.10 PRX302**

PRX302 is a modified form of proaerolysin, a highly toxic bacterial pore-forming toxin that requires proteolytic processing by prostate-specific antigen (PSA). [Singh et al., 2007]. The safety and efficacy of PRX302 was evaluated in men with moderate to severe BPH [Denmeade et al., 2010]. The patients were refractory, intolerant, or unwilling to undergo medical therapies for BPH and had an IPSS >12, a quality of life (QoL) score >3, and prostate volumes between 30 and 80 g. Fifteen patients were enrolled in phase 1 studies, and 18 patients entered phase 2 studies. Subjects received intraprostatic injection of PRX302 into the right and left transition zone via a transperineal approach in an office-based setting. Phase 1 subjects received increasing concentrations of PRX302 at a fixed volume; phase 2 subjects received increasing volumes per deposit at a fixed concentration. IPSS, QoL, prostate volume, Qmax, IIEF, serum PSA levels, pharmacokinetics, and adverse events were recorded at 30, 60, 90, 180, 270, and 360 days after treatment. Sixty percent of men in the phase 1 study and 64% of men in the phase 2 study treated with PRX302 had >30% improvement compared to baseline in IPSS out to day 360. Patients also experienced improvement in QoL and reduction in prostate volume out to day 360. Patients receiving >1 ml of PRX302 per deposit had the best response overall. There were no deleterious effects on erectile function. Adverse events were mild to moderate and transient in nature. The major study limitation was the small sample size. The promising safety profile and evidence of efficacy in the majority of treated subjects in these phase 1 and 2 studies supports further development of PRX302 as a minimally invasive, targeted treatment for BPH.

To overcome these limitations, a phase Ib study was carried out recently [Elhilali et al., 2013]. A total of 92 men with an IPSS ≥15, Qmax ≤12 ml/s and prostate volume between 30 and 100 ml were randomized 2:1 to a single ultrasound guided prostatic injection of PRX302 (0.6 mg per g prostate) or placebo. Benign prostatic hyperplasia medications were prohibited. The toxin decreased IPSS score by approximately 9-point and increase Qmax by 3 ml/s, both changes being statistically significant when compared to vehicle. Efficacy was sustained for 12 months. PRX302 apparent toxicity was mild, transient, and limited to local discomfort/pain and irritative urinary symptoms occurring in the first few days, with no effect on erectile function. Further developments are therefore awaited.

**11.2. Centrally Acting Drugs**

Many parts of the brain seem to be activated during storage and voiding [see, Griffiths 2007; Fowler et al., 2008; Griffiths and Tadic, 2008], and there is increasing interest in drugs modulating the micturition reflex by a central action [Andersson and Pehrson, 2003, Yoshimura et al., 2014]. Several drugs used for pain treatment also affect micturition; morphine and some antiepileptic drugs being a few examples (Figure 21). However, central nervous mechanisms have so far not been preferred targets for drugs aimed to treat OAB, since selective actions may be difficult to obtain. Holstege [2005], reviewing some of the central mechanisms involved in micturition, including the peri-aqueductal gray (PAG) and the pontine micturition center (PMC), suggested that “the problem in OAB or urgency-incontinence is at the level of the PAG or PMC and their connections, and possible treatments for this condition should target the micturition pathways at that level.”
11.2.1 Gonadotropin-releasing Hormone Antagonists

The beneficial effects of the 5α-reductase inhibitors, finasteride and dutasteride in the treatment of male LUTS are well documented. The efficacy of other hormonal treatments, for example, antiandrogens or gonadotropin-releasing hormone (GnRH; also known as luteinizing hormone-releasing hormone: LH-RH) agonists is either poor or at the expense of unacceptable side effects such as medical castration associated with hot flushes, decrease of potency and libido, and negative effects on bone density following long-term androgen ablation [Schroeder et al., 1986; Peters et al., 1987; Bosch et al., 1989; Eri and Tveter, 1993]. With GnRH antagonists submaximal, non-castrating blockade of the androgen testosterone and consequently of dihydrotestosterone (DHT) can be achieved, thus avoiding medical castration. Several GnRH antagonists – such as cetrorelix, ozarelix and teverelix - have been tested in Phase IIA/IIB clinical trials for their ability to improve LUTS in patients with BPH [Colli and Tanko, 2011].

Debruyne et al. [2008] demonstrated in a phase 2 RCT that the LHRH antagonist cetrorelix, given subcutaneously weekly for 20 weeks to 140 men with LUTS (IPSS > 13, peak urinary flow rates 5-13 ml/s), rapidly caused a significant improvement in the mean IPSS: the peak decrease was -5.4 to -5.9 vs -2.8 for placebo. All dosage regimens tested were well tolerated, and the authors concluded that the drug offered a safe and effective treatment of male LUTS.

Due to these results, two phase III studies were conducted in the United States and Europe [Aeterna Zentaris]; in the US study, 637 men were randomized to receive either two doses of placebo or cetrorelix on weeks 2 and 26. The drug showed no statistically significant benefit in improving IPSS. In addition, cetrorelix did not have a significant effect on peak flow rate or prostate volume versus placebo. It is difficult to reconcile this lack of efficacy given favorable prior results. A subsequent multicenter European trial also failed to show any treatment-related efficacy of cetrorelix. The experience with cetrorelix highlights the importance of randomized, placebo-controlled trials that are appropriately powered to show clinical benefit and safety.

11.2.2 Gabapentin

Gabapentin is one of the new first-generation antiepileptic drugs that expanded its use into a broad range of neurologic and psychiatric disorders [Striano and Striano, 2008]. It was originally designed as an anticonvulsant GABA (γ-aminobutyric acid) mimetic capable of crossing the blood-brain barrier [Maneuf et al., 2003]. The effects of gabapentin, however, do not appear to be mediated through interaction with GABA receptors, and its mechanism of action remains controversial [Maneuf et al., 2003]. It has been suggested that it acts by binding to a subunit of the α₂δ unit of voltage dependent calcium channels [Gee et al., 1996; Striano and Striano, 2008]. Gabapentin is also widely used not only for seizures and neuropathic pain, but for many other indications, such as anxiety and sleep disorders, because of its apparent lack of toxicity.

Carbone et al. [2006] reported on the effect of gabapentin on neurogenic DO. They found a positive effect on symptoms and significant improvement in urodynamic parameters, and suggested that the effects of the drug should be explored in further controlled studies in both neurogenic and non-

Figure 21: OAB drugs with a central mode of action. Several principles seem to work, but currently used drugs have low efficacy and/or unacceptable side effects. However, there is great potential for further developments
neurogenic DO. Kim et al. [2004] studied the effects of gabapentin in patients with OAB and nocturia not responding to antimuscarinics. They found that 14 out of 31 patients improved with oral gabapentin. The drug was generally well tolerated, and the authors suggested that it can be considered in selective patients when conventional modalities have failed. It is possible that gabapentin and other \( \alpha_2\beta_3 \) ligands (e.g., pregabalin and analogs) will offer new therapeutic alternatives, but convincing RTC are still lacking.

11.2.3 Tramadol

Tramadol is a well-known analgesic drug [Grond and Sablotzski, 2004]. By itself, it is a weak \( \mu \)-receptor agonist, but it is metabolized to several different compounds, some of them almost as effective as morphine at the \( \mu \)-receptor. However, the drug (metabolites) also inhibits serotonin (5-HT) and noradrenaline reuptake [Grond and Sablotzski, 2004]. This profile is of particular interest, since both \( \mu \)-receptor agonism and amine reuptake inhibition may be useful principles for treatment of LUTS/OAB/DO, as shown in a placebo controlled study with duloxetine [Steers et al., 2007].

In rats, tramadol abolished experimentally induced DO caused by cerebral infarction [Pehrson et al., 2003]. Tramadol also inhibited DO induced by apomorphine in rats [Pehrson and Andersson, 2003] – a crude model of bladder dysfunction in Parkinson’s disease. Singh et al. [2008] gave tramadol epidurally and found the drug to increase bladder capacity and compliance, and to delay filling sensations without adverse effects on voiding. Safarinejad and Hosseini [2006] evaluated in a double-blind, placebo-controlled, randomized study, the efficacy and safety of tramadol in patients with idiopathic DO. A total of 76 patients 18 years or older were given 100 mg tramadol sustained release every 12 h for 12 weeks. Clinical evaluation was performed at baseline and every two weeks during treatment. Tramadol significantly (p<0.01) reduced the number of incontinence periods per 24 hours from 3.2+/- 3.3 to 1.6+/-2.8) and induced improvements in urodynamical parameters. The main adverse event was nausea. It was concluded that in patients with non-neurogenic DO, tramadol provided beneficial clinical and urodynamic effects. However, the study was later retracted due to unacceptable statistical errors [Safarinejad and Hosseini, 2006; retracted 2014].

NK1-Receptor Antagonists

The main endogenous tachykinins, substance P (SP), neurokinin A (NKA) and neurokinin B (NKB), and their preferred receptors, NK1, NK2, and NK3, respectively, have been demonstrated in various CNS regions, including those involved in micriturition control [Lecce and Maggi, 2001; Saffroy et al., 2003; Covenas et al., 2003]. NK1 receptor expressing neurons in the dorsal horn of the spinal cord may play an important role in DO, and tachykinin involvement via NK1 receptors in the micriturition reflex induced by bladder filling has been demonstrated [Ishizuka et al., 1994] in normal, and more clearly, rats with bladder hypertrophy secondary to BOO. Capsaicin-induced detrusor overactivity was reduced by blocking NK1 receptor-expressing neurons in the spinal cord, using intrathecally administered substance P-saponin conjugate [Seki et al., 2002]. Furthermore, blockade of spinal NK1 receptor could suppress detrusor activity induced by dopamine receptor (L-DOPA) stimulation [Ishizuka et al., 1995].

In conscious rats undergoing continuous cystometry, antagonists of both NK1 and NK2 receptors inhibited micriturition, decreasing micriturition pressure and increasing bladder capacity at low doses, and inducing dribbling incontinence at high doses. This was most conspicuous in animals with outflow obstruction [Gu et al., 2000]. Intracerebroventricular administration of NK1 and NK2 receptor antagonists to awake rats suppressed detrusor activity induced by dopamine receptor (L-DOPA) stimulation [Ishizuka et al., 2000]. Taken together, available information suggests that spinal and supraspinal NK1 and NK2 receptors may be involved in micriturition control.

Aprepitant, an NK-1 receptor antagonist used for treatment of chemotherapy-induced nausea and vomiting [Massaro and Lenz, 2005], significantly improved symptoms of OAB in postmenopausal women with a history of urgency incontinence or mixed incontinence (with predominantly urgency urinary incontinence), as shown in a well-designed pilot RCT [Green et al., 2006]. The primary end-point was percent change from baseline in average daily micturitions assessed by a voiding diary. Secondary end points included average daily total urinary incontinence and urgency incontinence episodes, and urgency episodes. Aprepitant significantly (p<0.003) decreased the average daily number of micturitions (-1.3+/-1.9) compared with placebo (-0.4+/-1.7) at 8 weeks. The average daily number of urgency episodes was also significantly (p<0.047) reduced (-23.2+/- 32%) compared to placebo (-9.3+/-40%), and so were the average daily number of urgency incontinence and total urinary incontinence episodes, although the difference was not statistically significant. Aprepitant was generally well tolerated and the incidence of side effects, including dry mouth, was low. Since this initial proof of concept study suggested that NK-1 receptor antagonism hold promise as a potential treatment approach for OAB symptoms, a randomized, double-blind, multicenter trial enrolled 557 adults with overactive bladder (8 or more average daily micturitions and 1 or more daily urge incontinence episodes) [Frenkl et al., 2010]. After a 1-week placebo run-in the patients were randomized to treatment with 8 weeks of daily 0.25, 1 or 4 mg serlopitant, 4 mg tolterodine extended release or placebo. Patients kept 7-day voiding diaries. The primary end-point was change from baseline in micturitions per day. Secondary end points included urgency, total incontinence, urge incontinence episodes and incidence of dry mouth. Of the 557 patients randomized, 476 completed the trial and had valid efficacy data for analysis. Mean change
from baseline in daily micturitions was significantly greater for 0.25 (-1.1) and 4 mg (-1.1) serlopitant, and for tolterodine (-1.5) than for placebo (-0.5), but not for 1 mg serlopitant (-0.8). No serlopitant dose response was demonstrated. Tolterodine was numerically superior to all doses of serlopitant in mean micturitions per day and secondary end points. The incidence of dry mouth on serlopitant (3.3%) was comparable to placebo (4.6%) and lower than tolterodine (8.8%). Serlopitant was generally well tolerated.

Haab et al. [2014] performed a phase II, multicenter, double-blind study in which adults with OAB symptoms >6 months were randomized to receive 1 of 3 doses of netupitant (50, 100, 200 mg) or placebo once daily for 8 weeks. The primary efficacy endpoint was percentage change from baseline in average number of daily micturitions at week 8. Urinary incontinence, urge urinary incontinence (UUI), and urgency was percentage change from baseline in average number of daily micturitions at week 8. Urinary incontinence, urge urinary incontinence (UUI), and urgency episodes were also assessed. They found that the primary efficacy endpoint was similar in the treatment groups (-13.85 for placebo to -16.17 in the netupitant 200 mg group) with no statistically significant differences between netupitant and placebo.

NK-1 receptor antagonists may have a role in the treatment of overactive bladder, but at least the compounds tested so far do not offer advantages in efficacy compared to tolterodine.

A different approach, modulation of neuropeptide release rather than NK receptor blockade, was tested in a pilot study with cizolirtine, which is a substance-P and CGRP release modulator at the spinal cord level. The modulation of substance-P and CGRP is probably related to the increase of extracellular levels of noradrenaline and serotonin. Cizolirtine 200 and 400 mg were compared to placebo in 79 OAB patients. Although the decrease in key OAB symptoms was significantly higher in the active arms, adverse events were reported in 66% and 81% of the patients on cizolirtine 200 and 400mg. More commonly reported side effects were gastro-intestinal in nature, including dry mouth and vomiting [Martinez-Garcia et al., 2008]. No further developments of this compound have been reported.

11.3. Critical Summary

Based on review of the literature on what is described as “emerging” or “innovative” drugs/targets for treatment of LUTS/OAB, a long list of “possible” or “promising” alternatives can be constructed (Table 4). However, a critical review of these alternatives reveals that although many agents may have theoretically interesting profiles, they do not seem to be in active development for different reasons. For several drugs, proof-of-concept studies are available revealing either no effect, insufficient effect, or disturbing side effects.

Negative proof of concept (Table 4). K+ channel openers have shown great promise in preclinical experiments [Petkov, 2011], but so far the K-channel openers studied clinically have yielded disappointing results [Andersson et al., 2013]. PGE2, acting via EP1 receptors, stimulates bladder contractile activity by sensitization of afferent nerves, and is increased in urine from patients with LUTS [Rahnama et al., 2012]. Despite promising results in animal experiments, a double-blind, placebo-controlled phase II study in OAB patients concluded that the role of an EP1 receptor antagonist in the management of OAB syndrome is minimal [Chapple et al., 2014].

Positive proof of concept (Table 4) Several neurokinin receptor antagonists have shown clinical efficacy, but not sufficient for further development [Green et al., 2006; Frenkl et al., 2019; Haab et al., 2014]. The monoamine reuptake inhibitor, duloxetine showed good efficacy in a randomized controlled clinical trial [Steers et al., 2007], but had many side effects. Side effects also stopped development of different COX-inhibitors (2).

A positive proof-of-concept study was reported for the opioid receptor agonist, tramadol [Safarinejad et al. 2006]. However, the study was later retracted due to unacceptable statistical errors.

Promising based on animal data (Table 4). Up-regulation of the Rho-kinase pathway has been associated with bladder changes in diabetes, outflow obstruction, and idiopathic DO, making Rho-kinase inhibition a theoretically interesting principle for inhibition of bladder overactivity [Christ and Andersson, 2007]. The vitamin D3 agonist, elocalcitol, was shown to have an inhibitory effect on the RhoA/Rho kinase pathway [Morelli et al., 2007; Penna et al., 2009], and showed some promising effects in female patients with OAB symptoms [Digesu et al., 2012]. However, whether or not vitamin D3 receptor agonism (monotherapy or in combination) will be a useful alternative for the treatment of LUTS/OAB, requires further randomized controlled trials.

Several years ago Taylor and Bates performed a double-blind crossover trial of oral baclofen on patients with the “unstable bladder syndrome” with positive outcome [Taylor and Bates, 1979], but the principle of GABAA receptor stimulation was not further developed until recently. ADX71441 is a selective positive allosteric modulator of the GABAA receptor (GABAA-PAM), which is orally available and showed promising effects in animal models of micturition disturbances [Kalinichev et al., 2014]. Further studies of this agent would be of interest.

Other promising targets seem to be the purinergic [Ford and Cockayne, 2011; Ford and Undem., 2013; North and Jarvis., 2013; Andersson, 2015] and cannabinoid [Ruggieri. 2011; Hedlund, 2014; Hedlund and Gratze 2016] systems, and different members of the TRP channel family [Eevaerts et al., 2008; Andersson et al., 2010; Skryma et al., 2011; Avelino et al., 2013; Deruyver et al., 2014; Franken et al., 2014]. P2X3-receptor antagonists are currently being developed for treatment of non-bladder diseases, but clinical experiences in bladder disorders have not yet been reported. Clinical studies with the use of exo-
cannabinoids on LUTS are scarce and essentially restricted to MS patients, and the results have so far not been convincing. However, amplification of the activity of endocannabinoids by fatty acid amino hydrolase (FAAH) inhibitors, inhibiting their degradation, may be an attractive approach [Hedlund and Gratzke, 2016], but again clinical proof of concept is lacking. Several TRP channels, including TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1, are expressed in the bladder and urethra, and may act as sensors of stretch and/or chemical irritation [Everaerts et al., 2008; Andersson et al., 2010; Skryma et al., 2011; Avelino et al., 2013; Deruyver et al., 2014; Franken et al., 2014]. The therapeutic potential for TRPV1 channel antagonists (capsaicin, resiniferatoxin) has been convincingly demonstrated. However, the adverse effect of hyperthermia of the first generation TRPV1 channel antagonists has delayed development. Nevertheless, TRP channels still may be one of the most exciting targets for future LUT drugs.

III. DRUGS USED FOR TREATMENT OF STRESS INCONTINENCE

1. STRESS INCONTINENCE IN WOMEN

Many factors seem to be involved in the pathogenesis of stress urinary incontinence (SUI) in women: urethral support and function, bladder neck support and function of the nerves and musculature of the bladder, urethra, and pelvic floor [Delancey, 1997; Mostwin et al., 2005, Koelbl et al., 2009; Chapple and Milsom, 2012]. Pure structural factors cannot be treated pharmacologically. However, SUI in women is generally thought to be characterized by decreases in urethral transmission pressure and, in most cases, resting urethral closure pressure [Henriksson et al., 1979; Hilton and Stanton, 1983, Koelbl et al., 2009]. It, therefore, seems logical that increasing urethral pressure should improve the condition.

Factors which may contribute to urethral closure include the tone of the urethral smooth and striated muscle (the rhabdosphincter) and the passive properties of the urethral lamina propria, in particular its vasculature. The relative contribution to intraurethral pressure of these factors is still subject to debate. However, there is ample pharmacological evidence that a substantial part of urethral tone is mediated through stimulation of α-ARs in the urethral smooth muscle by released noradrenaline [Andersson, 1993; Andersson and Wein, 2004; 2012]. A contributing factor to SUI, mainly in elderly women with lack of estrogen, may be lack of mucosal function. The pharmacological treatment of SUI aims at increasing intraurethral closure forces by increasing the tone in the urethral smooth and striated musculature, either directly or through increased motoneuron activity. Several drugs may contribute to such an increase [Andersson and Wein, 2012], but relative lack of efficacy or/and side effects have limited their clinical use.

1.1. α-Adrenoceptor agonists

Several drugs with agonistic effects on peripheral α-ARs have been used in the treatment of SUI (Table 5). Noradrenaline (NA) has a central role in increasing the excitability of urethral rhabdosphincter motoneurons in the rat analogue of Onuf’s nucleus, an effect due at least in part to α1-AR dependent depolarization. This could contribute to the mechanism by which NA reuptake inhibitors improve SUI [Yashiro et al., 2010]. Ephedrine and norephedrine (phenylpropanolamine; PPA) seem to have been the most widely used [Andersson and Wein, 2012]. The original United States Agency for Healthcare Policy and Research Guidelines [Agency for Healthcare Policy and Research, 1992] reported 8 randomized controlled trials with PPA, 50 mg twice daily for SUI in women. Percent cures (all figures refer to percent effect on drug minus percent effect on placebo) were listed as 0% to 14%, percent reduction in continence as 19% to 60%, and percent side effects and percent dropouts as 5% to 33% and 0% to 4.3% respectively. The most recent Cochrane review on the subject [Alhasso et al, 2005, reprinted virtually unchanged in 2008] assessed randomized or quasi-randomized controlled trials in adults with stress urinary incontinence which included an adrenergic agonist drug in at least one arm of the trial. There were no controlled studies reported on the use of such drugs in men. Twenty-two eligible trials were identified, 11 of which were crossover trials, which included 1099 women, 673 of whom received an adrenergic drug (PPA in 12, midrodrine in 2, norepinephrine in 3, clenbuterol in 3, terbutaline in 1, and RO 115-1240 in 1). The authors concluded, “there was weak evidence to suggest that use of an adrenergic agonist drug in at least one arm of the trial. Regarding adverse events, the review reported similar numbers with adrenergic, placebo, or alternative drug treatment. Over 25% of subjects reported such effects, but when these consisted of effects due to AR stimulation, they caused discontinuation in only 4% of the total.

Ephedrine and PPA lack selectivity for urethral α-ARs and can increase blood pressure and cause sleep disturbances, headache, tremor, and palpitations [Andersson and Wein, 2012]. Kernan et al. [2000] reported the risk of hemorrhagic stroke to be 16 times higher in women less than 50 years of age who had been taking PPA as an appetite suppressant
(statistically significant) and 3 times higher in women who had been taking the drug for less than 24 hours as a cold remedy (not statistically significant).

There was no increased risk in men. PPA has been removed from the market in the United States. It is still allowed as a treatment for SUI in a few countries. Numerous case reports of adverse reactions due to ephedra alkaloids exist, and some [Bent et al., 2003] had suggested that sale of these compounds as a dietary supplement be restricted or banned. In December 2003, the Food and Drug Administration of the US decreed such a ban, a move which has survived legal appeal.

Midodrine and methoxamine stimulate $\alpha_1$-ARs with some degree of selectivity. According to the RCTs available, the effectiveness of these drugs is moderate at best, and the clinical usefulness seems to be limited by adverse effects [Alhasso et al., 2003; Radley et al., 2001; Weil et al., 1998].

Attempts continue to develop agonists with relative selectivity for the human urethra. Musselman et al. [2004] reported on a phase 2 randomized crossover study with RO 115-1240, a peripheral active selective $\alpha_{1A/1L}$-AR partial agonist [Blue et al., 2004] in 37 women with mild to moderate SUI.

A moderate, positive effect was demonstrated, but side effects have apparently curtailed further development of the drug. PF-374076, a CNS penetrating partial $\alpha_{1A}$-AR agonist, increased peak urethral pressure in dogs and was selective with respect to $\alpha_{1B}$ and $\alpha_{1D}$ receptors, but heart rate and blood pressure changes caused significant concern (Conlon et al., 2009). Furuta et al. [2009] reported that the $\alpha_2$-AR can inhibit the release of glutamate presynaptically in the spinal cord and proposed that $\alpha_2$-AR antagonists would be useful as a treatment for SUI. This hypothesis awaits testing.

### 1.2. $\beta$-Adrenoceptor Agonists. Clenbuterol

$\beta$-AR stimulation is generally conceded to decrease urethral pressure [Andersson, 1993], but $\beta_2$-AR agonists have been reported to increase the contractility of some fast contracting striated muscle fibers and suppress that of slow contracting fibers of others [Fellenius et al., 1980]. Some $\beta$-AR agonists also stimulate skeletal muscle hypertrophy – in fast twitch more so than slow twitch fibers [Kim et al., 1992]. Clenbuterol has been reported to potentiate the field stimulation induced contraction in rabbit isolated periurethral muscle preparations, an action which is suppressed by propanolol and greater than that produced by isoproterenol [Kishimoto et al., 1991]. These authors were the first to report an increase in urethral pressure with clinical use of Clenbuterol and to speculate on its potential for the treatment of SUI. Yaminishi et al. [1994] reported an inotropic effect of clenbuterol and terbutaline on the fatigued striated urethral sphincter of dogs, abolished by $\beta$-AR blockade.

Yasuda et al. [1993] described the results of a double-blind placebo controlled trial with this agent in 165 women with SUI. Positive statistical significance was achieved for subjective evaluation of incontinence frequency, pad usage per day, and overall global assessment. Pad weight decreased from $11.7 \pm 17.9$g to $6.0 \pm 12.3$g for drug and from $18.3 \pm 29.0$g to $12.6 \pm 24.7$g for placebo, raising questions about the comparability of the 2 groups.

The “significant” increase in MUCP was from $46.0 \pm 18.2$ cm H$_2$O to $49.3 \pm 19.1$ cm H$_2$O, versus a change of $-1.5$ cm H$_2$O in the placebo group. 56/77 patients in the clenbuterol group reported some degree of improvement versus 48/88 in the placebo group. The positive effects were suggested to be a result of an action on urethral striated muscle and/or the pelvic floor muscles.

Table 5. Drugs used in the treatment of stress incontinence. Assessments according to the Oxford system (modified)

Ishiko et al. [2000] investigated the effects of clenbuterol on 61 female patients with stress incontinence.
in a 12-week randomized study, comparing drug therapy to pelvic floor exercises. The frequency and volume of stress incontinence and the patient’s own impression were used as the basis for the assessment of efficacy. The improvement of incontinence was 76.9%, 52.6%, and 89.5% in the respective groups. In an open study, Noguchi et al [1997] reported positive results with clenbuterol (20 mg b.i.d. for 1 month) in 9 of 14 patients with mild to moderate stress incontinence after radical prostatectomy. No subsequent published reports have appeared. Further well-designed RTCs investigating effects of clenbuterol are needed to adequately assess its potential as a treatment for stress incontinence.

There have been no recent reports of clinical trials with $\alpha_1$- or $\beta$-AR agonists or antagonists for SUI.

1.3. $\beta$-Adrenoceptor Antagonists

The theoretical basis for the use of $\beta$-AR antagonists in the treatment of stress incontinence is that blockade of urethral $\beta$-ARs may enhance the effects of noradrenaline on urethral $\alpha$-ARs. Propranolol has been reported to have beneficial effects in the treatment of stress incontinence [Gleason et al., 1974; Kaisary, 1984] but there are no RCTs supporting such an action. In the Gleason et al. [1974] study, the beneficial effects become manifest only after 4 to 10 weeks of treatment, a difficult to explain phenomenon. Donker and Van der Sluis [1976] reported that $\beta$-AR blockade did not change UPP in normal women. Although suggested as an alternative to $\alpha$-AR agonists in patients with SUI and hypertension, these agents may have major potential cardiac and pulmonary side effects of their own, related to their therapeutic $\beta$-AR blockade.

1.4. Imipramine

Imipramine, among several other pharmacological effects has classically been reported to inhibit the reuptake of noradrenaline and serotonin in adrenergic nerve endings. In the urethra this could be expected to enhance the contractile effects of noradrenaline on urethral smooth muscle. Gilja et al. [1984] reported in an open study on 30 women with stress incontinence that imipramine, 75 mg daily, produced subjective continence in 21 patients and increased mean maximal urethral closure pressure (MUCP) from 34 to 48 mm Hg. A 35% cure rate was reported by pad test and, in an additional 25%, a 50% or more improvement. Lin et al. [1999] assessed the efficacy of imipramine (25 mg imipramine three times a day for three months) as a treatment of genuine stress incontinence in 40 women. A 20-minute pad test, uroflowmetry, filling and voiding cystometry, and stress urethral pressure profile were performed before and after treatment. The efficacy of “successful treatment” was 60% (95% CI 11.8-75.2). There are no RCTs on the effects of imipramine on SUI. No subsequent published reports have appeared.

Interestingly, Gillman [2007] reported that clomipramine had far greater 5-HT reuptake inhibition than imipramine and roughly similar NA reuptake inhibition. Desipramine and reboxetine had greater NA reuptake inhibition (desipramine superior), with less effects than imipramine on 5-HT uptake (desipramine superior).

1.5. Duloxetine

Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor, which has been shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function [Thor et al., 1995; Katofiasc et al., 2002]. Bladder capacity was also increased in this model, both effects mediated centrally through both motor efferent and sensory afferent modulation [Fraser et al., 2003]. The sphincteric effects were reversed by $\alpha_1$-AR (prazosin) and 5-HT$_2$ receptor (LY 53857) antagonism, while the bladder effects were mediated by temporal prolongation of the actions of serotonin and norepinephrine in the suprasacral cleft [Fraser et al., 2003]. Duloxetine is lipophilic, well absorbed, and extensively metabolized (CYP2D6). Its plasma half-life is approximately 12 h [Sharma et al., 2000].

Thor et al. [2007] describe the mechanisms of action and the physiologic effects of duloxetine. 5-HT (serotonin) and NA terminals are dense in spinal areas associated with lower urinary tract functioning especially around the pudendal nerve neurons in Onuf’s nucleus. These are projections from separate areas in the brain stem. Glutamate is the primary excitatory neurotransmitter in the spinal cord, activating the pudendal neurons in Onuf’s nucleus causing contraction of the urethral rhabdosphincter (Figure 22).

The rhabdosphincter innervation is proposed as distinct from that of the levator ani [Thor and de Groat, 2010]. The responsiveness of the rhabdosphincter motor neurons to glutamate is modulated (facilitated) by 5-HT (through 5-HT$_2$ receptors) and NA (through $\alpha_1$-ARs). 5-HT and NA, however, only modulate, and, when micturition occurs, glutamate excitation and the rhabdosphincter contraction cease. Excitatory effects on urethral sphincter activity are shared to a lesser extent by receptors for 5HT$_{1A}$ (indirect through a supraspinal stimulation), TRH, Vasopressin, NMDA and AMPA; inhibitory effects are similarly mediated by $\kappa_2$ opioid, $\alpha_1$-ARs, GABA-A, GABA-B and glycine receptors [Thor and de Groat, 2010]. Some CNS penetrant selective 5-HT$_{2C}$ agonists have been found to increase urethral muscle tone and inhibit micturition reflexes in animal models, and these are additional candidates for clinical development for the
Several RTCs have documented the effect of duloxetine in SUI [Norton et al., 2002; Dmochowski et al., 2003; Millard et al., 2004; Van Kerrebroeck et al., 2004; Ghoneim et al., 2005]. A Cochrane review of the effects of duloxetine for stress urinary incontinence in women is available, the last substantive amendment listed as 25 May 2005 [Mariappan et al., 2005]. Fifteen reports were deemed eligible for analysis, 9 primary studies and 6 additional reports related to 1 or 2 of the primary references. An additional analysis “performed under the auspices of the Cochrane Incontinence Group” was performed on just the 9 primary trials comparing duloxetine and placebo, and published separately [Mariappan et al., 2007]. The results can be summarized as follows. Subjective “cure” in the duloxetine 80 mg daily (40 mg b.i.d.) was higher than in the placebo group (10.8% vs 7.7%, overall RR = 1.42; 95% CI, 1.02-1.98; p = 0.04). The estimated absolute size of effect was about 3 more patients cured of every 100 treated. Objective cure data, available from only 1 trial, showed no clear drug/placebo difference. Duloxetine showed greater improvement in I-QOL (WMD for 80 mg: 4.5; 95% CI 2.83-6.18, p<0.00001). Adverse effects in 6 trials were analysed. These were reported by 71% of drug subjects and 59% of those allocated to placebo. Nausea was the most common adverse event and the incidence ranged from 23-25% and was the main reason for discontinuation. Other side effects reported were vomiting, constipation, dry mouth, fatigue, dizziness and insomnia, overall RR 1.30 (95% CI, 1.23-1.37). Across these 6 trials 17% in the drug group withdrew, 4% in the placebo arm. In the 2007 article, the authors conclude by saying that further research is needed as to whether management policies incorporating duloxetine are clinically effective and cost effective compared to other current minimally invasive and more invasive approaches in patients with varying severity of SUI, and that “longer term experience is now a priority to determine whether there is sustained efficacy during and after duloxetine use and to rule out complications”.

Hurley et al. [2006] characterized the safety of duloxetine for treatment of SUI in women, using an integrated database generated from four published placebo-controlled clinical trials. The database included 1913 women randomized to duloxetine (N=958) or placebo (N=955), examining adverse events (AEs), serious adverse events (SAEs), vital signs, electrocardiograms, and laboratory analytes. AEs occurring initially or worsening during the double-blind treatment period were considered treatment-emergent (TEAE). Differences between duloxetine-treated and placebo-treated groups were compared statistically. Common TEAEs included: nausea (23.2%), dry mouth (13.4%), fatigue (12.7%), insomnia (12.6%), constipation (11.0%), headache (9.7%), dizziness (9.5%), somnolence (6.8%), and diarrhea (5.1%). Most TEAEs that emerged early were mild to moderate, rarely worsened, and resolved quickly. Overall
AE discontinuation rates were 20.5% for duloxetine and 3.9% for placebo (P<0.001). Most discontinuations (83%) occurred within the first month of treatment. SAEs were uncommon and did not differ between treatments. Statistically significant, but clinically unimportant mean increases in heart rate (2.4 bpm) and systolic and diastolic blood pressure (<or=2 mmHg) occurred. No arrhythmogenic potential was observed and any rare, transient, asymptomatic increases in hepatocellular enzymes normalized. The authors concluded that duloxetine was safe and tolerable, although transient AEs were not uncommon. Hashim and Abrams [2008] suggested, to reduce the risk of nausea, to begin with a dose of 20 mg twice daily for 2 weeks, then to increase to the recommended 40 mg b.i.d. dosage.

Ghoniem et al. [2005] randomized women with SUI to 1 of 4 treatment combinations: duloxetine alone (40 mg b.i.d.), pelvic floor muscle training, combination and placebo. Overall, drug with or without PFMT was superior to PFMT alone or placebo, while pad results and QOL data favored combination therapy to single treatment. Cardozo et al. [2004b] reported that 20% of women awaiting continence surgery changed their minds while taking duloxetine. Duckett et al. [2006], offered a 4-week course to women awaiting a TVT operation. Thirty-seven percent (of 73) declined. Excluding women for whom concomitant prolapse surgery was planned, 8/33 (24%) scheduled for incontinence surgery alone came off the list. Sixteen (48%) discontinued duloxetine because of AEs, 9 (27%) found the drug ineffective.

Bent et al. [2008], reported on the effects of 12 weeks of duloxetine (40 mg b.i.d.) vs placebo in a large group of women with MUI. For SUI patients, the mean IEF (incontinence episode frequency) per week decreased 58.9% with drug (7.69 to 3.93) vs 43.3% for placebo (8.93 to 6.05). Interestingly, corresponding decreased for UUI episodes were 57.7% vs 39.6%. Both sets of values are statistically significant, but the baselines are different and the absolute mean IEF (incontinence episode frequency/week) was decreased for UUI episodes were 57.7% vs 4.2), fatigue (6.7 vs 2.8). Nausea and dizziness (9.7 vs 2.4), constipation (8.3 vs 3.9), dry mouth (12 vs 2.8), sweating (5.2 vs 0). Nausea was less than in other trials (7.5% vs 3.1%), perhaps due to the lower starting dose.

Other AEs included fatigue (14.2% vs 5.4), constipation (10.4 vs 0.8), dizziness (9.0 vs 4.6), excess sweating (5.2 vs 0).

Schagen van Leeuwen et al. [2008] investigated efficacy and safety of duloxetine in elderly women with stress urinary incontinence or stress-predominant mixed urinary incontinence. Duloxetine-treated patients had a significantly greater decrease from baseline to endpoint in mean incontinence episode frequency/week than placebo-treated patients (-52.47% vs. -36.70%). The responder rate (> or =50% reduction in incontinence episode frequency/week) was 57.1% in the duloxetine group and 35.2% in the placebo group (P<0.001). Significant benefits of duloxetine were also demonstrated for weekly continent pad usage, mean time between voids, incontinence quality of life questionnaire scores (P<0.001), and global impression of improvement ratings (P<0.001). Patients with depressive symptoms and cognitive impairments were few and changes were insignificant.

Persistence on duloxetine was studied by Vella et al. [2008] who found that only 31% of an original cohort of 228 were still taking drug beyond 4 weeks, 12% at 4 months, 10% at 6 months, and 9% at 1 year. Fifty-six percent of the discontinuations were attributed to side effects, 33% to lack of efficacy. Bump et al. [2008], however, reported that the positive effects of duloxetine were maintained in patients who continued treatment up to 30 months, but admitted that this subgroup was likely to include predominantly patients who had favorable responses. The number decreased from 1424 in this cohort at 3 months to 368 at 30 months

Shaban et al. [2010] concluded that duloxetine is “optional second line for women not willing or unfit for surgery after warning against side effects as recommended by NICE guidelines in the UK”. Similar sentiments are expressed by Robinson and Cardozo [2010].

Duloxetine is licensed at 40 mg twice daily for the treatment of SUI in the European Union (European Medicines Agency, Scientific Discussion, 2005) in women with moderate to severe incontinence (defined as 15 or more episodes per week). It was withdrawn from the FDA consideration process in the United States for the treatment of SUI, but is approved for the treatment of major depressive disorder (20-30 mg b.i.d. initially, 60 mg once daily maintenance), diabetic peripheral neuropathic pain (60 mg once daily), generalized anxiety disorder (60 mg once daily, fibromyalgia (c0 mg once daily initially, 60b mg once daily maintenance) and chronic musculoskeletal pain (30 mg once daily initially,60 mg once daily) as maintenance. The product information contains a “black box” warning of “increased risk of suicidal thinking and behavior in children, adolescents and young adults taking antidepressants for major depressive disorder and other psychiatric disorders”, noting also that “depression and certain other psychi-
atriac disorders are themselves associated with increases in the risk of suicide” [Prescribing Information, revised September 2011, Eli Lilly and Company, Indianapolis, Indiana 46285]. Other warnings and precautions in the U.S. in the United States Product Information for psychiatric indications, not SUI, include hepatotoxicity (not to be used in patients with substantial alcohol use or chronic liver disease), orthostatic hypotension, serotonin syndrome (general statement regarding SSRIs and SNRIs), abrupt discontinuation (may result in dizziness, paresthesias, irritability and headache), inhibitors of CYP1A2 (such as ciprofloxacin), thioridaxine (do not administer concomitantly) potent inhibitors of CYP2D6 (may increase concentration), and others. Adverse events for 6801 drug and 4487 placebo-treated patients reported in the US Product Information (treatment for the indications mentioned) are nausea (24% vs 8%), dry mouth (13 vs 5), fatigue (10 vs 5), somnolence (10 vs 3), insomnia (10 vs 6), constipation (10 vs 4), dizziness (10 vs 5).

2. STRESS URINARY INCONTINENCE IN MEN

Although a problem of significant magnitude, especially after radical prostatectomy (RP) for cancer, the pharmacologic treatment of male SUI is an area that has received relatively little attention.

Intrinsic sphincter function is the most important outlet factor maintaining continence in men. Urethral support is less important, and there is no entity similar to the hypermobility phenomenon in women. The proximal urethral sphincter extends from the bladder neck through the prostatic urethra. Its function is removed by radical prostatectomy. The distal urethral sphincter includes the rhabdosphincter, urethral smooth muscle and extrinsic paraurethral skeletal muscle, extending from the prostatic urethra below the verumontanum through the membranous urethra [Koelbl al., 2009].

Tsakiris et al (2008) searched for articles on drug treatment of male SUI published between 1966 and June 2007 and did a generalized database search in addition. Nine trials were identified using α-AR agonists, β-AR antagonists or SNRIs. Only one of these included a comparison arm (Filocamo et al, 2007). 40 mg b.i.d. duloxetine plus pelvic floor exercise (PFE) vs PFE with placebo. The results suggested a positive effect of drug, but were a bit confusing. Of those patients completing the 4-month trial (92/112) 78% of the drug treated patients vs 52% of those in the placebo group were “dry”. However, one month after the end of the study, the corresponding figures were 46% vs 73%, a shift still observed 2 months later. The authors of the review article suggested further larger and well designed studies on duloxetine for this potential usage.

Cornu et al. (2011) reported a series of post RP men with SUI or MUI (stress predominant) randomized to duloxetine (15) and placebo (16) after a 2-week placebo run in. Dosage was 20 mg b.i.d. for 7d, 40 mg b.i.d. for 67d, 20 mg for 14d. Subjects were at least 1 year post surgery. Outcome measures included percent decrease in IEF, 1h pad test and various QOL measures. Statistical significance for IEF percent decrease occurred only at week 8 & 12 [-0.52.2 ± 38.6% vs (+)19 ± 43.5%] but there was clearly a trend at 4 weeks. There was no statistical difference in 1h pad test weights but there was in various QOL scores. A 50-100% decrease in IEF was seen at 12 weeks in over half of the patients. Adverse events for drug and placebo included fatigue (50 vs 13%), insomnia (25 vs 7), libido loss (19 vs 7), constipation (13 vs 7), nausea (13 vs 7), diarrhea (13 vs 7), dry mouth (6 vs 0), anorexia (6 vs 0), and sweating (25 vs 20). Drawbacks and concerns are the small number (the original proposed sample size was 90) and the lack of any placebo effect on IEF and QOL. There were 4 men with MUI in the drug group, 5 in the placebo group. Results for SUI and UUI were not separated. One would logically not expect improvement to continue after drug withdrawal unless a permanent change occurred in behavior, anatomy or neuromuscular function. In an uncontrolled usage study on men with post RP SUI, Collado Serra et al. (2011) reported that the benefit remained in 85% after the drug was stopped. In that series, 25% of patients withdrew because of AEs and 33% because of lack of effect.

Usage of duloxetine for SUI in the male is universally off label. A drug for this indication would be welcome. Larger controlled and better designed studies are necessary to provide conclusive positive or negative data on this subject.

IV. DRUGS TO TREAT UNDERACTIVE BLADDER/DETRUSOR UNDERACTIVITY

The Underactive Bladder (UAB: symptom diagnosis) and Detrusor Underactivity (DUA: urodynamic diagnosis) have multifactorial pathophysiology, which introduce obvious therapeutic problems [Andersson, 2014; Miyazato et al., 2014; Osman et al., 2014; Osman and Chapple, 2014]. Not only can the pathophysiology vary between patients (Figure 23), but also in an individual patient several factors may contribute, and it is not always possible to identify “major” and “minor” players that can be targets for treatment. Since complete bladder emptying is dependent on an intact central nervous system (CNS) control, normal sensation and detrusor smooth muscle activity, coordinated bladder and urethral sphincter function, and voluntary initiation of voiding, incomplete bladder emptying and urinary retention can result from disturbances of any of these components. If there are irreversible changes at any level, e.g., in the bladder wall (loss of nerves, loss of muscle tissue, increased

The Underactive Bladder have multifactorial pathophysiology. Since complete bladder emptying is dependent on an intact central nervous system (CNS) control, normal sensation and detrusor smooth muscle activity, coordinated bladder and urethral sphincter function, and voluntary initiation of voiding, incomplete bladder emptying and urinary retention can result from disturbances of any of these components. From Andersson, Curr Opin Urol. 2014 Jul;24(4):363-9.

Figure 23: The Underactive Bladder have multifactorial pathophysiology. Since complete bladder emptying is dependent on an intact central nervous system (CNS) control, normal sensation and detrusor smooth muscle activity, coordinated bladder and urethral sphincter function, and voluntary initiation of voiding, incomplete bladder emptying and urinary retention can result from disturbances of any of these components. From Andersson, Curr Opin Urol. 2014 Jul;24(4):363-9.

collagen deposition), the possibilities of successful pharmacological treatment are reduced.

Detrusor Hyperactivity with Impaired Contractility [DHIC: Resnick and Yalla, 1987] is a diagnosis related to both overactive bladder (OAB)/detrusor overactivity (DO) and UAB/DUA, and the condition creates therapeutic problems. However, as pointed out by several investigators, UAB/DUA and OAB/DO may not be separate disease entities [Semins and Chancellor, 2004; Chancellor, 2014; Nomiya et al., 2014; Zhao et al., 2016]. Instead, chronic untreated or treatment-refractory OAB/DO, caused by neurologic diseases, diabetes, BOO, ischemic bladder dysfunction, or aging, may progress to DO with impaired contractility and eventually to UAB/DU. Progression of OAB/DO to UAB/DUA has been demonstrated in animal models [Nomiya et al., 2014; Zhao et al., 2016] and, if proven also in humans, suggests that early education, behavioral modification, and medical treatment may alter and/or prevent progression to UAB/DUA [Chancellor et al., 2014].

To what extent drug treatment of associated morbidities (e.g., diabetes, Parkinson’s disease, multiple sclerosis) also can improve impaired bladder emptying has only been investigated to a limited extent.

1. PHARMACOLOGICAL PRINCIPLES USED FOR TREATMENT

To improve bladder emptying, agents that increase the contractile force of the detrusor, decrease outflow resistance, or improve detrusor contractility and decrease outflow resistance at the same time, would theoretically be useful [Wein, 2012]. In addition, agents that improve decreased sensation (increase afferent activity and/or the perception of bladder filling) seem attractive [Smith, 2010]. However, in many cases the pathophysiology of UAB/DUA is complex, simultaneously involving several mechanisms [Andersson, 2014; Miyazato et al., 2014; Osman et al., 2014; Osman and Chapple, 2014]. This implies that targeting only one potentially important mechanism will not always have the desired effect.

1.1. Muscarinic Receptor Agonists and Cholinesterase Inhibitors

It is well established the acetylcholine is the main contractile transmitter in the detrusor muscle, and that release of this agent induced by activation of the parasympathetic outflow from the spinal cord leads to a co-ordinated bladder contraction and bladder emptying with simultaneous relaxation of the outflow region [Andersson and Arner, 2004]. Standard pharmacotherapy of impaired bladder emptying has for a long time included muscarinic receptor agonists, such as bethanechol and carbachol to directly stimulate muscarinic receptors on the detrusor muscle, or choline esterase inhibitors, like distigmine to reduce the degradation of acetylcholine. However, based on available information it has been considered that little, if any, beneficial effects can be obtained in preventing or treating UAB/DUA [Barendrecht et al., 2007; Andersson et al., 2013]. Why do these drugs work? One of the reasons is that direct stimulation of detrusor muscarinic receptors will cause contraction (contracture) of the bladder without simultaneous relaxation of the outflow region. Activation of the cholinergic nerves of the outflow region by spinal parasympathetic outflow will not only release acetylcholine for bladder contraction, but also nitric oxide, relaxing the urethra. In addition, systemic administration of a muscarinic receptor agonist has no selectivity for the bladder which means that action on non-target sites will cause adverse effects. Another factor is that both bethanechol and carbachol have low oral bioavailability which makes it difficult to attain “active” blood concentrations.

Bethanechol seems to be the best investigated of the parasympathomimetic drugs. Even if beneficial effects have been reported, most studies have shown no significant effect vs placebo in the treatment of UAB/DUA [Barendrecht et al. 2007]. Attempts have been made to increase the usefulness of muscarinic agonist stimulation. Riedl et al. [2000] used electromotive administration of intravesical bethanechol and could identify patients with an atonic bladder and adequate residual detrusor muscle function. They concluded that patients who do not respond to the electromotive administration of bethanechol do not benefit from oral bethanechol and are candidates for catheterization. To combine bladder contraction and outflow relaxation,

Hindley et al. [2004], in a placebo-controlled study, treated 19 patients with DUA with a combination of intravesical PGE2 and oral bethanechol. They concluded that there was evidence of a pharmacological
effect with a limited therapeutic efficacy compared with placebo. However, this treatment was not recommended as routine, but only for the occasional treatment of a patient with DUA. In summary, available information shows that the beneficial effects that can be obtained with carbachol and bethanechol in preventing or treating UAB/DUA are small or negligible [Bar-endrecht et al., 2007; Andersson et al., 2013].

A number of studies have tested the effect of distigmine bromide on voiding efficiency, but the results have been conflicting. In a double-blind study, Shah et al [1983] investigated the effect of distigmine bromide versus placebo on voiding after prostatectomy. The results showed a trend towards improvement, but no statistically significant increase in post-operative flow rates, in reduction in bladder volume, and in the incidence of re-catheterisation in the patients treated with the drug. In a prospective randomized study on 100 patients undergoing vaginal surgery for genital prolapse, Savona Ventura et al [1991] compared distigmine bromide, phenoxybenzamine hydrochloride, and prostaglandin F2p to prevent urinary retention. They found that all agents appeared to increase the incidence of an elevated residual urinary volume by about three times. Even if the mechanisms behind these findings are difficult to explain, they clearly do not encourage the use of these agents on the indication.

Philp and Thomas [1980] gave distigmine bromide to 23 patients with paraplegia due to suprasacral spinal cord injury who retained a reflex micturition. There was a marked reduction of the residual urine volume in all patients whilst being on parenteral distigmine. The oral preparation of the drug proved less effective and this was attributed to poor absorption from the gut. Tanaka et al. [2001] found in 14 patients with poor detrusor contractility after transurethral prostatectomy (TURP) that oral administration of distigmine bromide (5 mg three times daily for 4 weeks) resulted in subjective as well as objective improvement; the International Prostate Symptom Score (IPSS) was reduced from a mean of 18.9 to a mean of <10 and the maximum flow increased from a mean of 8.9 ml/sec to a mean of >12 ml/sec. In addition, detrusor contractility tended to improve. Bougas et al. [2004] investigated 27 patients (11 men and 16 women) with poor detrusor function established using pressure-flow studies. They were treated with distigmine bromide for 4 weeks which resulted in a statistically significant reduction of residual volume (from a mean of 329.1 to a mean of 156.8 ml), obviating the need for intermittent self-catheterisation in 11 patients. In addition, maximum flow rate and detrusor pressure at maximum flow increased, although not significantly. The drug was generally well tolerated by the majority of patients.

It is obvious that the most positive effects of distigmine have been obtained in non-placebo controlled studies with small patient materials with various diagnoses. It cannot be excluded that in some selected patient categories distigmine may have a positive effect, but the lack of adequately designed studies implies that a fair assessment of the drug as a general treatment of UAB/DUA is not possible.

In a recent pilot study on 19 patients with DUA, Sugimoto et al. [2015] studied the effects of acotiamide, a drug approved in Japan for treatment of various gastrointestinal disorders [Doi et al., 2004]. Acotiamide “appears to exert an antagonistic effect on muscarinic M1, M2, and M3 receptors and thereby inhibit the negative feedback system by blocking muscarinic auto receptors that regulate acetylcholine release.” The main outcome parameter of the study was post-void residual (PVR) which after acotiamide changed from 161.4±90.0 mL at baseline to 116.3±63.1 mL at 2-weeks post-treatment. This may be statistically significant but is not very impressive. If the mechanism of action of the drug is increased acetylcholine release, it may not differ from other parasympathomimetic drugs.

For all parasympathomimetic drugs, well-designed, randomized controlled trials on well-defined patient materials are lacking, implying that these drugs cannot be recommended for general use, but may be utilized for personalized treatment of UAB/DUA.

1.2. α-Adrenoceptor Antagonists

The role of α-adrenoceptor (AR) antagonists in the treatment of voiding symptoms in men with bladder outflow obstruction (BOO) is well documented [Michel, 2010; Lepor et al., 2012]. Although most men with voiding symptoms do not necessarily have UAB/DUA, the drugs may improve bladder emptying in these patients. The use of α1-AR antagonists has repeatedly been shown to be beneficial in patients with acute urinary retention due to benign prostatic enlargement [McNeill et al., 2004; 2005; Fitzpatrick et al., 2012]. These drugs are believed to facilitate bladder emptying by relaxing tone at the bladder neck. Administration of alfuzosin 10 mg daily almost doubles the likelihood of a successful trial without a catheter, even in patients who are elderly with a PVR > 100 mL. Continued use of alfuzosin significantly reduced the risk of BPH surgery in the first 3 months; however, this effect was not significant after 6 months [Fitzpatrick and Kirby, 2006; Emberton et al., 2008a; b; Kalejaiye et al., 2009]. Thus, α1-AR antagonists provide rapid symptom relief from outlet obstruction caused by benign prostatic enlargement and delay the time to acute urinary retention; however, they do not decrease the overall risk of acute urinary retention or surgery [Emberton et al., 2008a; b; Edwards, 2008; Fitzpatrick et al., 2012].

Acute urinary retention may occur after surgery. Buckley and Lapitan [2010] reviewed drugs used for treatment of post-operative urinary retention either alone or in combination, assessing cholinergic agents, α1-AR blockers, sedatives and prostaglandins. A statistically significant association between intravesically administered prostaglandins and successful voiding was detected, but no such association was found for the other drugs.
investigated. When cholinergic agents were combined with sedative there was an improved likelihood of spontaneous voiding compared with placebo.

Supporting this, α1-AR antagonists have been widely used in the conservative management of acute urinary retention caused by BOO as shown in systematic reviews of available data [Creta et al., 2015; Guan-Jun et al., 2015].

In patients with neurogenic bladder, reduction of urethral resistance during voiding by α-AR antagonists have been reported to be useful [Yamanishi et al., 1999, Sakakibara et al., 2000; Schulte-Baukloh et al 2002; Moon et al., 2015]. However, most of the studies have been performed on small patient materials with varying diagnoses and all studies have not been positive. In a study of 14 children from age 6 to 16 years with neurogenic bladder and LPP > 40 cm H₂O, Kroll et al. [2016] found no evident efficacy of doxazosin after 6-8 weeks of treatment. Yamanishi et al. [2004] reported in a prospective single-blind randomized study that the combination of a cholinergic drug (bethanechol) and a α1-AR antagonist (uraripidil) was more effective than monotherapy in improving urination in patients with UAB/DUA. Theoretically, the approach of enhancing detrusor contractility and lowering urethral resistance simultaneously seems attractive. However, in the study by Yamanishi et al. [2004], monotherapy with bethanechol seemed to be marginal, and whether the combination therapy really is better than monotherapy with α1-AR antagonist has to be confirmed in appropriately designed studies.

1.3. Prostanoids

Previous experimental studies have shown that e.g., prostaglandin (PG) E₂ can both increase detrusor contraction and relax the urethra in humans [Andersson and Wein, 2004]. PGE₂ does not only stimulate detrusor contraction directly, but may also enhance the efficacy of other contraction-mediating transmitters. In addition, PGE₂ can increase afferent activity both by stimulating the urethral and myogenic pathways [Maggi et al., 1984; 1988].

Intravesical instillation of PGE₂ and other prostanoids has been reported (no controlled randomized trials) to stimulate bladder contractile activity acutely [Andersson et al., 1978; Wagner et al., 1985, Tammela et al., 1987, Schlusser, 1990], but not without side effects (e.g., uterine contraction). Experiences from patients with chronic bladder emptying difficulties [Delaere et al., 1981] or neurogenic bladder dysfunction [Vaidyanathan et al., 1981] have not been encouraging. The question is whether useful actions can be sorted out from the mixture of effects exerted by PGE₂. The effects of this prostanoïd are produced by 5-HT₄ receptors via facilitation of cholinergic neurotransmission [Tonini et al., 1994; Candura et al., 1996], and an occasional case report suggests efficacy in some cases of UAB/DUA with cisapride [Franceschetti et al., 1997], a 5-HT₄ agonist with 5-
HT₃ antagonist activity, widely used to promote gastrointestinal motility, but withdrawn because of cardiac (long QT) side effects [Quigley et al., 2011]. Whether or not analogues without this side effect would be useful can only be speculated on.

1.6. Botulinum Toxin

Kuo [2007] treated 27 patients with idiopathic low detrusor contractility with urethral injection of onabotA. It was found that patients with normal bladder sensation combined with a poor relaxation or hyperactive urethral sphincter were significantly more likely to recover normal detrusor function. Further studies on such patients would be desirable.

Conclusions

The current pharmacological possibilities to effectively treat UAB/DUA are limited. Dependent on the multifactorial pathophysiology of the condition, treatment with approved agents have to be personalised and to be successful therapy has to be directed to both the major mechanism involved and the associated morbidities.

V. HORMONAL TREATMENT OF URINARY INCONTINENCE

1. OESTROGENS

1.1. Oestrogens and the Continence Mechanism

The oestrogen sensitive tissues of the bladder, urethra and pelvic floor all play an important role in the continence mechanism. For women to remain continent the urethral pressure must exceed the intra-vesical pressure at all times except during micturition. The urethra has four oestrogen sensitive functional layers all of which have a role in the maintenance of a positive urethral pressure 1) epithelium, 2) vasculature, 3) connective tissue, 4) muscle.

Two types of oestrogen receptor, (α and β) have been identified in the trigone of the bladder, urethra and vagina as well as in the levator ani muscles and fascia and ligaments within the pelvic floor [Smith et al., 1990; Copas et al., 2001; Gebhardt et al., 2001]. After the menopause oestrogen receptor α has been shown to vary depending upon exogenous oestrogen therapy [Fu et al., 2003]. In addition, exogenous oestrogens affect the remodeling of collagen in the urogenital tissues resulting in a reduction of the total collagen concentration with a decrease in the cross linking of collagen in both continent and incontinent women [Falconer et al., 1998; Keane et al., 1997]. Studies in both animals and humans have shown that oestrogens also increase vascularity in the peri-urethral plexus which can be measured as vascular pulsations on urethral pressure profilometry [Robinson et al., 1996; Endo et al., 2000; Versi and Cardozo, 1986].

1.2. Oestrogens for Stress Urinary Incontinence

The role of oestrogen in the treatment of stress urinary incontinence has been controversial despite a number of reported clinical trials [Hextall, 2000]. Some have given promising results but this may have been because they were small observational and not randomised, blinded or controlled. The situation is further complicated by the fact that a number of different types of oestrogen have been used with varying doses, routes of administration and duration of treatment.

Fantl et al. [1996] treated 83 hypo-oestrogenic women with urodynamic stress incontinence and/or detrusor overactivity with conjugated equine oestrogens 0.625 mg and medroxyprogesterone 10 mg cyclically for three months. Controls received placebo tablets. At the end of the study period the clinical and quality of life variables had not changed significantly in either group. Jackson et al. [1996] treated 57 post menopausal women with urodynamic stress or mixed incontinence with Oestradiol 2 mg or placebo daily for six months. There was no significant change in objective outcome measures although both the active and placebo groups reported subjective benefit.

Two meta-analyses of early data have been performed. In the first, a report by the Hormones and Urogenital Therapy (HUT) committee the use of oestrogens to treat all causes of incontinence in post menopausal women was examined [Fantl et al., 1994]. Of 166 articles identified, which were published in English between 1969 and 1992, only six were controlled trials and 17 uncontrolled series. The results showed that there was a significant subjective improvement for all patients and those with urodynamic stress incontinence. However, assessment of the objective parameters revealed that there was no change in the volume of urine lost, Maximum urethral closure pressure increased significantly but this result was influenced by only one study showing a large effect.

In the second meta-analysis Sultana and Walters [1990] reviewed eight controlled and 14 uncontrolled prospective trials and included all types of oestrogen treatment. They also found that oestrogen therapy was not an efficacious treatment for stress urinary incontinence but may be useful for the often associated symptoms of urgency and frequency. Oestrogen when given alone therefore does not appear to be an effective treatment for stress urinary incontinence.

Several studies have shown that oestrogen may have a role in combination with other therapies e.g. α-adrenoceptor agonists. However, phenylpropanaline (the most widely used α-adrenoceptor agonist in clinical practice) has now been restricted or banned by the US Food and Drug Administration (FDA).
In a randomised trial Ishiko et al. [2001] compared the effects of the combination of pelvic floor exercise and oestriol (1 mg per day) in 66 patients with post menopausal stress urinary incontinence. Efficacy was evaluated every three months based on stress scores obtained from a questionnaire. They found a significant decrease in stress score in mild and moderate stress incontinent patients in both groups three months after the start of therapy and concluded that combination therapy with oestriol plus pelvic floor exercise was effective and could be used as first line treatment for mild stress urinary incontinence. A further study evaluating the effects of intravaginal oestriol and pelvic floor rehabilitation on urogenital aging in post menopausal women randomised 206 women with symptoms of urogenital aging into two groups of 103 women each. Subjects in the treatment group received intravaginal oestriol ovules 1 mg once daily for 2 weeks and then 2 ovules weekly for a total of six months together with pelvic floor rehabilitation. Subjects in the control group received only intravaginal oestriol. Prior to treatment 83 (80.6%) of the women in the treatment arm complained of stress urinary incontinence compared to 103 (100%) of the control women. At the end of the study only 22 (21.4%) of the treated patients suffered from stress urinary incontinence compared to 93 (90.3%) of the control group representing a significant improvement in stress incontinence as a result of this combination therapy [Capobianco et al., 2012].

Thus even prior to the more recently reported secondary analyses of the heart and oestrogens/progestogen replacement study (HERS) [Grady et al., 2001] and women’s health initiative (WHI) [Hendrix et al., 2005] it was already recognised that systemic oestrogen therapy alone had little effect in the management of urodynamic stress incontinence [Al-Badr et al., 2003; Robinson and Cardozo, 2003].

1.3. Oestrogens for Urgency Urinary Incontinence and Overactive Bladder Symptoms.

Oestrogen has been used to treat post menopausal urgency and urge incontinence for many years but there have been few controlled trials to confirm that it is of benefit [Hextall, 2000]. A double blind multi centre study of 64 post menopausal women with “urge syndrome” failed to show efficacy [Cardozo et al., 1993]. All women underwent pre-treatment urodynamic investigation to ensure that they had either sensory urgency or detrusor overactivity. They were randomised to treatment with oral oestriol 3 mg daily or placebo for three months. Compliance with therapy was confirmed by a significant improvement in the maturation index of vaginal epithelial cells in the active but not the placebo group. Oestriol produced subjective and objective improvements in urinary symptoms but was not significantly better than placebo.

Another randomised controlled trial from the same group using 25 mg Oestradiol implants confirmed the previous findings [Rufford et al., 2003], and furthermore found a higher complication rate in the Oestradiol treated patients (vaginal bleeding).

Symptoms of an overactive bladder increase in prevalence with increasing age and lower urinary tract symptoms and recurrent urinary tract infections are commonly associated with urogenital atrophy. Whilst the evidence supporting the use of oestrogens in lower urinary tract dysfunction remains controversial there are considerable data to support their use in urogenital atrophy and the vaginal route of administration correlates with better symptom relief by improving vaginal dryness, pruritis and dyspareunia, greater improvement in cytological findings and higher serum oestradiol levels [Cardozo et al., 1998]. Overall vaginal oestradiol has been found to be the most effective in reducing patient symptoms although conjugated oestrogens produced the most cytological change and the greatest increase in serum oestradiol and oestrone. The most recent meta analysis of intravaginal oestrogen treatment in the management of urogenital atrophy was reported by the Cochrane group in 2012 (Cody et al., 2012) Overall 34 trials including 19676 continent women of whom 9599 received oestrogen therapy (1464 involved in trials of local vaginal oestradiol adnistratoin). The trials used varying combinations of oestrogen, dose, duration of treatment and length of follow up. The combined result of six trials of systemic administration (oral oestrogen) resulted in worse incontinence then placebo. However, there was some evidence that oestrogen used locally as vaginal creams or pessaries improved incontinence. Overall thefere was less frequency and urgency in those women treated with local oestrogen.

Thus, theoretically there could be a role for combination treatment with an antimuscarinic agent and vaginal oestrogen in post menopausal women. However, the three clinical trials which have been reported to date differ in their outcome. Tseng et al. [2009] showed superior efficacy in terms of symptom improvement for the overactive bladder when Tolterodine was used with vaginal oestrogen cream as opposed to Tolterodine alone. However, Serati et al. [2009] found no difference between Tolterodine with or without topical oestrogen in women with symptomatic detrusor overactivity. A further study compared the efficacy and safety of solifenacin succinate versus solifenacin succinate with local oestrogen for the treatment of overactive bladder in 104 post menopausal women randomised to receive either solifenacin 5 mg daily plus Promestriene vaginal capsules or solifenacin alone. The primary outcome measure was changed from baseline to end of treatment in the mean number of voids per 24 hours, quality of life was assessed using international prostate symptom score and overative bladder symptoms score questionnaires. The median decreases in number of voids in 24 hours in the two groups were 5.4 and 4.3 respectively which was not statistically different. The median decrease in urgency episdoes was 2.0 and 2.5 respitively. In addition, the quality of life scores significantly changed in both groups (both the <0.05).
concluded that solifenacin with or without local oestrogen was effective and safe for overactive bladder treatment in post menopausal women. The addition of local oestrogen improved subjective feelings and quality of life [Jiang et al., 2016].

There has been one study comparing the oestradiol vaginal ring with oral oxybutynin for treatment of overactive bladder [Nelken et al., 2011]. Participants were randomised to receive either the ultra low dose oestradiol vaginal ring or oral oxybutynin for 12 weeks. The primary outcome was a decrease in the number of voids in 24 hours. Secondary outcomes were quality of life questionnaires, vaginal pH levels and vaginal maturation index. 59 women were enrolled, 31 were randomised to receive oxybutynin whereas 28 received oestradiol vaginal ring. Women who received oxybutynin had a mean decrease of 3.0 voids per day and women who received the vaginal ring had a mean decrease of 4.5 voids per day with no significant difference between the groups. There was a significant improvement in urogenital distress inventory and incontinence impact questionnaire scores in both groups with no significant difference in improvement between the two groups, thus ultra low dose oestrogen seemed to be similarly effective in decreasing the number of daily voids in post menopausal women with overactive bladder.

1.4. Evidence Regarding Oestrogens and Incontinence from Large Clinical Trials.

The HERS study included 763 post menopausal women under the age of 80 years with coronary heart disease and intact uteri [Grady et al., 2001]. It was designed to evaluate the use of oestrogen in secondary prevention of cardiac events. In a secondary analysis 1525 participants who reported at least one episode of incontinence per week at baseline were included. Participants were randomly assigned to 0.625 mg of conjugated oestrogens plus 2.5 mg of medroxyprogesterone acetate in one tablet (N=768) or placebo (N=757) and were followed for a mean of 4.1 years. Severity of incontinence was classified as improved, unchanged or worsened. The results showed that incontinence improved in 26% of the women assigned to placebo compared to 21% assigned to hormones whilst 27% of the placebo group worsened compared with 39% of the hormone group (P<0.001). This difference was evident by four months of treatment, for both urgency and stress urinary incontinence. The number of incontinence episodes per week increased an average of 0.7 in the hormone group and decreased by 0.1 in the placebo group (p< 0.001). The authors concluded that daily oral oestrogen plus progestogen therapy was associated with worsening urinary incontinence in older post menopausal women with weekly incontinence and did not recommend this therapy for treatment of incontinence. However, it is possible that the progestogen component may have had an influence on the results of this study.

The Women’s Health Initiative (WHI) was a multicentre double blind placebo controlled randomised clinical trial of menopausal hormone therapy in 27347 postmenopausal women age 50-79 years enrolled between 1992 and 1998 for whom urinary incontinence symptoms were known in 23296 participants at baseline and one year [Hendrix et al., 2005]. The women were randomised based on hysterectomy status to active treatment or placebo. Those with a uterus were given 0.625 mg per day of conjugated equine oestrogen (CEE) plus 2.5 mg per day of medroxyprogesterone Acetate (CEE+MPA), whereas those who had undergone hysterectomy received oestrogen alone (CEE). At one year hormone therapy was shown to increase the incidence of all types of urinary incontinence among women who were continent at baseline. The risk was highest for stress urinary incontinence CEE+MPA: RR, 1.7 95% confidence interval CI (1.61-2.18); CEE alone RR 2.15 mg, 95% CI, 1.77-2.62, followed by mixed urinary incontinence CEE+MPA: RR 1.49 95% CI 1.10-2.01. On CEE alone RR was 1.79 95% CI, 1.26-2.53. The combination of CEE and MPA had no significant effect on developing urge urinary incontinence RR, 1.15; 95% CI, 0.99-1.34 but CEE alone increased the risk RR 1.32; 95% CI, 1.10-1.58. For those women experiencing urinary incontinence at baseline frequency worsened in both active groups CEE+MPA; RR, 1.38 95% CI 1.28-1.49; CEE alone: RR, 1.47 95% CI, 1.35-1.61. Quantity of urinary incontinence worsened at one year in both active groups, CEE+MPA: RR, 1.20 95% CI, 1.06-1.76; CEE alone: RR, 1.59 95% CI, 1.39-1.82. Those women receiving hormone therapy were more likely to report that urinary incontinence limited their daily activities CEE+MPA: RR 1.18 95% CI, 1.06-1.32. CEE alone: RR 1.29 95% CI, 1.15-1.45 at one year. Thus, based on this secondary analysis of data from a huge study conjugated equine oestrogen alone or in combination with Medroxyprogesterone Acetate was shown to increase the risk of urinary incontinence amongst continent women and worsen urinary incontinence amongst asymptomatic women after one year of therapy.

The Nurses Health Study [Grodstein et al., 2004] was a biennial postal questionnaire starting in 1976. In 1996 39436 post-menopausal women aged 50-75 years was reported no urinary leakage at the start of the study were followed up for four years to identify incident cases of urinary incontinence. 5060 cases of new onset cases of urinary incontinence among women who had never taken hormones (oral oestrogen: RR1.54 95% CI 1.44, 1.65; transdermal oestrogen: RR1.68, 95% CI 1.41, 2.00; oral oestrogen with progesterone: RR1.34, 95% CI 1.24, 1.44; transdermal oestrogen with progesterone: RR1.46, 95% CI 1.16, 1.84). After cessation of hormone therapy there was a decreased risk of incontinence such that 10 years after stopping
hormones the risk was identical in women who had and who never had taken hormone therapy.

The most recent meta analysis of the effect of oestrogen therapy on the lower urinary tract has been performed by the Cochrane Group [Cody et al., 2012] and is notable as the conclusions are starkly different from those drawn from the previous review [Moehrer et al., 2003]. Overall 34 trials were identified including 19676 incontinent women (1464 involved in trials of local administration) of which 9599 received oestrogen therapy.

Systemic administration (of unopposed oral oestrogens – synthetic and conjugated equine oestrogens) resulted in worse incontinence than placebo (RR1.32; 95% CI: 1.17-1.48). Although this is heavily influenced by the size of the WHI study [Hendrix et al., 2005]. When considering combination therapy there was a similar worsening effect on incontinence when compared to placebo (RR1.11; 95% CO: 1.04-1.08). There was some evidence suggesting that the use of local oestrogen therapy may improve incontinence (RR0.74; 95% CI: 0.64-0.86) and overall there were 1-2 fewer voids in 24 hours and less frequency and urgency.

The authors conclude that local oestrogen therapy for incontinence may be beneficial although there was little evidence of long term effect. The evidence would suggest that systemic hormone replacement using conjugated equine oestrogens may make incontinence worse. In addition they report that there are too few data to comment reliably on the dose type of oestrogen and route of administration.

2. GENITOURINARY SYNDROME OF MENOPAUSE

Following a consensus conference held in 2013 the Board of Directors of the International Society for the Study of Women’s Sexual Health (ISSWSH) and the Board of Trustees of the North American Menopause Society (NAMS) acknowledged the need to review current terminology associated with genitourinary tract symptoms related to menopause [Portman et al., 2014]. They agreed on the new term Genitourinary Syndrome of Menopause (GSM) as a more accurate all encompassing and publically acceptable term than vulvo-vaginal atrophy. As well as genital symptoms this covers the urinary symptoms of urgency, dysuria and recurrent urinary tract infections. It has long been appreciated that these symptoms respond well to low dose local (intravaginal) oestrogen therapy given long term to post menopausal women [Baber et al., 2016]. The most recent Cochrane review included 16 trials with 2129 women and intravaginal oestrogen was found to be placebo in terms of efficacy although there were no differences between types of formulation. Fourteen trials compared safety between the different vaginal preparations and found a higher risk of endometrial stimulation with conjugated equine oestrogens as compared to oestradiol [Suckling et al., 2003]. However, since then the traditional 25 microgram twice weekly dose of oestradiol vaginal tablets has been replaced by the ultra low dose 10 microgram twice weekly vaginal tablet [Simon & Maamari, 2013]. This has unfortunately led to reduced efficacy and does not appear to be adequate for the control of overactive bladder symptoms in post menopausal women, 50% of whom may suffer from genitourinary syndrome of the menopause if untreated.

3. OTHER HORMONES

Progesterone and progestogens are thought to increase the risk of urinary incontinence. Lower urinary tract symptoms especially stress urinary incontinence have been reported to increase in the progestogenic phase of the menstrual cycle [Hextall et al., 2001]. In similar studies, progesterone has been shown to increase beta adrenergic activity leading to a decrease in the urethral closure pressure in female dogs [Raz et al., 1973]. However, in the WHI there appeared to be no difference whether or not progesterin was given in addition to oestrogen [Hendrix et al., 2005].

Selective oestrogen receptor modulators (SERMS) have been reported to have varying effects. Each of the SERMS has receptor ligand conformations that are unique and have both oestrogenic and anti oestrogenic effects. In the clinical trials of levormeloxifene there was a fourfold increase in the incidence of incontinence leading to cessation of the clinical trial [Hendrix et al., 2001]. However, raloxifene has not been shown to have any effect at all on urinary incontinence [Waetjen et al., 2004]. There are no reported clinical trials evaluating the effect of androgens, and in particular testosterone, on urinary incontinence in women.

Conclusions. Oestrogen has an important physiological effect on the female lower urinary tract and its deficiency is an aetiological factor in the pathogenesis of a number of conditions. However, the use of oestrogen either alone or in combination with progestogen has yielded poor results. The current level 1 evidence against the use of systemic oestrogen for the treatment of urinary incontinence comes from studies powered to assess their benefit in the prevention of cardiovascular events and therefore the secondary analyses have only been based on self reported symptoms of urinary leakage without any objective data. Despite this all of these large randomised controlled trials show a worsening of pre-existing urinary incontinence both stress and urgency and an increased new incidence of urinary incontinence with both oestrogen and oestrogen plus progestogen. However, the majority of subjects in all of these studies were taking combined equine oestrogen and this may not be representative of all oestrogens taken by all routes of administration.

In a systematic review of the effects of oestrogens for symptoms suggestive of an overactive bladder the
conclusion was that oestrogen therapy may be effective in alleviating OAB symptoms, and that local administration may be the most beneficial route of administration [Cardozo et al., 2004]. It is quite possible that the reason for this is that the symptoms of urinary urgency, frequency and urge incontinence may be a manifestation of genitourinary syndrome of menopause atrophy in older post menopausal women rather than a direct effect on the lower urinary tract [Robinson and Cardozo, 2003]. Whilst there is good evidence that the symptoms and cytological changes of urogenital atrophy may be reversed by low dose (local) vaginal oestrogen therapy there is currently no evidence that oestrogens with or without progestogens should be used in the treatment of urinary incontinence. The International Menopause Society (IMS) has produced new 2016 recommendations on women’s midlife health and menopause hormone therapy (MHT) to help guide healthcare professionals in optimising their management of women in menopause transition and beyond. They have given a Grade A recommendation to the use of local oestrogens for urogenital symptoms and a Grade B recommendation for the long-term use of such treatment. They have also allocated a Grade B recommendation to the use of low dose local oestrogens in the management of recurrent lower urinary tract infection [Baber et al., 2016].

4. DESMOPRESSIN

The endogenous hormone vasopressin (also known as anti-diuretic hormone) has two main functions: it causes contraction of vascular smooth muscle and stimulates water reabsorption in the renal medulla. These functions are mediated by two specific vasopressin receptors of which there are two major subtypes, namely the V₁a and V₂ receptors. The V₂ subtype is particularly important for the anti-diuretic effects of vasopressin. A genetic or acquired defect in making and secreting vasopressin leads to central defects of vasopressin. A genetic or acquired defect in type is particularly important for the antidiuretic effects of vasopressin. Desmopressin is the most common vasopressin analogue used to treat nocturia. Desmopressin shows selectivity for anti-diuretic over vasopressor effects. It has a more powerful and longer-lasting antidiuretic action than vasopressin. It is available in formulations for oral, parenteral, and nasal administration. It has a fast onset of action, with urine production decreasing within 30 minutes of oral administration [Rittig et al., 1998]. Because of symptomatic hyponatraemia with water intoxication which is the only serious adverse event reported in children, occurred after intranasal or intravenous administration of desmopressin [Thumfart et al., 2005; Robson et al., 2007; Van de Walle et al., 2010], the U.S. Food and Drug Administration (FDA) and the European Medicines Agency (EMA) removed the indication for the treatment of primary nocturnal enuresis from all intranasal preparations of desmopressin. An oral lyophilisate (MELT) formulation requiring no concomitant fluid intake is currently available. In a recent open-label, randomized, cross-over study, desmopressin MELT was shown to have similar levels of efficacy and safety at lower doses than the tablet formulation of desmopressin in children. A recent study confirmed the superior pharmacodynamic characteristics of desmopressin MELT to desmopressin tablets [De Guchteneere et al., 2011].

The use of desmopressin in children with nocturnal enuresis was comprehensively reviewed by the Cochrane Collaboration in 2002 [Glazener et al., 2002]. These authors evaluated 47 randomized controlled trials involving 3448 children, of whom 2210 received desmopressin. According to their analysis, desmopressin was effective relative to placebo in reducing bed-wetting (e.g. a dose of 20 μg resulted in a reduction of 1.34 wets/night (95% CI 1.11; 1.57), and children were more likely to become dry with desmopressin (98%) than with placebo (81%). However, there was no difference between desmopressin and placebo after discontinuation of treatment, indicating that desmopressin suppresses symptom enuresis but does not cure the underlying cause. The Cochrane Group have reviewed a total of 40 randomised or quasi-randomised controlled trials of 1780 children who were in enrolled receiving an active drug other than desmopressin or a tricyclic. Thirtyone different drugs or classes of drug were tested. For drugs versus placebo, when compared to placebo indomethacin, diazepam, mestorelone and atomoxetine appeared to reduce the number of children failing to
have 14 consecutive dry nights. Although indomethacin and diclofenac were better than placebo during treatment, they were not as effective as desmopressin and there was a higher chance of adverse effects [Desphande et al., 2012]. Additionally, not all children responded sufficiently to desmopressin monotherapy. The combination of desmopressin and an antimuscarinic resulted in a greatly improved short-term success rate and decreased relapse rates [Aloussi et al., 2011]. The combination of desmopressin and an antimuscarinic resulted in better short- and long-term success rates as well as a lower relapse rate than desmopressin alone [Austin et al., 2008; Aloussi et al., 2009]. A recent Cochrane Review has shown that when Imipramine combined with Desmopressin was compared with Imipramine monotherapy there was no difference in outcomes. However, when imipramine plus desmopressin was compared with desmopressin monotherapy the combination was more effective with 15% not achieving 14 consecutive dry nights at the end of treatment for imipramine plus desmopressin versus 40% for desmopressin monotherapy [Caldwell et al., 2016]. For non-responders to desmopressin, replacement of desmopressin with other medications such as tricyclic antidepressants or loop diuretics could be of benefit, whereas muscarinic receptor antagonists may be ineffective in such children (De Guchtenaere et al., 2007; Neveus and Tullus, 2008). A study of enuresis patients thought to be resistant to desmopressin who were subsequently referred to a specialist centre showed that 1/3 of the children could become dry on desmopressin monotherapy under specialist care once their daytime symptoms had been addressed [Rittig et al., 2014]. This has led to recommendations for maximising the chances of treatment success in patients receiving desmopressin [Kamperis et al., 2016]

Other studies have explored a possible treatment role for desmopressin in the treatment of nocturia in adults. A search for these studies in Medline using the terms “desmopressin” and “nocturia” was performed and limited to clinical studies of de novo nocturia, i.e. those that excluded subjects in whom childhood enuresis persisted into adulthood. Several previous studies investigated the use of desmopressin for the treatment of nocturia in the context of multiple sclerosis [Eckford et al., 1994; 1995]. One study with single dose administration reported a reduction in nocturnal polyuria, but by design did not assess nocturia [Eckford et al., 1995]. Three placebo-controlled double-blind studies with a small patient number (16-33 patients total per study) reported a significant reduction in nocturia [Hilton et al., 1983; Eckford et al., 1994; Valiquette et al., 1996]. Other controlled studies of similar size, most with a crossover design, used micturition frequency within the first 6 h after desmopressin administration rather than nocturia as their primary endpoint. These studies consistently reported that desmopressin treatment for up to 2 weeks was efficacious [Kinn and Larsson, 1990; Fredrikson, 1996; Hoverd and Fowler, 1998]. While desmopressin treatment was generally well tolerated, 4 of 17 patients in one study discontinued treatment due to asymptomatic or minimally symptomatic hypotension [Valiquette et al., 1996]. Accordingly, desmopressin is now registered for the treatment of nocturia in multiple sclerosis patients [Cvetkovic and Plosker, 2005]. In a small open-label study, desmopressin was also reported to reduce nocturnal polyuria in spinal cord injury patients [Zahariou, Karagianis et al., 2007].

Further studies have explored the use of desmopressin in adults with nocturia in the apparent absence of neurological damage. The recruited patient populations were based upon different criteria, including having at least two nocturia episodes per night or having nocturnal polyuria. Earlier studies mostly used a desmopressin dose of 20 µg given either orally [Asplund et al., 1999] or intranasally [Hilton and Stanton, 1982; Cannon et al., 1999], and tended to be very small (<25 patients). Later studies, as part of the NOCTUPUS program, were considerably larger, involving a total of 1003 screened patients, and higher oral doses (0.1-0.4 mg) were administered for a period of 3 weeks of double-blind treatment in adults [Mattiasson et al., 2002; Lose et al., 2003; van Kerrebroek et al., 2007]. A total of 632 patients entered the dose-titration phase and 422 patients entering the double-blind phase of the three NOCTUPUS trials. To counter the argument that the study was performed in desmopressin responders after the dose titration phase, all patients in the NOCTUPUS trials were washed-out following the dose-titration phase and in order to be randomised, it was a requirement that the patients returned to baseline nocturnal diuresis before inclusion in the double-blind phase. The trials showed that oral desmopressin (0.1, 0.2 or 0.4 mg) is effective in both men and women aged ≥ 18 years with nocturia. The number of nocturnal voids decreased from 3 to 1.7 in the desmopressin group compared to 3.2 to 2.7 in the placebo group. In women, the number of nocturnal voids in the desmopressin group decreased from 2.92 to 1.61, whereas that in the placebo group decreased from 2.91 to 2.36. When clinical response was defined as ≥ 50% reduction in nocturnal voids from baseline, 34% of men experienced clinical response with desmopressin, compared with 3% of men who received placebo. In women, 46% of desmopressin-treated patients experienced a clinical response, compared with 7% of patients on placebo.

Weiss and colleagues reported outcomes on a four week multicentre randomised double blind placebo controlled trial to determine the efficacy of orally disintegrating sub-lingual Desmopressin i.e., "melt" formulation. The authors randomised patients to 10, 25, 50 and 100 micrograms. Approximately 90% of the subjects reported true nocturnal polyuria, 710 patients completed the study. A statistically significant difference in the number of nocturnal voids was seen for all patients with a 100 micrograms and 50 micrograms. Women responded to 25 micrograms as well, however for men there was only a statistically
significant difference with 100 micrograms. The proportion of patients with at least a 33% reduction in the number of nocturnal voids (primary outcome measure) increased with dosage for all patients but there was a stronger response seen in women at 25 micrograms. A total of 24 patients (3%) experienced hyponatremia which was a more likely occurrence in patients over the age of 65 years [Weiss et al., 2012].

The efficacy of desmopressin for the treatment of nocturia was confirmed in a long-term (10-12 months) open-label study involving 249 patients, which was an extension of the randomized studies in known desmopressin responders. However, a rebound effect was seen when treatment was withdrawn, confirming the association between continued treatment and response [Lose et al., 2004]. An open-label pilot study in a nursing home setting also reported that desmopressin had beneficial effects [Johnson et al., 2006].

Around 75% of community-dwelling men and women with nocturia (≥2 voids/night) have nocturnal polyuria (NP) [Rembratt et al., 2003; Swithinbank et al. 2004]. The key urological factors most relevant to nocturia are NP and OAB in women [Irwin et al., 2008], and NP and benign prostate hyperplasia (BPH) in men. Among 74% of women with OAB have nocturia and 62% of patients with OAB and nocturia have NP. Among men with nocturia, 83% have NP; 20% have NP alone, and 63% have NP in combination with another factor such as a small nocturnal bladder capacity or bladder outlet obstruction [Chang et al., 2006]. Therefore, desmopressin combination therapy with \( \alpha \)-adrenergic blockers and/or anticholinergics should be considered for patients with treatment-resistant nocturia. Seventy-three percent of \( \alpha \)-adrenergic blocker-resistant BPH patients experienced a ≥50% reduction in nocturnal voids with oral desmopressin [Rembratt et al., 2003; Yoong et al., 2005]. A randomized, double-blind, placebo-controlled study evaluating the long-term (1, 3, 6, and 12 months) efficacy and safety of low dose (0.1 mg) oral desmopressin in elderly (≥65 years) patients reported that low dose oral desmopressin led to a significant reduction in the number of nocturnal voids and nocturnal urine volume in patients with BPH [Wang et al., 2011a].

Because nocturia can be caused by different factors, several studies have investigated whether desmopressin may be beneficial in patients with other symptoms in addition to nocturia. In a small, non-randomized pilot study of men believed to have BPH, desmopressin was reported to improve not only nocturia, but also to reduce the overall international prostate symptom score (IPSS) [Chancellor et al., 1999]. An exploratory, placebo-controlled double-blind study in women with daytime urinary incontinence reported that intranasal administration of 40 \( \mu \)g desmopressin increased the number of leakage-free episodes 4 hours after drug administration (Robinson et al., 2004). One double-blind, placebo-controlled pilot study in patients with OAB treated with 0.2 mg oral desmopressin reported a reduction in voids along with an improvement in quality of life (QoL) [Hashim et al., 2009]. While these data indicate that desmopressin may be effective in treating voiding dysfunction not limited to nocturia, they are too sparse to allow treatment recommendations.

Desmopressin was well tolerated in all the studies and resulted in significant improvements compared to placebo in reducing nocturnal voids and increasing the hours of undisturbed sleep. There was also an improvement in QoL. However, one of the main clinically important side-effects of desmopressin usage is hyponatremia. Hyponatremia can lead to a variety of adverse events ranging from mild headache, anorexia, nausea, and vomiting to loss of consciousness, seizures, and death. Hyponatremia usually occurs soon after treatment is initiated. The risk of hyponatremia appears to increase with age, cardiac disease, and increasing 24-hour urine volume [Rembratt et al., 2003; 2006]. Based on a meta-analysis, the incidence is around 7.6% [Weatherall, 2004]. Increased age and female gender are well-known risk factors for the development of desmopressin-induced hyponatremia [Rembratt et al., 2006]. Bae et al. [2007] assessed the effects of long-term oral desmopressin on serum sodium and baseline antidiuretic hormone secretion in 15 elderly male patients with severe nocturia (greater than 3 voids nightly), who did not show hyponatremia within 7 days of administration of 0.2 mg desmopressin. Desmopressin (0.2 mg) was administered orally nightly for 1 year. Before and 1 month after the 1-year medication 24-hour circadian studies were performed to monitor changes in antidiuretic hormone. Every 3 months during the 1-year medication, serum changes and timed urine chemistry were monitored. The results showed that long-term desmopressin administration gradually decreased serum sodium and induced statistically, but not clinically significant, hyponatremia after 6 months of treatment Administration of desmopressin for 1 year did not affect baseline antidiuretic hormone secretion. The authors recommended that for long-term desmopressin administration serum sodium should be assessed regularly, at least every 6 months.

There has been some research exploring gender differences in the antidiuretic response to desmopressin. Juul et al. [2011] found an increasing incidence of hyponatremia with increasing dose, and at the highest dose level of 100 \( \mu \)g decreases in serum sodium were approximately twofold greater in women over 50 yr of age than in men. A new dose recommendation stratified by gender was suggested in the treatment of nocturia: for men, 50- to 100 \( \mu \)g melt was suggested to be an efficacious and safe dose, while for women a dose of 25 \( \mu \)g melt was recommended as efficacious with no observed incidences of hyponatremia. Weiss and colleagues investigated the efficacy and safety of 50 and 75 micrograms Desmopressin orally disintegrating tablets in 385 men with nocturia. They showed that both doses increased the time to first void from baseline by approximately 40
minutes compared to placebo. The response to Desmopressin was seen within a week of treatment and was sustained producing significant increases in health-related quality of life and sleep quality compared to placebo. Only 2 subjects aged 74 and 79 years respectively developed hyponatraemia [Weiss et al., 2013]. A similar study carried out in women explored the efficacy and safety of 25 micrograms of desmopressin orally disintegrating tablets compared to placebo. 261 women with nocturia were randomised to either 25 micrograms of desmopressin or placebo. Desmopressin significantly reduced the mean number of nocturnal voids compared to placebo and increased the mean time to first nocturnal void by 49 minutes compared to placebo. Once again response was seen within the first week of treatment and sustained throughout the 3-month trial. Desmopressin was well tolerated with only three transient decreases in serum sodium level [Sand et al., 2013].

Initiation of desmopressin is currently not indicated for patients aged ≥65 years. The mechanisms behind desmopressin-induced hyponatraemia are well understood, and serum sodium monitoring at baseline and early during treatment of older patients for whom treatment with desmopressin is indicated can greatly reduce their risk of developing the condition. Other advice regarding treatment administration, such as restriction of evening fluid intake and adherence to recommended dosing, should be followed to minimize the risk of hyponatremia [Vande Walle et al., 2007].

Desmopressin is useful for patients with nocturia as well as for children with nocturnal enuresis. The drug has been proven to be well-tolerated and effective by several randomized, placebo-controlled trials and is recommended as a first-line treatment (either as monotherapy or in combination with other agents) for patients who have been appropriately evaluated and whose nocturia is related to NP, whether or not this is accompanied by BPH or OAB. For assessment, see Table 2.

VI. CONSIDERATIONS IN THE ELDERLY

The mainstay of pharmacological therapy for OAB in the elderly has been antimuscarinic agents. However, antimuscarinics may be associated with side effects that result in poor persistence and contribute to the anticholinergic burden of polypharmacy. Since antimuscarinics and β3-AR agonists (mirabegron) are similarly efficacious, and mirabegron has a more favorable tolerability profile than antimuscarinics amongst older patients, this drug was suggested to provide an improved benefit-to-risk ratio and therefore should be considered as an alternative to antimuscarinics for older patients [Wagg et al., 2016]. Until recently, few studies had specifically evaluated the efficacy and safety of antimuscarinics in the treatment of OAB symptoms in elderly patients.

1. ANTIMUSCARINIC AGENTS – EFFICACY AND TOLERABILITY

The efficacy of antimuscarinic agents for treating symptoms of overactive bladder and urge urinary incontinence in older people is similar to that observed in younger and middle-aged adults. Age-related pooled results or sub-analyses from randomized controlled trials of tolterodine [Malone-Lee et al., 2001, Zinner et al., 2002], solifenacin [Wagg et al., 2006], darifenacin [Foote et al., 2007], fesoterodine [Kraus et al., 2010; Sand et al., 2012; see Wagg et al., 2015], and trospium chloride [Sand et al., 2011] indicate that reductions of 25-75% in urgency urinary incontinence episodes can be expected with use of these agents in older (65+) adults. Higher doses may be needed in those over age 75 [Kraus et al., 2010]. In a post-marketing surveillance study of darifenacin, Michel et al. [2010] found that increasing age was negatively associated with improvements in urgency episodes and incontinence, with a statistically significant, but non-clinically relevant effect (0.01 more urgency episodes per year of age). Older adults may derive greater benefit from use of a combined drug and behavioural therapy regime as compared to treatment with drug therapy alone [Burgio et al., 2000]. Dry mouth is the most frequently reported treatment-related adverse event, however overall tolerance has been reported as good to excellent with fewer treatment-motivated withdrawals in recent trials of older patients persisting on antimuscarinic therapy [Sand et al., 2012; Sand et al., 2011a,b]. Constipation is also common and may be particularly bothersome for older adults already suffering from chronic bowel dysmotility [Meek et al., 2011, Gallegos-Orozco et al., 2012].

However, the therapeutic effectiveness and tolerability of antimuscarinic agents in the elderly in the real-world practice setting may differ from the results obtained in randomized controlled trials for several reasons. First, research trials generally exclude individuals with concomitant consumption of other anticholinergic agents. In practice, older adults are a heterogeneous group, often consuming many medications that may augment, desensitize or alter the response to antimuscarinic therapy. As well, there is a higher prevalence of comorbidity among the elderly, which can further reduce treatment efficacy and heighten the potential for side effects to occur (see the Section on Incontinence in the Frail Elderly). Failure to acknowledge the multifactorial nature of urinary incontinence in the elderly often leads to sub-optimal treatment. Urgency symptoms may be exacerbated by consumption of caffeinated beverages, pelvic floor muscle weakness, diuretics or other functional and systemic dysfunctions. Treatment should therefore address all possible etiologies, and not be limited to a solitary intervention.

CONSIDERATIONS IN THE ELDERLY | 903
2. ANTIMUSCARINIC AGENTS – COGNITIVE SAFETY

A growing body of literature has emerged to address the concern that antimuscarinic agents used to treat symptoms of overactive bladder may cross the blood-brain barrier and provoke subtle or not so subtle cognitive impairment [Callegari et al., 2011; Jakobsen SM et al., 2011; Wagg et al., 2010; Pagoria et al., 2011; Gray et al., 2015]. Higher cumulative anticholinergic use seems to be associated with an increased risk for dementia [Gray et al., 2015]. Large randomized controlled trials were not designed to adequately measure central nervous system adverse events [Paquette et al., 2011]. As a result, evidence on the relative risk of different antimuscarinic agents for crossing the blood brain barrier and inducing changes in cognitive comes primarily from in-vitro studies and experimental studies using detailed neuropsychological testing.

Early studies suggested that administration of anticholinergic agents such as scopolamine could impair memory and attention in older adults, and possibly induce hallucinations and confusion [Flicker et al., 1992; Sperling et al., 2002]. Oxybutynin, in particular, due to its small molecular size and increased propensity to cross the blood-brain barrier, has consistently shown potential to elicit cognitive impairment in new users after a single high dose of this agent or at steady state, and should be avoided in the elderly [Donellan et al., 1997; Katz et al., 1998; Kay et al., 2008, Wesnes et al., 2009]. Katz et al. (1998) used a double-blind, placebo-controlled cross-over design to test a convenience sample of 12 healthy continent older adults, and revealed cognitive decrements on seven of fifteen cognitive measures resulting from oxybutynin use. Impairments were observed in verbal learning, memory, reaction time, attention, concentration and psychomotor speed. In a sleep study, oxybutynin was found to significantly alter EEG patterns to cross the blood-brain barrier and inducing changes in cognitive performance central nervous system adverse events [Paquette et al., 2011]. As a result, evidence on the relative risk of different antimuscarinic agents for crossing the blood brain barrier and inducing changes in cognitive comes primarily from in-vitro studies and experimental studies using detailed neuropsychological testing.

Studies with the antimuscarinic agents solifenacin, trospium chloride ER and darifenacin suggest that these agents confer significantly lower cognitive risk than oxybutynin. Administration of trospium chloride ER to 12 cognitively intact adults with overactive bladder aged 65-75 was found to have no effect on memory testing with the Hopkins Verbal Learning Test on day 10 post-administration compared to baseline, and was also found to be undetectable in the cerebral spinal fluid of participants [Staskin et al., 2010]. In a study of darifenacin among 129 older adults aged 65-84, no significant effects on cognition were observed (memory scanning sensitivity, speed of reaction time, and word recognition) compared with placebo [Lipton et al., 2005]. No data on fosoterodine and memory were found.

New onset delirium also does not appear to be a significant concern in patients taking antimuscarinic agents. Although several published case reports have documented the acute onset of delirium following initiation of tolterodine, in incontinent adults with and without dementia [Womack and Heilman, 2003; Salvatore et al., 2007; Williams et al., 2004; Tsao et al., 2003], these deficits resolved upon discontinuation or dose reduction of tolterodine. In a randomized controlled study of extended-release oxybutynin in nursing-home residents with mild to severe dementia, there was no incidence of delirium over the duration of the study [Lackner et al., 2008]. Furthermore, more recent evidence puts into question the traditionally held belief that new use of anticholinergic agents provokes incident delirium in hospitalized older patients [Campbell et al., 2011; Luukkanen et al., 2011].

Taken together, increasing evidence suggests that with the exception of oxybutynin, use of the other antimuscarinic agents poses little or no cognitive risk to otherwise healthy older adults with symptoms of overactive bladder [Esin et al., 2015]. However, two caveats apply. First, the integrity of the blood brain barrier may be compromised in many older adults with cerebrovascular disease, diabetes, or certain forms of dementia, with the results of studies in healthy older adults not generalizable to frailer individuals [Kay et al., 2005]. Second, long-term use of anticholinergic agents over months or years may yield more detrimental cognitive effects than single dose or short-term use. A number of large observational studies have linked chronic consumption of anticholinergic drugs with an increased risk of cognitive impairment, although most studies simultaneously examined the cumulative effect of drugs with any anticholinergic properties rather than each drug class alone [Ancelin et al., 2006; Campbell et al., 2009; Fox et al., 2011, Gray et al., 2015]. The Eugenius study of aging randomly recruited 372 adults 60 years and older from Montpellier, France, and showed that antimuscarinic drug users displayed significantly poorer reaction time, attention, immediate and delayed visuospatial memory, narrative recall, and verbal fluency than did non-drug users [Ancelin et al., 2006]. A 2-year longitudinal study of 13,000 participants enrolled in the Medical Research Council Cognitive Function and Ageing Study also showed that use of medication with anticholinergic effects was associated with a
Clinicians who remain wary of prescribing antimuscarinic agents for frail older adults with symptoms of overactive bladder are suggested to proceed with caution in prescribing these medications and fully weigh the risk-benefit ratio in light of other therapeutic options that can be equally effective for urgency and mixed incontinence in the elderly. If antimuscarinic medication include, among others, amitriptyline, clozapine, olanzapine, paroxetine, furosemide, hy-drococene, lansoprazole, levoffloxacin, and metfor-min.

A frequently asked clinical question is whether anti-muscarinic agents used to treat incontinence should be contraindicated in patients with dementia already taking cholinesterase inhibitors, as the mechanisms of these two medications are diametrically opposed. A number of small studies have shown that cholinesterase inhibitors used to improve cognition in Alzheimer’s disease precipitate urinary incontinence [Hashimoto et al., 2000]. A Japanese study followed 94 patients with mild to moderate dementia treated with donepezil [Hashimoto et al., 2000]. Seven patients developed urinary incontinence, although the event was transient in most patients. In Scotland, among 216 patients with Alzheimer’s disease initiating treatment with a cholinesterase inhibitor, incontinence was precipitated in 6.6%, and those with exist-ing incontinence worsened [Starr, 2007]. Epidemiologic studies also show associations between cholinesterase inhibitors and incontinence [Gill et al., 2005; Roe et al., 2002]. In a large population-based cohort study of 44,884 adults with dementia carried out in Canada, those who were dispensed cholinesterase inhibitors were more likely to subsequently receive an antimuscarinic drug for incontinence compared to those not receiving cholinesterase inhibitors (hazard ratio 1.55, 95% confidence interval 1.39-1.72) [Gill et al., 2005]. This finding was confirmed by a separate study in the U.S. documenting a two-fold risk of taking oxybutynin in dementia patients treated with donepezil compared to those not treated with donepezil [Roe et al., 2002]. A Japanese study examined the addition of a 3-month trial of propiverine 20 mg/day to donepezil in twenty-six cognitively im-paired older adults, and found improved dryness rates with no deleterious effect on cognition [Sa-kakibara et al., 2009]. A 6-month study also compared the effects of trospium, galantamine, or tro-spium plus galantamine in 178 older adults with urge incontinence (n=99), dementia (n=43) or dementia and incontinence (n=36) respectively [Isik et al., 2009]. Treatment with 45-60 mg/day of trospium chloride and combined use of trospium with galantamine 24 mg/day was found to have no adverse effect on cognitive or physical function scores in this group of patients. A larger observational study of 3,563 long-term care residents with dementia also failed to document an increased rate of cognitive decline with combined use of a cholinesterase inhibitor and anti-cholinergic therapy (oxybutynin or tolterodine) com-pared to cholinesterase therapy alone [Sink et al., 2008]. However, a 50% faster rate of physical func-tion decline was observed in higher-functioning partici-pants on dual therapy compared to cholinesterase inhibitor therapy alone. This evidence suggests the competing mechanisms of the antimuscarinics and cholinesterase inhibitors may indeed have clinical consequences in some, but not all patients.

It has been stated that a dementia diagnosis does not preclude management of incontinence, but it was em-phasized that treatment options may be more limited in those with advanced dementia who are unable to retain information and modify behaviors [Orme et al., 2015]

3. ANTIMUSCARINIC AGENTS – CARDIAC SAFETY

Another serious side effect of antimuscarinic drugs in the elderly is the risk of cardiac adverse effects and increased mortality, particularly due to increases in heart rate, prolongation of the QT interval, and induction of polymorphic ventricular tachycardia. These have been previously discussed, and it has been noted that studies specific to the elderly are lacking [Andersson et al., 2011]. Only one study prospectively examined the effect of anticholinergic drug use in 400 community-dwelling older people (aged 75-90 years) with stable cardiovascular disease in Helsinki, Finland [Uusvaara et al., 2011]. Bladder antimuscarinic agents were not examined individually, but were considered in a cumulative assessment of all drugs with anticholinergic properties being taken by the same individual. The unadjusted follow-up mortality was 20.7% and 9.5% among users and non-users of anticholinergic drugs, respectively (p = 0.010). How-ever, the use of drugs with anticholinergic properties was not a significant predictor of mortality in multivariate analysis after adjustment for age, sex and other comorbidities (hazard ratio 1.57; 95% CI 0.78, 3.15).
Rates of polypharmacy (>5 drugs per patient) are high in the geriatric population, and cause potential for drug-drug interactions that increase toxicity or reduce the efficacy of antimuscarinic agents [Chancellor and Miguel, 2007]. The relationship between the number of drugs and potential drug-drug interactions in the elderly is alarming. Consumption of 5 to 7 and 8 to 10 drugs places older adults at a 4-fold and 8-fold increased risk of potentially serious drug-drug interactions respectively, compared with consumption of 2 to 4 drugs [Johrell and Klarin, 2007]. Drug drug interactions frequently involve isoenzymes of the hepatic cytochrome CYP450 system [Zakrzewski-Jakubiec et al., 2011]. Of the antimuscarinic drugs, tolterodine, darifenacin, solifenacin, and oxybutynin are extensively metabolized by CYP450 and are at greater risk of having altered drug metabolism due to hepatic-based drug-drug interactions. Trospium is eliminated renally as unchanged drug, suggesting that it has lower potential for CYP450 drug-drug interactions [Sand et al., 2011]. Trospium may therefore represent a safer treatment option in the context of polypharmacy in the elderly.

5. B3-AR AGONISTS (MIRABEGRON)

Wagg et al. [2014] performed a prospective subanalysis of individual and pooled efficacy and tolerability data from three 12-week, randomised, Phase III trials, and of tolerability data from a 1-year safety trial in order to evaluate the efficacy and tolerability of mirabegron in subgroups of patients aged ≥65 and ≥75 years. Mirabegron 25 mg and 50 mg once-daily reduced the mean numbers of incontinence episodes and micturitions/24 h from baseline to final visit in patients aged ≥65 and ≥75 years. The drug was well tolerated. In both age groups, hypertension and urinary tract infection were among the most common adverse effects over 12 weeks and 1 year. The incidence of dry mouth, was up to sixfold higher among the older patients randomised to tolterodine than any dose of mirabegron.

Combined treatment for severe symptoms of OAB in elderly men and women with standard doses of solifenacin and mirabegron provided satisfactory therapeutic effect within short period of time without increasing the risk of side effects, and improved the quality of life and self-esteem of patients [Kosilov et al., 2015a]. In elderly men (≥65 years), combination of mirabegron as additional therapy to treatment with α-AR antagonists was effective, particularly if OAB was not controlled with α1-AR-blocker monotherapy. Mirabegron did not have negative effects on voiding function [Matsuo et al., 2016]. The combination of mirabegron with tamsulosin did not seem to cause clinically relevant changes in cardiovascular safety or safety profiles [van Gelderen et al., 2014].

I. INTRODUCTION

In this chapter the diagnostic and treatment modalities of urinary incontinence in childhood will be discussed. In order to understand the pathophysiology of the most frequently encountered problems in children, we shall also consider the normal development of bladder and sphincter.

Underlying pathophysiology will be outlined and the specific investigations for children will be covered but for general information on epidemiology and urodynamic investigations their respective chapters should be consulted.

1.1. Normal development of bladder and sphincter control

Normal bladder storage and voiding involve low-pressure and adequate bladder volume filling followed by a continuous detrusor contraction that results in bladder emptying, associated with adequate relaxation of the sphincter complex. This process requires normal sensation and normal bladder outlet resistance. The neurophysiological mechanisms involved in normal bladder storage and evacuation include a complex integration of sympathetic, parasympathetic and somatic innervation which is ultimately controlled by a complex interaction between spinal cord, brain stem, midbrain and higher cortical structures (1,2).

Achievement of urinary control is equally complex and as yet not fully understood: various developmental stages have been observed (2,3).

In new-borns, the bladder has been traditionally described as “uninhibited”, and it has been assumed that micturition occurs automatically by a simple spinal cord reflex, with little or no mediation by the higher neural centres. However, studies have indicated that even in full-term fetuses and new-borns, micturition is modulated by higher centres and the previous notion that voiding is spontaneous and mediated by a simple spinal reflex is an oversimplification (4). Fetal micturition seems to be a behavioural state-dependent event: intrauterine micturition is not randomly distributed between sleep and arousal, but occurs almost exclusively while the fetus is awake (4).

During the last trimester the intra-uterine urine production is much higher than in the postnatal period (30ml/hr) and the voiding frequency is approximately 3 times every 24 hours (5).

Immediately after birth voiding is very infrequent during the first few days of life. The first void may only take place after 12 to 24 hours. After the first week frequency increases rapidly and peaks at the age of 2 to 4 weeks to an average of once per hour. It then decreases and remains stable after 6 months to about 10 to 15 times per day. After the first year it decreases to 8 to 10 times per day, while voided volumes increase by three-to-fourfold.

During the postnatal period, micturition control mechanisms undergo further changes and extensive modulation. Using ambulatory bladder monitoring techniques in conjunction with polysomnographic recordings it has been shown that even in new-borns the bladder is normally quiescent and micturition does not occur during sleep (6).

This inhibition (or lack of facilitation) of detrusor contractions during sleep is also observed in infants with neurogenic bladder dysfunction who have marked detrusor overactivity while they are awake. In response to bladder distension during sleep, an infant nearly always exhibits clear electro-encephalographic evidence of cortical arousal, facial grimaces or limb movements, or actual awakening. Sleeping infants are always seen to wake up before the bladder contracts and voiding occurs. This arousal period may be transient and the infant may cry and move for a brief period before micturition and then shortly af-
terward go back to sleep. Because this wakening re-
sponse is already well established in new-borns, it fol-
lows that the control of micturition probably involves
more complicated neural pathways and higher cen-
tres than has been appreciated. There is also strong
evidence that a pronounced reorganisation of pre-ex-
isting synaptic connections and neural pathways in-
volved in bladder control occurs during the early post-
natal period.

In new-borns micturition occurs at frequent intervals
and may have an intermittent pattern although blad-
der emptying efficiency is usually good. In over 80
percent of voids the bladder empties completely (7).

During infancy voiding pressures are much higher
than in adults. It has also been noted that these pres-
sures are higher in boys than in girls (mean pdet max
of 118 vs. 75 cm H2O, respectively) (8,9).

These higher detrusor pressures decrease progres-
sively with increasing age. In up to 70 percent of in-
fants (up to the age of 3 years) with normal lower uri-
inary tracts, intermittent patterns of voiding were ob-
served. They tend to disappear with increasing age,
and are thought to represent variations between indi-
vidual infants in the maturation of detrusor and
sphincteric co-ordination during the first 1 to 2 years
of life. Videourodynamic studies have confirmed
these findings (6,8-11).

Between the age of 1 and 2, conscious sensation of
bladder filling develops. The ability to void or inhibit
voiding voluntarily at any degree of bladder filling
commonly develops in the second and third years of
life. Central inhibition is crucial to obtain continence.

During the second and third year of life, there is pro-
gressive development towards a socially conscious
continence and a more voluntary type of micturition
control develops. The child becomes more aware of
the sensation of bladder distension and the need to
urinate, as well as social norms and embarrassment
associated with urinary incontinence. Through an ac-
tive learning process, the child acquires the ability to
voluntarily inhibit and delay voiding until a socially
convenient time, then actively initiate urination even
when the bladder is not completely full, and allows
urination to proceed to completion. During the first
years of life, gradual development to an adult type of
voluntary micturition control that conforms to the so-
cial norms depends on an intact nervous system, in
addition to at least three other events occurring con-
comitantly:

- a progressive increase in functional storage ca-
pacity,
- maturation of function and control over the ex-
ternal urinary sphincter,
- and most importantly, achievement of volitional
control over the bladder-sphincteric unit so that
the child can voluntarily initiate or inhibit a mic-
turition reflex (12).

The final steps are usually achieved at the age of 3 to
4 years when most children have developed the adult
pattern of urinary control and are dry both day and
night. The child has learned to inhibit a micturition re-
flex and postpone voiding and voluntarily initiate mic-
turition at socially acceptable and convenient times
and places. This development is also dependent on
behavioural learning and can be influenced by toilet
training, which in turn depends on cognitive percep-
tion of the maturing urinary tract.

It is understandable that this series of complex events
is highly susceptible to malfunction. Various func-
tional derangements of the bladder-sphincter-peri-
neal complex may occur during this sophisticated
course of early development of normal micturition
control mechanisms. These acquired "functional" dis-
orders overlap with other types of bladder functional
disturbances that may have a more organic underly-
ing pathophysiological basis.

2. NORMAL VALUES

2.1. Normal bladder capacity

Bladder capacity increases during the first 8 years of
life roughly with 30 ml per year, so with an average
capacity of 30 ml in the neonatal period, a child's blad-
der volume can be calculated as Y = 30 + 30 X, where
Y = capacity in ml and X = age in years (Fig 1) (13).

Hjälmås described a linear correlation that could be
used up to 12 years of age: in boys, Y = 24.8 X + 31.6,
in girls Y = 22.6 X + 37.4, where Y is capacity in ml,
and X is age in years (14).

It should be noted that these data were obtained dur-
ding cystometric investigations. Cystometric capacity
is generally less than normal bladder volumes. Obvi-
ously, the relation between age and bladder capacity
is not linear for all ages, nor is the relation between
body weight and bladder capacity (15).

Another formula to calculate bladder capacity in in-
fants is: bladder capacity (ml) = 38 + (2.5 x age (mo))
(11).

Kaefer and co-workers demonstrated that a non-line-
ear model was the most accurate for the relation be-
tween age and bladder capacity, and they determined
two practical linear equations:

Y = 2 X + 2 for children less than 2 years old, and Y
= X/2+6 for those 2 years old or older; Y = capacity in
ounces, X = age in years (Fig. 2) (16).
Fig 1. Bladder capacity using the formula

\[ Y = 30 + 30X \]

(\( Y = \) capacity in ml, \( X = \) age in years)

None of these formulae have been acquired from a population based study and do not reflect normal bladder capacity. Normal bladder capacity should be regarded as the maximum voided volume of urine and shows huge variation. Recent work of Rittig et al looked at Maximum Voided Volumes (MVV). The Koff Formula showed a reasonably good correlation with 2836 daytime voids, if first morning voids were neglected (17). Girls were found to have a larger capacity than boys, but the rate of increase with age was not significantly different between them. Data on ‘normal’ bladder capacity have been obtained in continent children undergoing cystography, with retrograde filling of the bladder. Data obtained from the International Reflux Study indicate that there is not a linear relation between age and capacity and that there is a huge variability. (Fig. 3) (18).

2.2. Normal voiding

The micturition frequency of the fetus during the last trimester is approximately 30 per 24 hours. It decreases to 12 during the first year of life, and after that it is gradually reduced to an average of 5±1 voids per day (11, 16). The normal range for the micturition frequency at age seven is 3 to 7 (19).

By age 12, the daily pattern of voiding includes 4-6 voids per day (20). Mattson and Lindström emphasize the enormous variability of voiding frequencies in children: also in individual children, the weight-corrected diuresis could vary up to 10-fold (21).

Fig 2. Bladder capacity using the formula

\[ Y = (2X + 2) \times 28.35 \text{ ml} < 2 \text{ years} \]

\[ Y = (X/2+6) \times 28.35 \text{ ml} > 2 \text{ years} \]

(\( Y = \) capacity in ml, \( X = \) age in years)

Fig 3. Bladder capacities determined by VCUG in the International Reflux Study

2.3. Normal voiding pressures

Bladder dynamics in children have demonstrated developmental changes with age. Detrusor pressures at voiding in children after the age of 2 years are similar to adults, with a mean maximum pressure of 66 cm H₂O in boys, and 57 cm H₂O in girls (22).

These pressures are lower than those reported in infancy by Yeung et al, who found boys having pressures of 118 cm H₂O and girls 75 cm H₂O (6).

2.4. Normal urinary flow rates

Urinary flow rates in normal children have been only minimally described. Szabo et al published nomograms for flow rates vs. age in normal children (23).

As in adults, flow rates are clearly dependent upon voided volume, and normal values can only be applied to flow rates that have been registered when
EVALUATION IN CHILDREN WHO WET

Even with clear definitions, the approach to history-taking and physical examination should be structured. The child’s complaints at presentation are not synonymous with the signs and symptoms that have to be checked to arrive at a diagnosis. Also, sociocultural aspects and psychomotor development will distort the presentation. The International Children’s Continence Society has provided two standardisation documents on the diagnostic evaluation of children with daytime incontinence as well as on the evaluation of and treatment for monosymptomatic enuresis (1,2). Standardisation reports on urodynamic studies of the lower urinary and on initial diagnostic evaluation, follow-up and therapeutic intervention in congenital neurogenic bladder and bowel dysfunction in children are available (3,4).

Validated questionnaires are very helpful in structuring the history-taking; they at least provide checklists (5). With a structured approach the diagnosis of monosymptomatic nocturnal enuresis can be made with confidence.

When ultrasound imaging of kidneys and bladder, recording of urinary flow, and measurement of post-void residual are added to history and physical examination, the clinical entities caused by functional disturbances of the bladder and sphincter mechanism (non-neurogenic detrusor and pelvic floor dysfunction) can be diagnosed accurately in the majority of cases, and a high level of suspicion can be maintained towards incomplete bladder emptying in both neurogenic pelvic floor dysfunction and structurally caused incontinence. This is important in view of the potential these conditions have to cause irreversible loss of kidney function.

In a minority of incontinent children the non-invasive assessment yields equivocal results, or results suggesting gross deviations from normal function. Only in these situations is there an indication for invasive investigations, such as:

- Voiding cystourethrography.
- Invasive urodynamics (cystometry, pressure/flow/EMG studies, videocystometry).
- Renal scans or intravenous urography.
- Cystourethroscopy.

II. EVALUATION IN CHILDREN WHO WET

For the paediatric age group, where the history is jointly obtained from parents and child, and where the failure to develop bladder control generates specific problems, a structured approach with a questionnaire is recommended (5,6).

Level of evidence: 3
Grade of recommendation: B

Many signs and symptoms related to voiding and wetting are new to the parents, and they should be specifically asked for, using the questionnaire as checklist. If possible the child should be addressed as the patient and questioned directly, as the symptoms prompting the parents to seek consultation may be different from those are problematic for the child.

A voiding diary is mandatory to determine the child’s voiding frequency and voided volumes. Checklists and frequency volume chart can be filled out at home, and checked at the first visit to the clinic. History-taking should also include assessment of bowel function; a similar proactive process using a questionnaire should be followed for defaecation and faecal soiling (7).

The general history-taking should include questions relevant to familial disorders, neurological and congenital abnormalities, as well as information on previous urinary infections, behavioural problems, relevant surgery and menstrual and sexual function (in pubertal and older children). Information should be obtained on medication with known or possible effects on the lower urinary tract.

The ICCS recommends to screen all children with incontinence with validated questionnaire forms such as CBCL (Achenbach) or Strengths and Difficulties Questionnaire (SDQ) (8,9).

A short screening instrument for psychological problems in enuresis (SSIPPE) and a disease specific quality of life questionnaire for children with LUTD called PinQ are also validated tools available to the clinician (10,11). If a clinically relevant behavioural or emotional disorder is suspected, a full child psychological or psychiatric assessment is recommended (8).

Sexual abuse can be signalled first by symptoms of the lower urinary or gastrointestinal tract (12). However, other more specific symptoms of abuse predominate (13).

Level of evidence: 4
Grade of recommendation: C

1. HISTORY TAKING

For the paediatric age group, where the history is jointly obtained from parents and child, and where the failure to develop bladder control generates specific problems, a structured approach with a questionnaire is recommended (5,6).

Level of evidence: 3
Grade of recommendation: B

Many signs and symptoms related to voiding and wetting are new to the parents, and they should be specifically asked for, using the questionnaire as checklist. If possible the child should be addressed as the patient and questioned directly, as the symptoms prompting the parents to seek consultation may be different from those are problematic for the child.

A voiding diary is mandatory to determine the child’s voiding frequency and voided volumes. Checklists and frequency volume chart can be filled out at home, and checked at the first visit to the clinic. Sexual abuse can be signalled first by symptoms of the lower urinary or gastrointestinal tract (12). However, other more specific symptoms of abuse predominate (13).

Level of evidence: 4
Grade of recommendation: C

2. PHYSICAL EXAMINATION

Apart from a general paediatric examination, the physical examination should include the assessment of perineal sensation, the perineal reflexes supplied by the sacral segments S1-S4 (standing on toes, bulbocavernosus) and anal sphincter tone and control. Special attention should be paid to inspection of the male or female genital region, and of the urethral meatus. Asymmetry of buttocks, legs or feet, as well
as other signs of occult neurospinal dysraphism in the lumbosacral area (subcutaneous lipoma, skin discoloration, hair growth and abnormal gait) should be specifically looked for (14).

In examining the abdomen for the presence of a full bladder, a full sigmoid or descending colon is a significant finding with a history of constipation.

Detailed questioning of the parents’ observation of the child’s voiding habits is essential as is direct observation of the voiding, if possible. Children may have their voiding dysfunction ameliorated or even eliminated by correcting anomalies of body position detected when observing the child's micturition. Children may void in awkward positions, e.g. with their legs crossed or balancing on the toilet without proper support of the legs, thereby preventing the pelvic floor relaxation and obstructing the free flow of urine (15) (Fig. 4).

Level of evidence: 4
Grade of recommendation: D

3. URINALYSIS

In order to be comprehensive, physical examination should include urinalysis to identify patients with urinary tract infection, diabetes mellitus, diabetes insipidus and hypercalcuria if indicated (16).

4. NON-INVASIVE TECHNIQUES

The frequency/volume chart is a detailed diary recording each void by time and urine output over 24-hour periods. The chart gives objective information on the number of voidings, the distribution of day and night voids, along with the voided volumes and episodes of urgency and leakage, or dribbling. In order to obtain a complete picture, defaecation frequency and/or soiling are often also recorded: this becomes termed as bladder-bowel diary due to its complexity.

For a complete picture of the child’s elimination habits, a 14-day defaecation diary that includes frequency, soiling and stool consistency based on the Bristol Stool Form scale and Rome III criteria should be documented (17).

The frequency volume chart provides the maximum storage capacity as the largest voided volume, exclusive of the first morning micturition which reflects overnight urine production and capacity, and is termed maximum voided volume (MVV) (18). MVV should be referenced during cystometry to prevent overfilling. Whenever possible, filling out the chart is the responsibility of the child: the parents provide assistance and support. Ideally the chart should cover 3 complete days, but in reality completion over a weekend restricts the record to 2 days (19). The frequency volume chart is a reliable non-invasive measure of maximum bladder storage capacity and can be used as an outcome measure in children with bladder dysfunction if care is taken to minimise confounding factors and sources of error during chart completion (19). The amount of urine voided by a non-supervised child during the day varies considerably since the child's voidings are dictated more by social circumstances and/or bladder activity rather than by bladder capacity. Children with bladder symptoms void smaller volumes of urine than may be expected from traditional estimates (19). This is unrelated to either gender, type of presenting incontinence or a positive family history of bladder dysfunction. The only significant influence upon voided volumes recorded on a frequency volume chart is the age effect, and voided volumes, even in incontinent children, increase incrementally with age. The frequency volume chart is useful when comparing the mean voided volume and standard deviation by a child's age (20,21).

Validation and test/retest data on frequency/volume charts whilst scarce indicate that voiding interval is the most variable parameter. Data in normal children and in children with different categories of incontinence are available for comparison (19,22,23).

In order to obtain a complete picture it is better to ask for a bladder diary: fluid intake as well as voiding frequency, voided volumes, incontinence episodes and defaecation frequency and/or soiling are recorded.
Test/retest evaluation is not available; trend analyses of frequency/volume charts can be extracted from currently available data.

**Level of evidence: 3**

**Grade of recommendation: B**

### 5. QUANTIFICATION OF URINE LOSS

Subjective grading of incontinence may not indicate reliably the degree of dysfunction. For objective grading, 12-hour pad test and frequency/volume charts are validated instruments (23-25). One should be aware that children tend to do their utmost best when filling out diaries and doing pad tests: underestimation is more the case than overestimation (26).

In children, the 12-hour pad test should also give information about fluid intake. The pad test is complementary to the bladder diary, which denotes more the frequency of incontinence and the distribution of wetting episodes than the quantities of urine lost.

The amount of urine lost during sleep can be determined by weighing diapers or absorbent pads, before and after sleep. To obtain a measure of the total nocturnal urine output, the volume of the early-morning voiding should be added to the amount lost during sleep.

### 6. SCORING SYSTEMS

At present three scoring systems, based on validated questionnaires have been described. Specific scores correlated with lower urinary tract dysfunction with a specificity and sensitivity of about 90% (27-29).

The value of these scoring systems to determine the cause of incontinence seems to be of limited value to the individual patient, but can be very useful in studies to determine and compare treatment outcome.

**Level of evidence: 3**

**Grade of recommendation: C**

#### 6.1. Quantification of constipation

Scoring a plain X-ray of the abdomen (Barr score) yields inconsistent results in grading constipation. (17,30-32) Reproducibility seems to be best using the method described by Leech (33-35). A better way to match clues from the medical history with signs and symptoms is the measurement of colonic transit time. As many children with an overactive bladder habitually use their pelvic floor as an “emergency brake”, anomalous defaecation frequency and constipation have a high prevalence in this group.

Diagnosing constipation is important: we recommend using the Rome III criteria listed in the table below (36).

The Rome III paediatric criteria for functional constipation

<table>
<thead>
<tr>
<th>Functional constipation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Must include ≥ 2 of the following in a child with a developmental age of ≥ 4 years with insufficient criteria for diagnosis of IBS:</td>
</tr>
<tr>
<td>• ≤ 2 defaecations per week</td>
</tr>
<tr>
<td>• ≥ 1 episode of faecal incontinence per week</td>
</tr>
<tr>
<td>• History of retentive posturing or excessive volitional stool retention</td>
</tr>
<tr>
<td>• History of painful or hard bowel movements</td>
</tr>
<tr>
<td>• Presence of a large faecal mass in the rectum</td>
</tr>
<tr>
<td>• History of large diameter stools that obstruct the toilet</td>
</tr>
</tbody>
</table>

For a complete picture of the child’s elimination habits, a 14-day defaecation diary that includes frequency, soiling and stool consistency based on the Bristol Stool Form scale and Rome III criteria is documented (17).

A non-invasive way to determine faecal retention is the estimation of rectal diameter on ultrasound. In children without constipation the mean diameter was 2.2, 2.1 and 2.4 cm in three different studies respectively (37-39). In children with constipation the rectal diameter was on average 3.4 cm in the first, 4.9 in the second and 4.2 cm in the third study, significantly different from the non-constipated children. Joensson et al. also re-measured constipated children 4 weeks after treatment with laxatives finding the rectal diameters in the constipation group were significantly reduced (p < 0.001) (40).

Finding a dilated and filled rectum on ultrasound while the child feels no need to defaecate probably can replace a digital rectal examination and a distended rectum in ultrasound of 35 mm or more may be one of the signs indicative of constipation.

Overt constipation should be dealt with before embarking on treatment of incontinence or bladder and pelvic floor dysfunction (41,42).

**Level of evidence 3**

**Grade of recommendation: B**

### 7. URINARY FLOW

Voiding should be analysed in detail in all incontinent children, with the exception of monosymptomatic bedwetting, where voiding, as far as we know, is normal. Graphic registration of the urinary flow rate during voiding is a standard office procedure. Flow patterns and rates should be repeated to allow for evaluation, and several recordings are needed to obtain consistency. Afterwards, parents are asked if their child’s flowmetry pattern was representative of their voiding.
Approximately 1% of school children have a voiding that can be labelled abnormal with flattened or intermittent flow curves. The remaining 99% have a bell-shaped flow curve (43). It should be noted that a normal flow does not exclude a voiding disturbance, nor does an abnormal flow pattern automatically mean a bladder or voiding dysfunction, as in asymptomatic normal schoolchildren abnormal patterns were also found (44,45).

Flow recordings with a voided volume of less than 50% of the functional capacity are not consistent: they represent voiding on command, and many children will try to comply by using abdominal pressure. On the other hand, overdistension of the bladder can result in abnormal uroflow recordings also (46).

A helpful tool in this respect is the use of transabdominal ultrasound (e.g. bladder scan) before micturition in order to assess the bladder volume (47,48). If the bladder is still nearly empty the child should be asked to drink some water until the bladder is full enough for a reliable flow. Urinary flow may be described in terms of rate and pattern and may be continuous, intermittent (in fractions), or staccato (fluctuating). An intermittent flow pattern shows a interrupted flow, whereas in staccato voiding the flow does not stop completely, but fluctuates due to incomplete relaxation of the sphincter.

Measurement of urinary flow is performed as a solitary procedure, with bladder filling by diuresis (spontaneous or forced), or as part of a pressure/flow study, with bladder filling by catheter. Patterns and rates should be consistent to allow for evaluation, and several recordings are needed to obtain consistency (49,50).

The same parameters used to characterise continuous flow may be applicable, if care is exercised, in children with intermittent, or staccato flow patterns (Fig. 2 - 5). In measuring flow time, the time intervals between flow episodes are disregarded. Voiding time is total duration of micturition, including interruptions. (Figures 5 – 8)

Sonographic estimation of Post Void Residual volume completes the assessment. In children >6 years, a repetitive PVR of >20 ml or >10% bladder capacity is considered elevated. In children > 7 years, repetitive PVR>10ml or 6% bladder capacity is regarded as elevated (51). Ideally 3 uroflows are representative but 2 will suffice as this maintains accuracy and consistency.

First morning uroflows should be avoided as they may exceed normal voided volumes

Level of evidence: 3
Grade of recommendation: B

Figure 7: intermittent flow curve in a child voiding with abdominal straining
8. ULTRASOUND IMAGING OF UPPER AND LOWER URINARY TRACT

In most clinical settings, ultrasound-imaging techniques are routinely used in children with incontinence. Upper tract abnormalities such as duplex kidney, dilatation of the collecting system, and gross reflux nephropathy can be readily detected, but detection of the more subtle expressions of these abnormalities requires urological expertise on the part of the ultrasound operator (52).

Lower urinary tract abnormalities are even more difficult to assess for the inexperienced, aside from bladder wall thickness: a bladder wall cross-section of more than 3-4 millimetres, measured at 50% of expected bladder capacity, is suspicious of detrusor overactivity (53,54). Because only a few studies have been conducted to compare bladder wall thickness in normal children without complaints and in children with lower urinary tract dysfunction, more studies need to be performed to validate these non-invasive techniques (55,56).

Another possibility is to assess bladder volume and bladder wall thickness to calculate the Bladder Volume / Bladder Wall Thickness index. In children with nocturnal enuresis this index correlated well with response to treatment (57).

8.1. Post-void residual volume

Except in small infants, the normal bladder will empty completely at every micturition (58).

The identification or exclusion of post-void residual is therefore an integral part of the study of micturition. However, an uneasy child voiding in unfamiliar surroundings may yield unrepresentative results, as may voiding on command with a partially filled or overfilled bladder. When estimating residual urine, voided volume and the time interval between voiding and estimation of post-void residual should be recorded. This is of particular importance if the patient is in a diuretic phase. In patients with gross vesicoureteral reflux, urine from the ureters may enter the bladder immediately after micturition and may falsely be interpreted as residual urine. The absence of residual urine is an observation of clinical value, but does not exclude bladder outlet obstruction or sphincter / pelvic floor overactivity with absolute certainty. An isolated finding of residual urine requires confirmation before being considered significant, especially in infants and young children.

8.2. Ultrasound-flow-ultrasound

This combination of imaging and non-invasive urodynamics is a standardised procedure used to obtain representative data on flow rate and flow pattern, as well as post-void residual volumes. With ultrasound, bladder filling is assessed and when the bladder capacity is equal to the functional or expected bladder capacity for age, the child is asked to void into the flowmeter. After recording the flow, post-void residual is assessed again.

This procedure avoids the registration of flow rates at unrealistic bladder volumes.

Alternatively, children can be asked to use a flowmeter at home: a special flowmeter has been designed to use at home (59). For those children who have difficulty voiding in a strange environment, this option can be useful.
9. **INVASIVE DIAGNOSTIC TECHNIQUES**

The important question (for the incontinent child) “whether invasive diagnostic procedures are necessary” is decided by the results of the non-invasive procedures.

At present, there are no studies indicating that a videocystourethrogram (VCUG) is useful in children with incontinence, but without urinary tract infections.

In general urodynamic studies will only be done if the outcome will alter the management, and this will also depend on whether the possible treatments being considered are invasive. The diagnostic information needed is that which is necessary to find the correct treatment. Indicators include, straining or manual expression during voiding, a weak urinary stream, previous febrile urinary tract infection, continuous dribbling incontinence or pronounced apparent stress incontinence, or previously identified dilating vesicoureteral reflux.

The finding of genitourinary abnormalities or signs of occult spinal dysraphism at physical examination also indicate the need for further diagnostics. Urinary flow registration will detect the plateau-shaped flow curve typical for structural bladder outlet obstruction, and an intermittent flow suggesting detrusor –sphincter- pelvic floor dys-coordination (48).

A clinically significant post-void residual on repeated occasions clearly points to incomplete bladder emptying. The pad test will detect the cases with obvious stress and urgency incontinence, or continuous dribbling. Ultrasound imaging will raise suspicion of an ectopic ureter.

In short, invasive diagnostics are indicated when the non-invasive testing raises suspicion of neurogenic detrusor-sphincter dysfunction (ocul spinal dysraphism), obstruction (especially posterior urethral valves), genitourinary abnormalities (e.g. epispadias), advanced non-neurogenic detrusor-sphincter- pelvic floor dysfunction (as in children with vesicoureteral reflux and upper tract dilatation and/or febrile urinary tract infections), or significant post void residuals.

To diagnose the complex of non-neurogenic detrusor-sphincter dysfunction, recurrent urinary tract infections and vesicoureteral reflux, urodynamic studies are needed in only a minority of all children.

9.1 **Technique of VCUG in children**

Cleanse and rinse the external genitalia with lukewarm water: do not use detergents. Use a feeding tube with side holes and a rounded tip (Ch 06-08) or balloon catheter to catheterise the bladder; check the urine for infection. Empty the bladder completely before filling. Use a radio-opaque dye of maximum 30% concentration, at body temperature, and fill the bladder by slow-drip infusion, with a hydrostatic pressure of not more than 40 cm H2O. Note the volume of the contrast medium instilled. Use fluoroscopy during filling at regular intervals.

Take spot-films (70mm or 90mm camera) with the child in supine position, with partial filling and at the end of filling, in AP projection, of the complete urinary tract. Upper and lower tract should be visible.

When voiding is imminent, change the position of the child so that spot films of bladder and urethra in 3/4 projection can be taken during voiding. Also take a spot film of the upper urinary tract during voiding, as the degree of vesicoureteral reflux (VUR) may change with the pressure generated by the detrusor muscle during voiding. Post-void residual volumes vary very considerably with VCUG. The voiding phase is critically important to VCUG, both for reflux detection and for assessment of voiding dynamics. Without a voiding phase the VCUG is incomplete.

Prophylactic antibiotics are indicated in all children, to minimise the risk for post-VCUG urinary tract infection especially in children with an anatomic abnormality.

9.1.1 **Indications for VCUG**

A VCUG is an invasive procedure and should only be done if the outcome will influence the management. It is indicated in children with recurrent urinary tract infections to detect reflux, in children with a dilated system on ultrasound and in children with an abnormal flow pattern to detect bladder outlet abnormalities (like valves, strictures or a syringocele).

In children with incontinence the lateral projection during voiding is the most important part of the study. Especially in children with stress incontinence or a neurogenic bladder the position and configuration of the bladder neck during filling and voiding should be noted.

In children with non-neurogenic detrusor-sphincter-pelvic floor dysfunction as well as in children with neurogenic detrusor-sphincter dyssynergy, the proximal urethra may show the so-called ‘spinning top’ configuration, during filling and during voiding. With detrusor and pelvic floor muscles contracting at the same time, the force of the detrusor contraction will dilate the proximal urethra down to the level of the forcefully closed striated external sphincter. The resulting ‘spinning top’ configuration used to be seen as a sure sign of distal urethral stenosis, a concept held responsible for recurrent urinary tract infections in girls, with urethral dilatation or blind urethrotomy as the obvious therapy. However, urodynamics made it clear that the ‘spinning top’ will only appear when detrusor and pelvic floor contract synchronously, which makes it a functional anomaly, not an anatomical one (60, 61).

Women often recall their experience with VCUG as young girls in terms bordering on abuse. The use of
VCUG in children should be limited to the absolutely necessary.

9.1.2 (Video)-Urodynamics

In children urodynamic investigations should only be performed if the outcome will have consequences for treatment (62-64). Furthermore like VCUG it may be considered when invasive or surgical interventions are planned. The main question is whether the urodynamic study will provide new information that cannot be obtained otherwise and will influence the further management. From the few studies that have addressed this issue it can be concluded that urodynamic studies in the majority of cases do not provide significant additional information to justify this type of investigation as a routine procedure in children (65-67).

Both children and parents need careful preparation and adequate information before the study is done. It is an invasive procedure and artefacts may occur. Because of the invasiveness of the investigations all children are anxious and this may be reflected in the outcome of the study. Especially during the first filling cycle, when the child does not know what to expect, detrusor overactivity may be seen and the voiding phase can be incomplete due to contraction or incomplete relaxation of the pelvic floor muscles during voiding. Once the child knows that filling and voiding are not painful a subsequent filling and voiding cycle may show a completely different pattern. The study should be repeated at least 2 or 3 times. Only if during the first filling cycle, no detrusor contractions are seen and also the voiding phase is in accordance with history and uroflow, it is probably sufficient to do only one complete filling and voiding cycle (68).

Still the results may not always be reproducible and it should be stressed that the primary objective is to treat the child and not a “urodynamic abnormality” per se.

Special attention should be given to a pleasant surrounding for the child: one or both parents should be present and young children may be given a bottle. Older children may be distracted by watching a video movie. The child should be awake, non-anaesthetised and neither sedated nor taking any drugs that affect bladder function. Intranasal midazolam may be administered in certain situations where high anxiety levels cannot be mollified, as this drug appears to be innocuous regarding outcome of the study (69).

During the study the investigator has the opportunity to observe the child and discuss various findings and correlate them to what the child feels and/or normally would do in such circumstances. Because UDS is an invasive procedure artefacts may influence accurate interpretation of results (70)

In children, the transition from filling phase to voiding phase is not as marked as in adults. To avoid missing this important transition, cystometry and pressure-flow/EMG measurements are performed as one continuous study in paediatric urodynamics.

Electromyography of the pelvic floor muscles is assumed to evaluate the activity of the striated urethral sphincter, in the filling phase and in the voiding phase. Surface skin electrodes are usually used to record the EMG. In children the pelvic floor EMG is probably of much more importance than in adults as it helps to differentiate the different voiding disorders.

Filling the bladder can be achieved by diuresis (natural fill cystometry) or retrograde by catheter. For retrograde filling by catheter, saline 0.9% or contrast medium at body temperature is recommended in children. Especially in young children some urodynamic parameters, such as capacity and detrusor activity are influenced by the temperature of the filling fluid. Although the clinical relevance is as yet unknown, it is recommended to fill the bladder with fluid of body temperature (71).

When filling by catheter, slow fill cystometry (5 – 10 percent of expected bladder capacity per minute (based on the voiding diary), or < 10ml/min) is recommended in children.

Involuntary detrusor contractions may be provoked by rapid filling, alterations of posture, coughing, walking, jumping, and other triggering procedures.

The presence of these contractions does not necessarily imply a neurological disorder. In infants, detrusor contractions often occur throughout the filling phase (Figure 9).

Bladder sensation is difficult to evaluate in children. Only in toilet-trained cooperative children is it a relevant parameter. Normal desire to void is not relevant in the infant, but can be used as a guideline in children of 4 years and older. Normal desire to void should be considered the volume at which some unrest is noted, e.g. wriggling the toes; this usually indicates voiding is imminent. In the older child, the volume may be small with the first cystometry, for fear of discomfort. Also involuntary detrusor contractions occur more often during the first filling cycle (71). This is the reason that in paediatric urodynamics at least two cycles of filling are recommended.
Maximum cystometric capacity (MCC) is the volume in the bladder at which the infant or child starts voiding. The value for maximum cystometric capacity is derived from volume voided plus residual volume. Values for MCC should be interpreted in relation to normal values for age.

Compliance indicates the change in volume for a change in pressure. For children with neurogenic detrusor-sphincter dysfunction, data are available relating poor compliance to the risk of upper urinary tract damage (73).

The usual notation for compliance is a single value, but a full characterisation of compliance may be helpful, as some children have varying compliance factors throughout filling (74). This variability depends on several factors: rate of filling, which part of the curve is used for compliance calculation, shape (configuration) of the bladder, thickness, and mechanical properties of the bladder wall, contractility, relaxability of the detrusor, and degree of bladder outlet resistance (68).

The urethral closure mechanism during storage may be normal or incompetent. The normal urethral closure mechanism maintains a positive urethral closure pressure during filling, even in the presence of increased abdominal pressure or during detrusor overactivity (guarding reflex) (72). An incompetent closure mechanism is defined as one that allows leakage of urine in the absence of a detrusor contraction. In urodynamic stress incontinence, leakage occurs when Pves exceeds Purethra (intraurethral resistance) as a result of an increase in intraabdominal pressure, often in conjunction with low Purethra (72). Although common in multiparous females, it is exceedingly rare in paediatrics but may be noted in athletically active teenage girls (77). Immediately prior to micturition the normal closure pressure decreases to allow flow.

Bladder outlet obstruction, recorded with a pressure / flow study, may be anatomical or functional in nature. An anatomical obstruction may be present at the bladder neck or in the urethra as a stenosis or a stricture when there is a small and fixed urethral diameter that does not dilate during voiding. As a result, the flow pattern is plateau shaped, with a low and constant maximum flow rate, despite high detrusor pressure and complete relaxation of the urethral sphincter. In a functional obstruction, it is the active contraction of the urethral sphincter or pelvic floor during passage of urine, that creates the narrow urethral segment as a constant or intermittent obstruction. To differentiate anatomical from functional obstruction, information is needed about the activity of the urethral sphincter during voiding. This information can be obtained, and recorded together with pressure and flow, by monitoring the urethral pressure at the level of the urethral sphincter, or by recording a continuous electromyogram of the pelvic floor, as in clinical practice the urethral sphincter is not readily accessible, and the electromyogram of the external anal sphincter is
often used to monitor activity of the striated urethral sphincter. This corresponds to activity of the pelvic floor muscles. Also the use of video urodynamics can be very helpful in this respect, as contractions of the pelvic floor muscles can actually be seen during the voiding phase (Fig 5 and 6).

In infants and small children, pelvic floor muscle overactivity during voiding (with post-void residuals) is not uncommon: in all probability, it is a normal developmental feature (75,76).

9.1.3 Cystoscopy

In the majority of children cystoscopy is not indicated. In boys with therapy resistant incontinence, an abnormal flow pattern, especially in combination with a history of (recurrent) urinary tract infection is suspicious of infra-vesical obstruction such as bladder neck obstruction, urethral valves, syringocele etc. A VCUG may not always show these abnormalities and pressure flow curves may be equivocal (78).

In girls the flow may be directed upward, indicating an abnormal meatal position or stenosis. A dorsal meatalotomy generally solves this problem. It has been postulated that in girls the abnormal direction of the stream triggers the bulbocavernous reflex resulting in dysfunctional voiding (79).

III. CHILDREN WITH NIGHT TIME INCONTINENCE

Nocturnal enuresis is a complex disorder, with multiple pathogenetic factors, treated by multiple disciplines but seldom in a multidisciplinary setting, leading to confusing terminology. To avoid further confusion, this an update to previous ICI-papers, largely keeping the same definitions and structure [1], integrating with recent ICCS standardisation papers [2].

1. DEFINITION

Nocturnal enuresis (NE) is involuntary voiding of urine during sleep a week, in children over 5 years of age in the absence of congenital or acquired defects of the central nervous system [3]. Parental concern and child distress affect the clinical significance of the problem [4], and is to some extent country and culture dependent. Most children who wet at night after age five should be considered as patients with enuresis, although decision to start diagnostic and therapeutic approach must take in account that several factors including the child’s development level play a role. The age criterion of five is not only epidemiology driven, but reflects the natural course of achieving bladder control [5-7], as well the maturation of the circadian rhythm of diuresis. Epidemiology demonstrates that girls acquire earlier continence than boys, a gender difference that disappears after age of 10 years [5,8,9]. Research on pathophysiology has demonstrated that both diuresis-rate and bladder dysfunction might play a role in this sex difference.

NE is bedwetting without daytime symptoms. Non-monosymptomatic or polysymptomatic NE describes children with both day and night-time wetting [10], but further finetuned by including also patients with other daytime symptoms (LUTS) than incontinence [2,11]. This subtyping is essential for appropriate diagnostic and therapeutic approach in first line, but there is a large overlap in pathogenesis between both groups. Where all patients with NMNE have underlying bladder dysfunction

2. SEVERITY

Nocturnal enuretics vary in wetting frequency. Although fifteen percent wet each night, most children wet less frequently [2, 12]. In a population survey of nearly 1,800 Irish children aged 4 –14 years, Devlin found the frequency of wetting as follows: less than once per week in 33 percent, once per week in 11 percent and 2 to 4 times per month in 25 percent [13]. Some children and parents are concerned about an occasional wet bed, while others accept regular wetting.

Various definitions have complicated the literature and research. Applying the criteria set forth by the DSM-5 and ICD-10, enuresis and daytime urinary incontinence is a significant condition if it occurs >1 episode per month and a frequency of 3 episodes over 3 months. We propose in the future to follow the ICCS definition to qualify the significance of enuresis as frequent (>4 per week) or infrequent (<4 per week), to homogenise literature and future studies [2]. Severe bedwetters at the age of 5 years have a poor prognosis, with a spontaneous regression-rate of only 50-60% [9].

3. PREVALENCE

Bedwetting is common. In the United Kingdom, estimates approximately 750,000 children and young people over 7 years regularly wet the bed. In the United States 5 to 7 million children regularly experience primary NE [14-16]. The prevalence of bedwetting might vary regionally, although self-reporting might underestimate the real problem, because of the taboo in several cultures. In China, where parents take children out of diapers earlier, bedwetting seems to resolve more quickly. For example, in a large survey from Shandon, the proportion of children attaining nocturnal urinary control before age 2 was 7.7%; by age 3, this had increased to 53.1%, and by age 5 to 93%. The overall prevalence of NE was 4.3%, with a significantly higher prevalence in boys than girls. There was no additional decrease in the prevalence of enuresis between 6 and 16 years [17]. This can suggest that structured awakening and toileting is effective treatment for monosymptomatic NE, even in
small children, although the observation of CK Yeung suggests that in Hong Kong a progressive increase of self-reported enuresis rate could be explained by increased awareness and less taboo, but probably also because of changing lifestyle and nutritional habits [8, 9, 18].

Bedwetting becomes less common with advancing age. In the West, 15 per cent of children each year develop nocturnal bladder control [3]. By adulthood, bedwetting is rare. Hirasing et al sampled over 13,000 adults [18-64 years] and found only two decades ago an overall prevalence rate of NE at 0.5% [19]. Of these, 12 percent of men and 29 percent of women had daytime incontinence. Despite persistence of wetting into adulthood, 50 percent of men and 35 percent of the women never seek help for their problem. The enuresis prevalence of 0.5% in otherwise healthy adults in Hirasing’s study refers to a largely untreated population. Fifty percent of the men had primary enuresis and had never been consistently dry at night. Assuming a prevalence of enuresis of 8 percent in 7-year-old boys, the risk for an enuretic boy to remain so for the rest of his life is 3 percent. CK Yeung documented that the severe cases had only a spontaneous regression-rate of 50-60 % [18].

Adults with enuresis represent a “hard core” group with worse symptoms. These individuals are likely to have associated LUTS during daytime. Goessaert with worse symptoms. These individuals are likely to have associated LUTS during daytime. Goessaert et al documented that in patients with long-term follow up 1/3 patients persisted to have symptoms into adulthood, especially in a subgroup with nocturia (p<0.01) [22].

4. INHERITANCE

Bedwetting runs in the family of many children who suffer from bedwetting. In one study, a positive family history was found in 94 families (23%) of 411 probands with PNE, including 49% of fathers, 9% of mothers, 6% of both parents, 6% of the siblings and 30% of grandfathers or (and) mothers. Among the probands the ratio of male to female was 1.3:1 excluding sex-linked inheritance. Family studies indicated autosomal dominant inheritance in 15%, and autosomal recessive inheritance consistent in 1.46% of families. Thus, the mode of inheritance is usually autosomal dominant; if both parents were nocturnal enuretics as children, the risk for their children is from 65 to 85 % [3,23]. If only one parent has NE the risk is about 45 percent [24].

Molecular studies have clearly shown that NE is a complex disease with locus heterogeneity and no clear genotype-phenotype association.

Linkage studies to determine the location of the genetic changes have suggested loci on several genes. Linkage studies to markers on chromosomes 4p, 8q, 12q and 13q and 22s demonstrate both clinical, as well as genetic heterogeneity in nocturnal enuresis [25-29]. So far, there has been no reported association of the genotype with a phenotype of enuresis [29]. The weak indications from genetic studies might indicate only autosomal monogenetic inheritance in a minority of cases, where in many families the predisposition might be multifactorial.

5. SEX AND MONOSYMPTOMATIC NE

Boys suffer nocturnal enuresis more frequently. In a population survey in London of 706 families, a higher prevalence was found for boys than girls, at age 3 years, with 56 percent of boys and 40 percent of girls being wet at night more than once a week [30]. More recent studies are consistent [31]. Surveys of monosymptomatic NE undertaken in Great Britain, Holland, New Zealand and Ireland suggest that the prevalence for boys is 13-19% at 5 years, 15-22% at 7 years, 9-13% at 9 years and 1-2% at 16 years. For girls, the prevalence rates are about half: 9-16% at 5 years, 7-15% at 7 years, 5-10% at 9 years and 1-2% in the late teenage years [5, 6, 13]. Although monosymptomatic NE is more common in young boys, by adolescence the incidence in males is the same as in females [9, 32]. This might be explained by gender difference in maturation of the bladder, but also in renal sensitivity to vasopressin, not only in the elderly but also in children [33,34,35,36].

6. CLASSIFICATION

6.1. Primary versus secondary nocturnal enuresis

Children who have never been free of bedwetting for 6 months have primary NE. Secondary NE is the re-emergence of wetting after a period of being dry for at least six months. A birth cohort of 1265 New Zealand children studied over 10 years by Fergusson et al found an increased risk of secondary nocturnal enuresis with age [37]. The proportion of children who developed secondary enuresis was 3.3 percent at 5 years, 4.7 percent at 6 years, 6.2 percent at 7 years, 7.0 percent at 8 years, 7.5 percent at 9 years and 7.9 percent at 10 years. But all studies failed to document how many patients with secondary enuresis, were totally symptom free, including absence of LUTS during daytime and nocturia. In the past, major attention was given to the psychological comorbidities: Secondary NE is associated with a higher incidence of stressful events particularly parental separation, disharmony between parents, birth of a sibling, early separation of the child from parents and psychiatric disturbance in a parent [24, 37, 38]. Von Gontard and colleagues found children with secondary enuresis had significantly more emotional difficulties compared to those with primary NE. Their evidence also suggests children with secondary enuresis, compared to those with primary enuresis, are more likely to have behavioural problems, a finding which corresponds to that of McGee et al [1, 39, 40].
Both Jarvelin and Fergusson et al argue that primary and secondary enuretics are similar [37, 41]. They believe the two share a common organic aetiological basis. The rate the child acquires primary control influences his or her risk of secondary enuresis. The primary form is the consequence of a delay in maturation of the physiological mechanisms. The child’s capacity to sustain and maintain nocturnal bladder control is manifest in the rate at which he or she acquires control. On the other hand, this capacity determines the child’s susceptibility to lapsing back to night wetting when exposed to stress. Psychological factors should be considered as comorbidities.

Other sources of secondary enuresis must be excluded prior to proceeding with treatment for enuresis. These include sleep apnoea from obstructive airway disease, obesity, constipation and infrequent or dysfunctional voiding. Treatment of sleep apnoea from an obstructed airway has been shown to improve or eliminate NE in some children following surgery or medical management [42, 43]. Obesity has been associated with nocturnal enuresis both independently [44-47] and in the context of sleep apnoea [48-51].

6.2. Mono-symptomatic versus non-mono-symptomatic NE

Mono-symptomatic NE refers to those children who report no other bladder or voiding problems associated with wetting. Non-mono-symptomatic NE refers to bedwetting, that is associated with overt detrusor overactivity or voiding problems such as urgency, frequency and bladder holding during the day [52, 53].

This classification becomes important when considering the most appropriate treatment intervention. Many parents are unaware of daytime symptoms when seeking help for bedwetting and when identified these symptoms should be treated prior to intervention for the NE. Between 10-28% of children with NE have associated daytime wetting, and were considered according to the old ICCS standardisation [54] as NMNE. If so, these children should be considered day and night incontinent. In these cases, night time incontinence is not any longer an isolated phenomenon but part of the symptomatology of day and night time incontinence. These children are more resistant to treatment and more vulnerable to relapse [55]. These boys and girls are more appropriately managed in the context of the primary bladder problem.

7. PATHOPHYSIOLOGY OF MONOSYMPTOMATIC NE

NE stems from a mismatch of functional bladder volume overnight and, nocturnal urine output and the ability for the child to arouse during sleep. Night wetting is considered normal/acceptable until age 5. Delayed maturation in one or more of the following systems results in NE: overactive bladder (OAB), or decreased arginine vasopressin (AVP) release are considered to play a major role. In desmopressin refractory nocturnal polyuria, more complex pathogenetic mechanisms are involved, such as abnormal circadian rhythm of different renal functions resulting in a relative increased solute excretion during the night [56-60]. The third parameter is an inability to wake from sleep to full bladder sensations [61, 62]. Combinations of all three problems may be present.

A unifying and simplistic concept with important clinical implications, is that NE is caused by a mismatch between nocturnal bladder capacity and the amount of urine produced during the night, combined with delayed or incomplete arousal response to the afferent neurological stimulus of the full bladder (Figure 1 and 2).

7.1. Increased nocturnal urine output

In normal children, the circadian rhythm of urine production results in a nocturnal reduction in diuresis to approximately 50% of daytime levels [63, 64]. In children, this is the result of nocturnal release of hormones that regulate free water excretion (arginine vasopressin, (AVP) [65, 66] or solute excretion (angiotensin II and aldosterone) as well [67, 68] as haemodynamic homeostasis [69] and may result from circadian changes in glomerular filtration [70-72]. In the normal child, this results in increased urine concentration and reduced urine volume during sleep, in presence of decreased osmotic excretion. Therefore, children who are not enuretic sleep through the night without being wet and do not need to rise to void.

Two thirds of patients with mono-symptomatic NE [2] have been found to have a lack of circadian rhythm of vasopressin, resulting in high nocturnal urine production, which exceeds bladder capacity [65, 73, 74]. Rittig et al and Norgaard et al demonstrated abnormalities in the circadian rhythm of AVP secretion resulting in increased nocturnal urine output that exceeded bladder capacity in children with nocturnal enuresis [65] [66, 73]. These children make more urine at night, and often overcome their bladder capacity and wet early in the night. Abnormalities can also be intrinsic, related to reduced nocturnal circadian changes in glomerular filtration rate (GFR) [70, 72] or in sodium and calcium excretion [59, 75-78]. Detection of low plasma vasopressin levels, GFR assessments or specific sodium and calcium excretion are too difficult to measure as first line investigation. Instead, we look for clinical signs of low vasopressin during the assessment interview. Weighing the diapers and adding the first morning void provides the total nocturnal urine output. If this total exceeds the child’s functional bladder capacity this may indicate nocturnal polyuria. Nocturnal polyuria is defined as nocturnal diuresis >130% of expected bladder capacity for age, this is based on expert opinion [79]. If we would indicate the diuresis volume that might predict desmopressin response, >100%EBV seems to be more appropriate [80]. Nocturnal urine output varies appreciably from night to night [36, 81], but seems...
larger in children with NE who respond best to desmopressin (dDAVP) [82].

By the time the child becomes an adolescent, the circadian rhythm is less prominent. In adolescents and adults with nocturnal enuresis, there is no diurnal rhythm of plasma vasopressin concentration. The changes in urine production at night occur from a decrease in the urinary sodium excretion that is not due to differences in concentration of AVP but due to a lack of sensitivity to AVP [64, 83] [84] with resultant increased urine output [56, 85].

There may be a small sub-group of children with impaired renal sensitivity to vasopressin or desmopressin [57, 81, 86]. Recent work by Devitt et al suggests that 18 percent of children have 'normal' levels of plasma vasopressin release but remain enuretic [74, 87]. These children all failed to respond to a therapeutic dosage of desmopressin. This finding could indicate renal insensitivity to vasopressin but could also be indicative of detrusor overactivity or a small functional bladder capacity. Total urine output during the night could be helpful in differentiating between the two conditions. The archetype of patients with NE and increased nocturnal urine output generally has a normal functional bladder capacity and a favourable response to dDAVP [88] [11, 80, 82], while the archetype of patients with OAB, will reduce fluid intake as a response to dDAVP [97] [98]. When further segregated prior to treatment, increased bladder wall thickness and bladder volume predicted the response to therapy in children with their primary nocturnal enuresis (more than three nights weekly). In one study, Yeung, et al. [97], correlated ultrasound measured parameters and urodynamic findings. Of 35 children with frequent NE, bladder wall thickness index was normal in only eight patients. It was less than 70% of predicted in 24, and more than 130% in three. When bladder volume and wall thickness index was correlated with ultrasound, 87% of the patients with a normal index exhibited a normal bladder pattern on imaging and 96% of patients with an index less than 70 exhibited detrusor over activity on ultrasound. All the children with a normal index either had a complete or good response to conventional treatment for nocturnal enuresis, whereas 62% of those with an index less than 70 % did not respond to treatment. With longer follow-up, bladder dysfunction had resolved in 38% of the children with an initial index of less than 30, all of whom had a good response to treatment. The bladder dysfunction persisted in the 63% of children who had partial or no response to treatment. What this means is that ultrasound measured bladder parameters may segregate children, prior to management of primary nocturnal enuresis, into groups that have a favourable outcome and those that do not, following conventional treatment. These studies will become more and more important in helping to predict response of various treatment regiments in the future.

This approach may be even more important in adults with refractory monosymptomatic nocturnal enuresis. Bower, et al. [99] found that in 56 consecutive adolescents and adults compared with 293 normal adults, there were significantly higher childhood scores of urgency, frequency, urgency incontinence, infrequent voiding and small volume voids than their normal non-enuretic counterparts. This suggests that adolescents and adults with persistent nocturnal enuresis may have a more significant bladder component, particularly since the majority of patients with adult type nocturnal enuresis do not seem to exhibit the nocturnal polyuria problem seen more commonly in the smaller children.

7.2. Detrusor overactivity during the night

The detrusor, to function appropriately, needs to be relaxed during filling and allow an appropriate functional capacity. Detrusor overactivity usually causes small voided volumes resulting in a decreased functional bladder capacity [89].

Watanabe and his colleagues, employing EEG and cystometry recording during sleep, discovered that 32 percent of children with NE had involuntary detrusor contractions that resulted in enuresis [90-93]. These children had smaller functional bladder capacities at the point of wetting, than children with enuresis who did not have detrusor overactivity. Functional bladder capacity – defined as the largest daytime void on a frequency- volume (F/V) chart, after excluding the first morning void, may give a reasonably accurate assessment of daytime functional bladder capacity (FBC). Reduced functional bladder capacity, when below 70% of predicted FBC for age, is likely to result in poor response to dDAVP treatment [80, 94]. Daytime bladder capacity is smaller than night time capacity in children without NE [95].

The pattern may be different at night. Yeung et al reported that 44 percent of treatment failures [with desmopressin or the enuresis alarm] have normal daytime bladder function but marked detrusor overactivity during sleep resulting in enuresis [96]. Almost none of these children had nocturnal polyuria. Ultrasound studies of the bladder furthermore revealed an increased bladder wall thickness in these children [97] [98].

When further segregated prior to treatment, increased bladder wall thickness and bladder volume predicted the response to therapy in children with their primary nocturnal enuresis (more than three nights weekly). In one study, Yeung, et al. [97], correlated ultrasound measured parameters and urodynamic findings. Of 35 children with frequent NE, bladder wall thickness index was normal in only eight patients. It was less than 70% of predicted in 24, and more than 130% in three. When bladder volume and wall thickness index was correlated with ultrasound, 87% of the patients with a normal index exhibited a normal bladder pattern on imaging and 96% of patients with an index less than 70 exhibited detrusor over activity on ultrasound. All the children with a normal index either had a complete or good response to conventional treatment for nocturnal enuresis, whereas 62% of those with an index less than 70 % did not respond to treatment. With longer follow-up, bladder dysfunction had resolved in 38% of the children with an initial index of less than 30, all of whom had a good response to treatment. The bladder dysfunction persisted in the 63% of children who had partial or no response to treatment. What this means is that ultrasound measured bladder parameters may segregate children, prior to management of primary nocturnal enuresis, into groups that have a favourable outcome and those that do not, following conventional treatment. These studies will become more and more important in helping to predict response of various treatment regiments in the future.

This approach may be even more important in adults with refractory monosymptomatic nocturnal enuresis. Bower, et al. [99] found that in 56 consecutive adolescents and adults compared with 293 normal adults, there were significantly higher childhood scores of urgency, frequency, urgency incontinence, infrequent voiding and small volume voids than their normal non-enuretic counterparts. This suggests that adolescents and adults with persistent nocturnal enuresis may have a more significant bladder component, particularly since the majority of patients with adult type nocturnal enuresis do not seem to exhibit the nocturnal polyuria problem seen more commonly in the smaller children.

7.3. Lack of arousal

The fundamental mechanism resulting in nocturia or NE is that the bladder fills to its capacity during sleep and needs to empty (Figure 1). Bladder fullness is due to nocturnal polyuria and/or a reduction of the bladder capacity due to detrusor overactivity during sleep. The arousability differentiates patients with diuresis/ bladder volume mismatch into enuresis versus nocturia, but does not reflect underlying /associated sleep disturbances neither CNS dysfunction.

From an adult patient point of view, these factors do not fully explain why the enuretic child does not wake
up during the night to the sensation of a full or contracted bladder. Regardless of whether the child has detrusor overactivity or nocturnal polyuria, the enuresis event results from the child’s inability to awaken from sleep to empty prior to the wetting episode. However, we must admit that the majority of children become dry, without nocturia, what might indicate that nocturia is a defence against diuresis/mismatch only present in children with high arousability.

Recent findings suggest that the issue of decreased arousability is not the same as deep sleep.

There is a widely-held belief amongst parents and some clinicians that enuretics are deep sleepers. This is logical, since many of the children exposed to alarm therapy sleep through the alarm while family members awaken. Nevéus reviewed by questionnaire 1413 schoolchildren between the ages of six and ten and noted that enuresis was associated with subjectively high threshold arousal and significant confusion upon awakening from sleep [100]. Wolfish, in a study of 15 enuretic and 18 control boys and girls found that enuretics wet most frequently during the first two-thirds of the night and that arousal attempts were less successful in enuretics than in normals [101, 102]. This might explain why the most heavily endorsed view of both children and parents, regarding the aetiology of NE is a belief in deep sleep [103]. The recent findings of Dhont and Van Herzeele favour a disrupted sleep, with increased arousals, rather than a deep sleep [104-110].

Enuretic episodes occur during all stages of sleep in proportion to the amount of time spent in that stage and appear to occur independent of sleep stage but occur when the bladder is at a volume equivalent to the maximal daytime functional capacity [111-114]. Bedwetting children sleep normally but are unable to suppress nocturnal detrusor contractions or awaken in response to them or to bladder fullness.

Waking becomes easier as the night progresses. However, several authors have found that children with NE are also more likely to wet in the first third of the night, often in the first two hours following sleep [101, 102, 113, 115-119]. Thus, the point of bladder fullness for most enuretic children coincides with a time of night where they find it most difficult to wake from sleep, and not always when there is already an apparent diuresis / bladder mismatch: maybe diuresis-rate is more important than absolute volume, or OAB overnight is unidentified [120].

7.4. Comorbidities

There is increasing interest in comorbidities, not only coinciding with enuresis, but with common pathways in pathogenesis and/or interfering with therapy response.

7.4.1 Sleep disturbance

There is increasing evidence that sleep disturbance alone, or in combination with disrupted homeostasis play a role in the pathogenesis of nocturnal enuresis. Recently it was documented that enuretic children did not exhibit deep sleep, but rather a disturbed sleep with increased PLMS, cortical arousals, and awakenings [104, 107-110], both in patients with refractory enuresis and in children with monosymptomatic + nocturnal polyuria. Polysomnography studies documented a significant difference in PLMS index, arousal index, and awakening index compared with healthy control subjects. The presence of sleep fragmentation does not exclude a high sleep pressure or high arousal threshold. The role of sleep fragmentation in children with NE was earlier emphasised using sleep actigraphy [121]. Obstructive airway syndrome
(OSAS) causes nocturnal polyuria in both children and adults, eventually resulting in enuresis. The prevalence of this NE subtype in patients primarily consulting for enuresis is not known, but the anti-enuretic response to OSAS therapy suggests that in refractory cases this might be considered [48-51].

In conclusion, albeit there is little doubt that sleep and/or arousal plays a role in the pathophysiology of NE the clinical relevance and possible implications are still unclear and, so far, sleep investigation is not part of routine evaluation of enuretic children.

Dhont and van Herzeele published evidence that the superficial sleep, was coinciding with neurocognitive dysfunctions, thereby undermining earlier opinions that sleep patterns of children with NE are no different from control children [107, 110]. These neurocognitive dysfunctions were already documented in the past. In patients with enuresis, treatment of the enuresis resulted in amelioration of sleep quality and neurocognitive functioning [110].

7.4.2 Neurocognitive comorbidities.

Several neurocognitive comorbidities, coincide with nocturnal enuresis and might play a role, not only in pathogenesis but certainly in therapy resistance, such as psychological / behavioural problems; and attention deficit, neurocognitive dysfunction.

Psychological comorbidity among children with functional urinary incontinence is high: 20-30% of children with nocturnal enuresis (NE), 20-40% of children with daytime urinary incontinence (DUI), and 30-50% of children with faecal incontinence (FI) have clinically relevant comorbid disorders [1, 122-134]. Both internalising and externalising characteristics are represented [131, 135-137]. The best documented comorbidity conditions are attention deficit/hyperactivity disorder (ADHD) and oppositional defiant disorder (ODD). Attention deficit disorders coincide with higher prevalence of enuresis (both MNE and NMNE), where the prevalence of ADHD in the enuresis population is up to 4 times higher than the background population. The association of abnormal prepulse inhibition (Startle reflex) in both ADHD and enuresis patients, might suggest a common central nervous pathogenetic pathway but this is far from fully understood [138-141].

Frietag et al studied brainstem evoked potentials in 37 children with nocturnal enuresis and compared these aged 8 to 14 years, with 40 controls, mean age 10 years, and found that interpeak latencies of the brainstem evoked potentials were increased in children with nocturnal enuresis, suggesting that a maturational deficit of the brainstem was present in children with nocturnal enuresis. Differences in visually evoked potential latencies might point to a reason behind functional cortical differences in children with family history of nocturnal enuresis [142].

Frietag's study would suggest that a maturational effect is present [143]; however, overnight studies in enuretic children with simultaneous sleep electroencephalographic and cystometry have revealed marked detrusor overactivity, only occurring after sleep at night and not during wakeful periods during the day [143]. Because this pattern has not been observed in normal non-enuretic subjects, even during the new-born period, one may hypothesize that this could be due to a small neurologic lesion affecting a tiny area near the pontine micturition centre, the posterior hypothalamus (responsible for secretion of antidiuretic hormone) or the locus coeruleus which may be the cortical arousal centre [144] [145].

Another interesting study by Baeyens et al. [138] showed a convincingly significant difference between children with enuresis and control groups, and the startled eye blink reflex which improved with maturation but did not seem to correlate with resolution of enuresis. Clearly there is considerable work that is required to further unravel the mechanisms behind perceived differences in arousal between enuretic and non-enuretic children.

7.4.3 Constipation

The coexistence of LUT symptoms and functional constipation and/or faecal incontinence in children is not uncommon and was previously identified as Dysfunctional Elimination Syndrome' [146-148] and more recently as ‘Bladder and Bowel Dysfunction’ (BBD) [147].

Although the association with dysfunctional voiding, decreased voiding frequency and underactivity is obvious, there is also a clear comorbidity between bladder overactivity (urgency), increased voiding frequency, bladder underactivity and constipation. It is a well-established clinical experience that treatment of defecation problems in children with BBD enhances successful management of lower urinary tract disturbances such as daytime urinary incontinence (DUI), enuresis, and urinary tract infections (UTIs) [40, 147, 149, 150]. Treatment of the bowel dysfunction gives amelioration of the voiding disorder and should be first line treatment [151].

7.4.4 Mentally and motor disabled

It is evident that many of these children have underlying or associated bladder-dysfunctions. These children may also suffer from typical enuresis nocturna, but we should consider their maturation level, and, if this is delayed, initiate appropriate therapy which takes this into account [152].

Children who do wake up but are afraid to go to the bathroom [63], and therefore wet their bed should be identified as their treatment, for obvious reasons, is completely different [153].
8. MANAGEMENT OF NOCTURNAL ENURESIS

The age at which the child and his or her parent begins to be concerned about bedwetting varies. Hjalmas et al. noted that, “for successful treatment of nocturnal enuresis, the child must be brought to the physician by the parents who are concerned and the physician must have the necessary knowledge about the condition and be motivated to start treatment [63]. To fulfill these requirements, parents, teachers, and nurses in primary care need to understand nocturnal enuresis and be ready to treat the child, regardless of age according to EBM-based guidelines, against “Dr. Google” directed information. There remains a big task for demystification not only for patients/parents but also care givers in primary care.

Nocturnal enuresis is thought of as a social problem and less of a medical problem; therefore, since most children stop wetting as they mature and since no ill health follows bedwetting in most cases, there is a tendency for many practitioners to take a “wait and see” approach despite the fact that the family and the child in many cases are quite disturbed. In one study, 3803 French school children aged between five and ten years noted the prevalence of primary nocturnal enuresis to be 9.2%. The majority of the children noted that bedwetting bothered them and hoped that a doctor could help them. In this survey, a questionnaire was addressed to mothers of enuretic children, 100 school teachers and 100 school doctors. The mothers had a relatively tolerant attitude but two-thirds had consulted a doctor. Most of the doctors had proposed no solution or a “wait and see” attitude or treatment with a drug rather than an alarm. From this study, we may conclude that considerable work needs to be done to help educate not only parents but teachers and even physicians about the importance of treatment of nocturnal enuresis as well as supportive care [154].

The actual timing of treatment for nocturnal enuresis may vary depending on the needs of the child and the parent. Toilet training age may be different in different societies [155]. For example, toileting in Asia may begin earlier than in North America or other parts of the world [61, 154, 156, 157]. Toilet training should be started when both the child and parents are ready. Most studies appear to show that children start training between 24 and 36 months of age with a current trend toward later completion than in previous generations. This is markedly different than noted in some Asian cultures where training appears to begin much earlier. Toilet training should occur in an environment that is comfortable for the child. Unfortunately, toilets in most household bathrooms are adult sized, making it difficult for the child who needs to climb to the top of the toilet to relax. In these cases, a potty chair to toilet train the child, and once the child is old enough, he or she should be transitioned to an over-the-toilet seat with a footstool to allow optimal posture for voiding. Parents should encourage children to relax and take time to completely empty the bladder [63].

It is essential that both the child and his or her parents understand bedwetting pathophysiology and treatment philosophy. The clinician should give the child general advice such as what to eat and drink and to void regularly during the day, abstain from drinking too much during the late afternoon and evening and have relaxed routines at bedtime. The clinician should stress that NE is common and usually represents a delay in maturation without any psychopathological undertone. Up to 19 percent of children will become dry within the next 8 weeks without any further treatment besides good counselling [63, 156, 158].

8.1. Evaluation / intake

Over past decades several attempts have been made to standardise qualitative intake of patients, although still limited translated into primary care. Hjalmas recommended a careful history which will be summarised in these next few paragraphs. (Figure 2, table 1). This approach, which has been recommended by the International Children’s Continence Society, provides an excellent guide toward the taking of a history for a child with nocturnal enuresis, with a few adaptations over time [11, 63, 159-161].

8.2. **frequency volume chart (FVC).**

Parents are asked to record a two-day three-night record. This includes recording the child’s fluid intake and urine output, frequency of micturition and the frequency and pattern of voiding. The largest single micturition is considered the functional bladder capacity. This chart can be performed beginning on a Friday evening and concluding on Sunday on any weekend [11].

**Symptoms of nocturnal enuresis [11, 53, 161].** A careful history should include questions about the age of onset of nocturnal enuresis, length and circumstances of dry spells, number and time of episodes of nocturnal enuresis or nocturia, presence of daytime voiding symptoms or urinary tract infection, posture while voiding, daytime and evening fluid intake, sleep habits, frequency and consistency of bowel movements and psychosocial situation. One must establish whether, or not, symptoms represent primary or secondary nocturnal enuresis. It is critical to search for new psychological problems that might cause secondary nocturnal enuresis, particularly when the child presents with nocturnal enuresis after a prolonged period of dryness. The personality of the child, family situation, school environment, and presence of alternative caregivers might have an appreciable impact on voiding habits and will influence management options (43). Children may drink large volumes of fluid in the hours before sleep and this may result in nocturnal enuresis or nocturia.

It is helpful to determine the number of hours of sleep and to compare this to standard charts of average duration of sleep by age. Morning fatigue may be the result of obstructive sleep apnoea or restless legs syndrome. Other symptoms of sleep apnoea include mouth breathing, snoring, and restless sleep [11, 63]. More attention should be given to sleep hygiene: is the child drinking, eating prior to sleep? Is the child voiding just before bedtime? Is the light turned off immediately after going to bed?

It is important to rule out symptoms of anatomical or physiological urological conditions that may lead to nocturnal enuresis. Many of these conditions are covered in other parts of this section, and include a failure to store urine or failure to empty urine. Storage symptoms include increased frequency, urgency, and urgency incontinence including squatting behaviour, daytime incontinence and the sensation to need to void again. The clinician must carefully assess daytime wetting, particularly in older children. In many cases, the child may hide these symptoms from the clinician and the family.

Children void four to seven times a day or about every two to three hours [11, 80, 162]. If the child is voiding significantly more frequently than eight or more times a day, this may suggest incomplete emptying or overactive bladder. Urgency is present in many children and posturing, including squeezing or crossing the legs, squirming while standing or sitting, or physically compressing the genital area with a hand is all suggestive of overactive bladder due to detrusor overactivity which may or may not be associated with dysfunctional voiding. Other causes include urinary tract infection, polyuria from diabetes mellitus or diabetes insipidus, which can also cause more frequent voiding [63]. Treatment for these symptoms is covered in other sections within this chapter.

Additional symptoms during the daytime include continuous dribbling between voids that can come from an ectopic ureter bypassing sphincter mechanisms, from failing to empty the bladder or from sphincter incompetence. Also, continuous leakage can result from neurological causes or anatomical causes such as epispadias, or a closed bladder extrophy or urogenital sinus.

Lastly, children may have incomplete emptying from true dysfunctional voiding which results from the sphincter or pelvis floor contracting at the same time as the detrusor contracts during micturition. In addition, detrusor underactivity may result from neuropathy from diabetes mellitus and in some cases conditions such as the prune belly syndrome will result in detrusor underactivity. Lastly, urethral strictures may result in incontinence due to detrusor overactivity with poor bladder emptying. Boys with posterior urethral valves or Cobb’s collar may also have incomplete emptying. Lastly, the clinician should be alert for symptoms of constipation and faecal incontinence [163]. It is a common misconception that if a child is stooling once per day then he or she is not constipated. In fact, the best symptom of constipation is the infrequent or painful passage of hard small pellet-like stools. Faecal incontinence may also be present, the principal sign of this being faecal material in the underwear. Excessive stool retention may result in bladder dysfunction. In these cases [164], this may result in increased urethral sphincter and pelvic floor activity and explain the association of voiding dysfunction with incomplete voiding. Treatment of constipation may result in improvement in enuresis [151].

#### 8.3. Physical examination

Anatomical and behavioural causes for enuresis may be identified through a careful physical examination. Evidence of improper gait, spinal deformities, and foot abnormalities including asymmetry, high-arched feet, or hammer toes are signs of sacral neuropathy. Physical signs of occult spinal abnormalities such as dimples, tufts of hair, skin discoloration, lipoma, asymmetrical buttocks and gluteal clefts are also important. A careful abdominal examination with emphasis on the left lower quadrant may identify the colon full of firm stool. In most cases, a rectal examination is not performed but in some cases this may also be indicated. Occult faecal impaction, poor perineal sensation and reduced anal sphincter tone can be indicative of neuropathy.

In boys, marked narrowing of the urethral meatus (when the meatal lips are separated and no mucosa is seen), must be identified and carefully noted. If these signs are present, the boy should be asked to void so the clinician can witness and record the flow rate and residual urine. Narrowed or displaced urinary stream is suggestive of meatal stenosis.

In girls, the introitus should be identified for the position of the urethra. Evidence of wetting or irritation of the labia or vagina should be identified, as this could be suggestive of post-void dribbling or incomplete emptying with incontinence due to either detrusor overactivity or sphincter weakness [2, 146].

#### 8.4. Laboratory examination

There is very little laboratory examination that is required in patients with nocturnal enuresis other than a urinalysis to rule out UTI and evidence of glycosuria and a urine culture if the urinalysis is suggestive of infection [63].

Urodynamics and imaging have no place in the initial intake and therapeutic approach of a child with monosymptomatic nocturnal enuresis. If there is any suggestion, however, that daytime wetting is occurring,
9. THERAPY

The management of NE depends on:

- the child’s motivation to participate in treatment
- exclusion of confounding psychosocial factors
- providing information and instruction about daily habits, underlining the importance of having regular fluid intake, regular voidings, and relaxed routines at bedtime
- regular review of the new intervention

The therapist should convey a sense of understanding and compassion to both the child and the family. Education about the problem and a realistic discussion about the prognosis will help instil competence in the treatment offered which may improve both compliance and outcome [82, 165-167].

First line treatment and preliminary steps: primary and secondary forms of nocturnal enuresis are treated the same. If faecal incontinence, constipation or daytime wetting is present, these should be treated first [146, 151, 164].

All guidelines advocate urotherapy as first line therapy, although the evidence in children with NMNE is low, and efficacy is questioned [161, 168]. However, it is rational to initially normalise lifestyle and to give first urotherapy-advice.

However, treatment modalities like lifting, fluid restriction, dry-bed training, retention control training, psychotherapy, acupuncture, and hypnosis all have insufficient data in the literature to recommend any of them. However, non-invasive behavioural modifications such as resisting over-hydration in the evening are appropriate recommendations at the initiation of therapy. Normal fluid intake, but spread over the day should be advocated, to reduce osmotic excretion overnight [59]. The child must void before bed. Excessive protein or sodium intake should be avoided in the evening, since it will result in osmotic diuresis [59, 75, 76, 78]. During the day, the child should be instructed to void regularly, not to hold urine until the last minute, and to relax and take time to completely empty. If deemed important by the parents, a letter should be sent to the school to explain this.

Timing of treatment for the child who wets is dependent on the family’s desire and the child’s desire. As a good rule of thumb, children should be six to eight years of age. Some children, however, may want to wait until later. Others may be ready closer to age six. It is important for the parents to know that relapses can occur. The successful treatment of children with nocturnal enuresis has a foundation of realistic expectations and a motivated family [63].

Before starting treatment, a “baseline” meeting with counselling, provision of information, positive reinforcement, reassurance that 15% of children with mild enuresis (<4/7d) resolve each year, and increasing motivation should occur first. Children are asked to fill out a calendar or chart depicting the wet and dry nights. Children became significantly drier in two non-randomised trials associated with fewer wet nights simply by focusing them more on record keeping and true reward charts [121].

It is also important to be realistic about parental expectations, including the next steps of EBM, the alarm and desmopressin, where success-rates after 1 year do not exceed 60%, relapse free.

9.2. Enuresis alarm

The underlying mechanism of action of the alarm remains uncertain [169], and interpretation of the data in the literature when using the new ICCS definitions, unknown, since almost all studies have been performed with poor differentiation of MNE from NMNE, according to the new standards [2, 54, 63, 79, 170].

In unselected or poorly subtyped patients with enuresis, the enuresis alarm is the most effective means of facilitating arousal from sleep and remains the most effective way to treat NE [171-174]. There is an average success rate of nearly 68% with efficacy increasing with the duration of therapy. Relapse rates in the 6 months following treatment are in the order of 15 - 30 %, significantly lower than for desmopressin in unselected populations. Alarm therapy has been shown in a meta-analysis to have a 43% lasting cure rate [175-178].

Better results occur with optimal motivation of the child and family and higher frequency of wet nights. Reduced efficacy is associated with the lack of concern shown by the child, lack of supervision, inconsistent use, family stress, abnormal scores on behaviour system checklists, psychiatric disorder of the child, failure to awaken in response to the alarm, unsatisfactory housing conditions and more than one wetting episode per night. Enuresis alarms require several months of continuous use and are, therefore, unsuitable for some families [11, 179, 180].

For optimal results, alarm therapy should be individualised; it requires a motivated family and child with significant commitment to time and effort. The impact on other family members should be considered. In some families, alarm therapy may wake other members of the family and may increase parental annoyance and place a child at increased risk for physical or emotional abuse. Be aware of the burden, if the alarm is activated early in the night or several times per night, especially because these are predictive of resistance. Close follow-up is important to sustain motivation, troubleshoot technical problems, monitor the therapy [63], and identify the burden. The exact
mechanisms of action for alarm treatment are unknown. The effects are not due to classical conditioning, as stimulus awakening occurs after and not before wetting. Instead it is clearly an operant type of behavioural approach, i.e. a learning programme with positive reinforcement that includes aversive elements. Dryness is reached either by waking up leading to "nocturia" in 35% of children or by sleeping through the night with a full bladder in 65%. Body worn (vibrating) alarms are at least as effective as bedside alarms [121].

The family should continue alarm therapy for at least 14 consecutive dry nights – or a maximum of 16 weeks before discarding it as ineffective [11]. Compliance remains a problem: dropout rates are rarely disclosed in reported studies. Proper guidance and instructions are mandatory.

The key to success is not the stimulus intensity of the alarm triggering, but the child’s preparedness to awake and respond to the signal. Comparison of the different types of alarm did not show significant outcomes.

In general, alarm treatment is more effective than other forms of treatment and the lasting cure rate about twice as high.

Level of evidence 1

Grade of recommendation A

In some cases, alarm therapy can be enhanced using the alarm in addition to other behavioural components. Overlearning (giving extra fluids at bedtime after successfully becoming dry using an alarm) and avoiding penalties may further reduce the relapse rate [171].

9.3. Dry bed training

This is a package of behavioural procedures used in conjunction with the enuresis alarm first described by Azrin et al [181, 182]. It incorporates:

- the enuresis alarm
- cleanliness training (encouraging the child to take responsibility for removing of wet night clothes and sheets, re-making the bed and resetting the alarm),
- waking schedules – to ease arousability from sleep as described above and involving:
  - for the first night, waking the child each hour, praising a dry bed, encouraging the child to decide at the toilet door whether he or she needs to void, and on returning to bed the child is encouraged to have a further drink
  - On the second night, the child is awakened and taken to the toilet 3 hours after going to sleep. For each dry night, the waking time is advanced by 30 minutes. If the child is wet on any night, the waking time stays at the time of the previous evening. The waking schedule is restarted if the child begins wetting twice or more in any week, stating again 3 hours after sleep.

High success rates and low drop out have been reported although relapse rates are no different than enuresis alarm treatment alone. Modifications are advocated to remove some of the more punitive elements of the programme but at best, it is a complex, time consuming and a demanding technique [171, 183, 184].

Hirasing et al found 80% success with group administered dry bed training. Girls responded better than boys [185]. Most parents were satisfied with the programme but opinions of the children were divided. Factors related to failure were the child’s age, bed-wetting frequency, secondary enuresis or family history. In another study, they found a positive effect on behavioural problems [186].

An important component analysis by Bollard & Nettelbeck found that the enuresis alarm accounted for most of the success achieved through dry bed training. They believe that a large proportion of the components of the procedure can be eliminated without sacrificing much of its overall effectiveness and that the waking schedule coupled with the enuresis alarm is as effective as the complete dry bed-training programme [187, 188].

Level of evidence: 2

Grade of recommendation D (no more effective than alarm treatment alone)

9.4. Arousal training

Arousal training entails reinforcing appropriate behaviour [waking and toileting] in response to alarm triggering. The aim is to reinforce the child’s rapid response to the alarm triggering, not on ‘learning to keep the bed dry’.

The instructions involve: setting up the alarm before sleep

- when the alarm is triggered the child must respond by turning it off within 3 minutes
- the child completes voiding in the toilet, returns to bed and re-sets the alarm
- when the child reacts in this fashion he is rewarded with 2 stickers
- when the child fails to respond in this way the child pays back one sticker

Van Londen et al first described this procedure with a group of 41 children, aged 6-12 years, with predominantly primary enuresis [189]. They reported 98 percent success [14 consecutive dry nights] compared to 73 percent success with alarm monotherapy. The difference was significant [p<0.001]. Ninety-two per cent remained dry after 2 ½ years: a very low relapse rate. An extraordinary aspect of this study was the lack of
contact between therapist and parents. All those included were parents who had ordered an alarm from a rental agency and were given the instructions with the alarm. The authors conclude that arousal training is ‘definitely the treatment of choice for enuretic children between 6 and 12 years’. Compared with other studies, and considering experience of daily practice, one may question the very high success rate in this group of patients.

**Level of evidence: 3**

**Recommendation: grade C**

9.5. Pharmacological treatment

Based on the three main causes of enuresis, namely nocturnal polyuria, detrusor overactivity, and disorder of arousal, the pharmacological treatment is designed to address these three areas. Table 2 shows rates of efficacy.

9.5.1 Desmopressin therapy [190-198]

Arginine vasopressin (AVP) or antidiuretic hormone (ADH) is normally produced in the hypothalamus and released in the pituitary in response to hyperosmolality or hypovolaemic conditions. Vasopressin acts on the collecting ducts and distal tubules to enhance water absorption. AVP, by virtue of an independent vasoconstrictor effect, is also a potent vasopressor. Desmopressin (or dDAVP) is an analogue of vasopressin created by deaminating the cystine residue at position 1 and substituted D-arginine for L-arginine at position 8. These changes result in significantly increased antidiuretic activity but loss of vasopressor activity. The half-life of Desmopressin is 1.5 to 3.5 hours. In a larger portion of children with monosymptomatic nocturnal enuresis, the normal circadian variation in urine production with nocturnal rise of vasopressin is absent. In these cases, dDAVP would seem to be particularly appropriate. Desmopressin is easy to administer and the clinical effects appear within 1 hour.

Several formulations are on the market: rhinyl nasal solution, desmopressin nasal spray, desmopressin oral tablet and the desmopressin oral lyophylisate (sublingual), all characterized by rather low bioavailability, with large intra-individual variability (0.08-0.16% in adults); only the last 2 formulations have a licence for enuresis in children [196, 197]. The intranasal form is no longer recommended for nocturnal enuresis, because of concern about water-intoxication, because of unpredictable nasal reabsorption in children.

The low bioavailability is largely related to the peptide structure, making oral /intestinal reabsorption very difficult, although pharmacodynamic effects remains very predictable, and when used *lege artis*, is rarely associated with serious adverse effects. It is available as a tablet (dosage, 0.2–0.6 mg) or a fast-melting oral lyophilisate (Melt; dosage, 120–240 μg). The latter is recommended formulation for all children and is preferred by children under 12 years [197, 199-201]. It is not affected by nasal congestion or gastrointestinal transit and does not require fluid intake. Since tablets require up to 200 ml of fluid intake, which is ~25% of a 7-year-old’s bladder capacity, the Melt formulation is more suited to the antidiuretic indication of desmopressin. Good pharmacodynamic data are available for the Melt and its dosing in children with enuresis [197, 202] [58].

Some patients have a delayed response and a small group of children who do not respond to desmopressin in ordinary dosage will become dry when the dose is increased, but this off-label use should be restricted to expert centres [203, 204]. Desmopressin may be particularly beneficial in the child with limited numbers of wet episodes per week. Often advice is given to use it as added security on special nights such as a sleepover. There is no sound medical evidence for this advice as intermittent regimens have never been proven to be beneficial [80].

Nocturnal polyuria is a characteristic of children that respond the best to desmopressin [56, 80, 205]. ICCS defines nocturnal polyuria >130% of expected bladder capacity for age, but the DRIP study showed that diuresis lower than 60%;EBV is likely desmopressin resistant, where diuresis>100% has a 60% response-rate.

The efficacy of desmopressin in the treatment of enuresis is well documented [57, 192, 193, 206]. In a Cochrane Library, meta-analysis 17 controlled trials all showed superiority of desmopressin compared to placebo regardless of the route of administration [194, 207]. An estimated 70% of the enuresis population has full or partial response to the drug [110] and the response to desmopressin is highly dependent on factors such as nocturnal urine production and bladder capacity. The few studies that have tried to compare different doses of the drug reveal comparable efficacies [191, 208-210]. Several key issues should be taken into consideration, when the drug is prescribed. 200 to 400 mg tablets are considered bio-equivalent to 120-240 μg Melt and are the therapeutic range for children with MNE between 7 - 18 years. The recently documented size relationship could mean that higher dosages might be needed in some of the larger children [200].

Medication should be taken 1 h before the last void before bedtime to allow timely enhanced concentration of urine to occur. Fluid intake should be reduced from 1 h before desmopressin administration and for 8 h subsequently to encourage optimal concentrating capacity and treatment response, as well as to reduce the risk of dilutional hyponatraemia/ water intoxication [82, 194, 197, 199].

Desmopressin is only effective on the night of administration; therefore, it must be taken daily. Full adherence is required to avoid wet nights. Desmopressin acts immediately, but in our expert opinion, the initial duration of treatment should be for 2–6 weeks, to ascertain its anti-enuretic effect [11]. If a sufficient degree of improvement is experienced, then treatment
can be continued for an additional 3 months—where appropriate. Country-specific regulations regarding treatment breaks should be followed. If patients are dry on treatment after this initial period, breaks are recommended to ascertain whether the problem has resolved and therapy is no longer necessary. If the child does not achieve complete dryness, or if wetting resumes once treatment is withdrawn, it should be continued or resumed. There is some evidence that structured withdrawal of medication may reduce relapse rates following its discontinuation [211,212]. Desmopressin is well tolerated, but clinicians should be aware that it is a potent antidiuretic and families must be educated regarding the rare possibility of patients developing hyponatraemia/water intoxication with symptoms including headache, nausea, and vomiting [196]. Self-titration of medication should be avoided (opinion).

Adherence to the drug is important. It is estimated that ~30% of non-responders are not taking medication correctly [166, 167, 213]. Non-adherence to recommendations regarding timing of medication, voiding before bed time, and limitation of evening fluids can increase treatment success [214]. Moreover, compliance is often overestimated, both by patients and clinicians; therefore, it should be documented in a diary. Regular contacts between caregiver and patient are necessary to keep up compliance. Patients who appear treatment-resistant should be advised of the importance of full adherence and asked if they have had any difficulty with complying with recommendations. We may also neglect that in divorced families, information must be given to both parents, so that the treatment is appropriately given on daily basis.

Desmopressin has higher success rates in children with large bladder and nocturnal polyuria [35, 80, 215]. The response rate of the initial studies of >70% have been decreasing in more recent studies to 20-30%, since the prevalence of occult OAB patients with small bladder volume and low nocturnal diuresis volume was high in these populations [216]. There are several unanswered questions regarding desmopressin therapy. It is still unclear whether desmopressin treatment leads to better long-term outcome than the spontaneous cure rate. The long-term cure rate of 15-30% annually is higher than the spontaneous cure rate [193, 206, 217]. Long-term follow up showed persistent LUTs symptoms in the patients with NMNE and not in the MNE patients [22]. The suggestion that tapering of the dose and the structured withdrawal programme should be beneficial is still unproven [211, 218].

**Desmopressin: Tolerability and Safety**

Considering the worldwide prescription-rate, desmopressin, is an extremely safe product, if correctly dosed and fluid intake is withheld after administration. There are no reports of water-intoxication with the melt or the tablet, at correct doses, since the spray was withdrawn. On the other hand, we cannot stress enough that the drug should be correctly administered, since every year there are reports of children taking it in the morning.

We reinforce the ICI-advice that a rigid regimen of water restriction must be enforced for two hours prior to bedtime and to allow one eight-ounce (300 ml) glass of water at dinner and nothing for two hours prior to bedtime. In a survey on hyponatraemia in patients with nocturnal enuresis, by Robson and Noorgard in 1996, it was found that in most children water intoxication was due to considerable intake of water during the time the child was taking the desmopressin [219-221].

The results of numerous clinical trials have shown that desmopressin is well tolerated even during long-term treatment and associated with a low risk of adverse events. In the SWEET study, only six of 242 children (2.5%) withdrew during the long-term treatment because of very mild adverse events following the administration of intranasal desmopressin.

**Predictors of Response:**

Translating results from historical studies with no, or old ICCS standardisation of enuresis-patients remains difficult. The SWEET study found that those who improved or became dry during desmopressin were older (greater than 8 years), had fewer wet nights during baseline, and had only one wet episode during the week and responded initially to the smallest dose of desmopressin used in the study [52, 206, 208, 222, 223]. The DRIP study documented that the highest response rate was in older children, with less severe bedwetting, nocturnal polyuria and larger functional bladder volumes. A low diuresis-volume, <60% of EBV overnight, is highly predictive of desmopressin resistance; this is logical, since low diuresis-volume coincides with already presence of maximal concentrating activity of the kidney, where desmopressin cannot have additional value [80, 201].

There is considerable evidence that desmopressin works better than placebo. In one study, patients on desmopressin were 4.6 times more likely to achieve 14 consecutive dry nights compared with placebo [207]. However, relapse after short-term treatment is common. Sixty-one percent of 399 patients six to 12 years of age recruited from a primary care in one study responded to desmopressin initially [206]. Using intention to treat analysis 19% (77 of the 399) remained dry off medication and 18% were dry while still on desmopressin, thus not significantly better than the spontaneous cure rate. This suggests that desmopressin, by reducing the urine output overnight, reduces nocturnal enuresis but does not significantly affect the resolution rate over time above the spontaneous rate.

Although several studies have shown that dDAVP is a well-tolerated and safe drug, even during long-term usage, one must be aware that dDAVP is a potent antidiuretic drug and that there have been reports of
severe water retention with hyponatraemia and convulsions, but these are infrequent [204, 208, 219, 220, 224-231].

Level of evidence: 1
Grade of recommendation: A

9.5.2 Combined treatment with alarm and desmopressin

Combined treatment may be superior to use of the alarm alone, especially for non-responders of each individual treatment. In this approach, treatments are started at the same time: the rapid action of dDAVP is believed to facilitate the child’s adaptation to the alarm [232-237]. After 6 weeks, the dDAVP is discontinued while the alarm treatment is continued until the child becomes completely dry. Compared with either therapy alone, the combination is particularly effective in children with high wetting frequencies and behavioural problems. Combination with full-spectrum therapy may even yield higher success rates [232, 236].

van Kampen et al reported their results of ‘full-spectrum’ therapy in 60 patients: they were treated for 6 months with a combination of alarm, bladder training, motivational therapy and pelvic floor muscle training: 52 patients became dry. The combination of alarm with six weeks of 40ug Desmopressin intranasally was better than alarm treatment alone, especially with high micturition frequency and comorbid behavioural symptoms [239]. In a Chinese study comparing alarm, desmopressin and a combined therapy, the latter had the highest rate of sustained response (40.6%). However, there was a high relapse rate after discontinuing medication [240].

In another randomised-controlled, double blind study, the addition of 3 weeks of 40ug and 3 weeks of 20ug Desmopressin to alarm use, lead to temporary, short-term reduction of wet nights compared to controls on alarm and placebo [237]. The long-term success rate did not differ between the two groups and were low (36% and 37%, respectively). In the subgroup of Desmopressin non-responders, the combination of alarm plus Desmopressin was not more successful (51.5% remission) than alarm plus placebo (48.1% remission), so that this cannot be recommended as a routine strategy [241].

Theoretically, the combination of alarm and desmopressin makes little sense: alarm treatment is an operant type of behavioural therapy that requires a certain number of wet nights to be effective: by reducing the number of wet nights through desmopressin, the child will have less opportunity to ‘practice’ and ‘learn’ continence by the alarm therapy.

9.5.3 Antimuscarinic drugs for OAB

Antimuscarinic drugs should not theoretically be efficacious in children with monosymptomatic nocturnal enuresis. However, because there is considerable misdiagnosis of monosymptomatic nocturnal enuresis, some children with mild daytime symptoms of overactive bladder may have symptoms of overactive bladder at night. Moreover, it has been shown that on urodynamics, 73% of adults with primary nocturnal enuresis have some form of functional bladder outlet outflow obstruction classified as (1) “primary bladder neck dysfunction” or “detrusor sphincter dyssynergia” [242]. That would suggest then that antimuscarinic drugs might be a useful alternative in some children who are unresponsive to DDAVP. Antimuscarinic therapy is also indicated in combined day and nighttime incontinence [86, 243, 244].

In general, antimuscarinic drugs are well tolerated but there are some side effects, namely vasodilatation, dryness of the mouth, constipation and vertigo (rare), and symptoms of hyperactivity and concentration disorders, especially in a population of children with ADHD. These side-effects are more predominant with oxybutynin, than with the newer anticholinergics. Constipation can also pose a problem since the development of constipation may aggravate detrusor overactivity and thus counteract the beneficial effects of the drug. Antimuscarinics may also result in increased residual volumes which may make it difficult for the child to empty prior to bedtime. Antimuscarinic treatment in conjunction with desmopressin may have a role in cases with suspected day and nighttime detrusor overactivity.

The combination of alarm and anticholinergics should be considered if overactive bladder is suspected. If the alarm is set off several times per night, indicative of overactive bladder, this combination has been proven to be successful. For example, 5 mg of oxybutynin in the evening, combined with an alarm could be tried in these cases. If higher levels of anticholinergics are required, several doses should be given over the day. Other programmes such as ‘full spectrum treatment’ remain treatment forms that are reserved for therapy-resistant cases.

Level of evidence: 2
Grade of recommendation: B.

In those children who have NE due to detrusor overactivity during the night, treatment with an antimuscarinic drug should be considered [245, 246]. Because it is difficult to perform a night time cystometry in these children, it may be tried in children who have more than 2 wetting episodes per night and who do not respond to dDAVP or be given in combination with alarm or dDAVP [244] [247]. At present, no studies have been performed to demonstrate its efficacy in this circumstance.

Level of evidence: 3
Grade of recommendation: C

9.5.4 Tricyclic antidepressants

Although tricyclic antidepressant drugs, particularly imipramine, have worked in many children, most of
the studies that recommend this drug are relatively old. The major drawbacks to imipramine therapy are cardiotoxic side effects, in some cases even with therapeutic doses, and the possibility of death with overdose.

Because imipramine and other drugs of the same family have potential cardiotoxic side effects they cannot be generally recommended for treatment of this non-lethal disorder [248]. Although treatment with tricyclic drugs is associated with a decrease of one wet night per week, the lasting cure rate of only 17 percent restricts the use of these drugs [249].  

Only in selected cases (like adolescent boys with Attention Deficit Hyperactivity Disorder and persistent NE) or refractory cases should it be considered [250], and use restricted to expert centres. The need to perform an a priori ECG remains open for discussion, but obtaining a clinical history to exclude familial sudden death in adolescents and adults is mandatory.

**Level of evidence: 1**

**Grade of recommendation: C (due to potential cardiotoxicity)**

**9.5.5 Alternative regimens:**

Several other drugs, such as carbamazepine and NSAIDS (indomethacin, ibuprofen) have also been investigated: based on study design as well as study outcomes, these drugs are not recommended [251-256].

Acupuncture, laser acupuncture and neurostimulation have also been suggested, but none has demonstrated a convincing positive effect in primary care enuresis patients [257-262].

In one randomised controlled trial that examined acupuncture, 40 children were allocated either to dDAVP or acupuncture, 75% of children were dry after 6 months of therapy (while still on medication), while 65% of patients were completely dry after a mean of 12 sessions. The evidence from these alternatives is too weak to recommend them as a first line approach. It is concluded that as an alternative, cost-effective and short-term therapy, acupuncture should remain among available treatment options. Another meta-analysis provides some evidence for the efficacy of acupuncture for the treatment of childhood nocturnal enuresis. Comparison of treatment outcome and cure rates is difficult because of the inconsistent use of definitions, the inclusion of children with daytime symptoms, and the variable follow-up periods in most studies. For a pragmatic approach, see Figure 3.

**Level of evidence: 4**

**Recommendation: grade D**

**9.6. Conclusion**

Based on current evidence, the enuresis alarm remains the most effective means of facilitating arousal from sleep in unselected patients. The key to success is not the stimulus intensity of the alarm triggering, but the child’s preparedness to awake and respond to the signal. As an adjunct programme, arousal treatment is easy to perform and effective. But this evidence is obtained from meta-analysis comparing the use of alarm and desmopressin in poorly characterised enuresis populations, mixing up MNE with non-MNE, if we use the recent ICCS standardisation criteria.

A second therapy regimen involves individualising the treatment to the characteristics of nocturnal diuresis and functional bladder volume overnight.

The ideal therapy regimen for children with a large bladder volume, a high diuresis volume with low urinary osmolality overnight will most likely be desmopressin responsive, and would only respond to the alarm by acquiring nocturia.

The 2nd archetype is children with a small bladder volume, low diuresis volume, with already maximal concentrating capacity who are likely to be desmopressin resistant, and where the alarm is the first choice. But there are many patients who overlap between these two types, where combination therapy will be necessary, even with associated anticholinergics.
10. REFRACTORY MNE:

About one third of children do not respond to treatment with alarm and/or dDAVP. The majority of these children are likely to have a small nocturnal bladder capacity and suffer from “detrusor dependent NE”.

Most patients with MNE who are non- or partial responders are likely to have underlying bladder dysfunction, missed during the initial assessment, because 1) it was not performed appropriately, or 2) patients were classified according to the old ICCS standardisation, when according to the new ICCS-standardisation they should be considered as NME. The full screening should be redone, with history of incontinence diurna (ID), diurnal symptoms after the age of 3,5 years, high / low frequency, postponing during normalised fluid intake as well as small enuresis volumes early in the night are very suggestive for bladder dysfunction. Spontaneous low fluid intake is suggestive of a defence mechanism, and may mask OAB symptoms. These symptoms are often not mentioned by parents, and deserve repeated questioning or documentation in a bladder diary during standardised fluid intake 1,5ml/1.73m²/day: this can give additional information. Uroflow and bladder ultrasonography may also be useful. These children benefit from a multidisciplinary approach and should not be treated in a primary care [264, 265].

But, in the absence of any bladder dysfunction we should concentrate on the desmopressin effect in differentiating different pathophysiological characteristics that may be involved 1) anti-enuretic effect (= number of wet nights), 2) the anti-diuretic effect (= nocturnal diuresis rate) 3) concentrating capacity (= urinary osmolality). Partial response to desmopressin in MNE (anti-enuretic effect) is related to persistent nocturnal polyuria on the wet nights [81].

Poor compliance should be excluded [167], including not taking the drug (consider letting the patient fill out a drug-diary and register the number of prescriptions/compliance):

1. the child forgets to void before going to bed, and already starts the night with a filled bladder
2. exclude drinking overnight, because fluid intake overnight or even the hour before desmopressin administration reduces both maximum and duration of anti-diuretic effect and concentrating capacity significantly.

**Figure 3: Treatment algorithm for enuresis.**
3. intermittent polyuria might as well be related to the PK/PD characteristics of desmopressin [82, 199-202, 213]:

   a. The 3 formulations (tablet, melt and spray) have poor bioavailability, ranging respectively 0,2 - 2% - 4%, but with a rather large SD = intra-individual variability. Only for the melt are dose-response-data and proper pharmacodynamic and kinetic data in children available. The melt showed superior PK and PD profile, better compliance and some indication of higher response rates. Before considering desmopressin resistance, a switch to the melt should be considered.

   b. The child takes the drug just before sleeping time (the time to reach maximum concentrating capacity and anti-diuretic effect is 1-3 hours, and therefore the drug should be taken at least one hour before the last void before sleeping). Interference with nutrition (the tablet should be given on an empty stomach (= at least 2 hours after the last meal [85, 199, 200, 266].

   But 2 hours after the last meal, and 1 hour before sleep is not realistic in most children: a consideration that favours the melt above the tablet.

   c. The melt study has demonstrated that, even in the therapeutical range of 120-240µg there is a large variation in maximal concentrating capacity and antiurea, as well as duration of action. Better understanding of these PK/PD dynamics, can lead to more personalised medicine, with individualised dosing. The PK/PD data demonstrate that at least 25% of patients might benefit from higher doses, patients that can be identified by a pharmacodynamics test in an ambulatory setting in the individual patient (24h concentration-profile), especially in the older patients. Increasing the dose without this test is indefensible, because of the risk for toxicity.

In desmopressin refractory nocturnal polyuria with low urinary osmolality, diabetes insipidus should be excluded. X-linked DI in boys does not present as enuresis, but female carriers might have a more forme fruste pattern with enuresis as major symptom. Many renal diseases (CKD, tubulopathies, renal dysplasia, uropathy) present with enuresis. Hypertension, and especially night time hypertension, coincides with nocturnal polyuria, and should be considered in refractory patients. Although there might be some anti-diuretic effect of desmopressin, these patients never reach maximum concentrating capacity. A desmopressin / vasopressin concentration test may be helpful if conventional diagnostic tests (ultrasound, lab) fail. It should be noted that the majority of studies on desmopressin in children with MNE demonstrate that up to 25% of patients do not reach >850 mOsmol/L after desmopressin therapy. Although these patients do not fulfil the criteria of DI, there is an increased prevalence of patients at the lower end of the normal range of concentrating capacity in these children. A 20% decrease in concentrating capacity will result in 20% increase in diuresis, and this may be the difference between continence and enuresis in many patients.

Desmopressin resistant nocturnal polyuria, with high urinary osmolality overnight might be associated / correlated with high urinary osmolality overnight. This can be caused by an increased solute load only in the evening or during 24 h [59, 60]. Sodium is the major osmotic agent [59, 72, 76, 267]. Although nutritional intake plays a major role, abnormalities of several circadian rhythms like prostaglandins [268-270], GFR [70, 72], blood pressure [69] and sleep pattern [104, 105, 108] have a significant impact in selected tertiary care patient populations. Extrapolation of these findings to primary care enuresis patients is premature. But these findings offer indications of future treatment options. Some pilot studies have promising results, such as sodium restricted diet, diuretics (Furosemide) [76, 251, 271, 272], NSAID, and treatment of sleep disturbances, (OSAS and melatonin) [48, 50, 273-276]. In the past much attention was put on the role of calcium, and a calcium restricted diet might be effective [77, 78, 277], but hypercalcaemia might be a secondary phenomenon due to differences in diet [75, 84, 278].

Symptoms resistant to conventional therapy cannot only be related to underlying bladder dysfunction and renal response to desmopressin, but also to associated comorbidities. Identifying these, and addressing them if possible might increase the response rate. Constipation and faecal incontinence should be treated before the treatment of MNE but are often underestimated and underreported. Psychological comorbidities, as well internalising as externalising are more frequent in enuresis-patients. Attention deficit disorders, and autism are well studied and seem to have common pathways. A structured therapeutic approach is mandatory. Renal dysfunction, hypertension, diabetes mellitus and sleep disturbances should be treated appropriately. Many drugs interfere with the circadian rhythm of biorhythms, including diuretics, steroids, cyclosporine A, and neurotropic drugs and may be a possible trigger to offset enuresis in a sub-set of children: this is largely speculative, as good studies are lacking.

**Conclusion [11, 82]**

In children with MNE two first-line treatment options are available - desmopressin and the enuresis alarm. Without further individualised treatment, success rates of monotherapy may not exceed 30%, with a relapse rate up to 50%.

Optimally;

1. the initial treatment selection should be guided by the family’s level of motivation and their preference.

2. and be based on the information from diaries: this will identify subtypes of MNE allowing further fine-tuning of treatment according to the child’s characteristics and family motivation.
• Children with a normal urine output during the night and normal bladder capacity can be given either the alarm or desmopressin.
• Children with smaller than expected bladder capacity for age will likely be desmopressin-resistant and more sensitive to the alarm.
• Children with NP and normal bladder volume will be more sensitive to desmopressin.
• Children with both excessive urine output and reduced bladder capacity may find combined therapy of alarm and desmopressin to be successful. This strategy lessens the burden of alarm treatment as the alarm is triggered several times per night.

Despite best efforts, up to 30% of enuretics will be therapy resistant. We advocate to individualize therapy based upon the identification of the most likely pathophysiological mechanisms, bladder, kidney; sleep and comorbidities, in a multidisciplinary setting.

IV. CHILDREN WITH BOTH DAY AND NIGHT TIME INCONTINENCE

Urinary incontinence in children may be caused by a congenital anatomical or neurologic abnormality, such as ectopic ureter, bladder extrophy or myelomeningocele (MMC). In many children, however, there is no such obvious cause for the incontinence and they are referred to as having “functional incontinence.”

Becoming continent is a complicated process: there is a progressive development towards normal storage and emptying of the bladder at a socially accepted place and time, mostly achieved by age 3-4.

Bladder control is believed to be under the influence of the central nervous system. The pontine region is considered to be responsible for detrusor sphincter coordination while the cortical area is responsible for inhibition of the micturition reflex and voluntary initiation of micturition (detrusor overactivity control). Formerly it was believed that bladder maturation followed maturation of cortical inhibition processes. However, recent work of CK Yeung suggests bi-directional maturation of both the coordinating influence on the bladder and the pons may be implicated. This implies that a condition such as detrusor overactivity would be the result of loss of cortical control or of deficiency in cortical control, while dysfunctional voiding would be the result of non maturation of the coordination.

With the emergence of functional MRI, future studies will be able to illuminate this enigma.[1,2] This opens an era of corticocentric thinking on lower urinary tract dysfunction, moving away from the current trend of vesicocentric thinking. Detrusor overactivity may be a symptom of a centrally located dysfunction affecting bladder, bowel, sexual function and even mood and behaviour.[3] Indeed many studies indicate that there exists a link between lower urinary tract dysfunction and behav-ioral disorders such as ADHD (attention deficit / hyperactivity disorder) [4-5].

The desire to void is a sensation which, in the developing child, is incorporated into daily life so that voiding takes place at an appropriate time and place. Problems with training or psychological difficulties possibly have a great impact on the results of training; some parents send their child to the toilet many times, though his/her bladder may be empty [6,7]. Voiding in these circumstances can only be achieved by abdominal straining. The positive reinforcement that the child receives by voiding even a small amount may lead to the development of an abnormal voiding pattern. The same is true when children receive negative feedback relating to voiding [8-10]. At present no evidence exists to prove these assumptions.

Urinary incontinence in children may be due to disturbances of the filling phase, the voiding phase or a combination of both. In the ICCS terminology, these conditions are termed functional bladder disorders or Lower Urinary tract (LUT) conditions. They are divided into either overactive bladder (OAB) or dysfunctional voiding [11]. While the former condition is a filling disorder the latter is considered an emptying disorder. They can of course coincide and one may even be causative of the other. No evidence exists however for this last assumption. It has been postulated that detrusor overactivity may eventually lead to poor bladder emptying due to underactivity of the detrusor or severe dyscoordination between detrusor, sphincter and pelvic floor. However, the natural history of many of these children does not confirm this hypothesis, nor the early onset of severe pathology in some of them. Hoebeke et al found no evidence for this dysfunctional voiding sequence: children with functional incontinence have different primary diseases, but all have a common risk of incontinence, UTI, VUR [15%] and constipation [17%] [12].

Detrusor overactivity may lead to disturbances in the filling phase characterized by urgency, frequency and at times urgency incontinence. Girls present with OAB symptoms more often than boys. In addition to the urinary symptoms, children with functional urinary incontinence may also have recurrent urinary tract infections (UTI) and constipation.

Incomplete relaxation or tightening of the sphincteric mechanism and pelvic floor muscles during voiding results in an interrupted or staccato voiding pattern, that may be associated with elevated bladder pressures and post-void residuals. Such individuals with dysfunctional voiding are also prone to constipation and recurrent UTIs [13]. Bladder function during the filling phase in these children may be essentially normal, alternatively OAB may be present. In children with a underactive detrusor, voiding occurs with reduced or minimal detrusor contractions with post-void residuals, and incontinence is a characteristic symptom.
1. PREVALENCE

For more detailed information on the prevalence of daytime incontinence the Chapter on Epidemiology should be consulted. The main problem is that it is impossible to draw any conclusions from the presented data as different studies have used different definitions and criteria. Furthermore, it is virtually impossible to identify the prevalence of detrusor overactivity or dysfunctional voiding as the studies tended to look primarily at daytime versus night-time incontinence and made no effort to evaluate the type of daytime incontinence.

Daytime or combined daytime and night-time incontinence at least once a week seems to occur in about 2-4 percent of 7-year-old children and is more common in girls than in boys [14]. Overall the rates of prevalence vary from 1 to 10 percent, but in general for 6 to 7-year-old children the prevalence is somewhere between 2 and 4 percent, and rapidly decreases during the following years [15-19]. Sureshkumar et al in a population-based survey of over 2000 new entrant primary school children (age 4-6 years) in Sydney, Australia noted an overall prevalence of daytime wetting of 19.2% defined as at least one daytime wetting episode in the prior 6 months with 16.5% having experienced more than one wetting episode and only 0.7% experiencing wetting on a daily basis [20]. Multivariate analysis showed that recent stress, a history of daytime wetting along the maternal line, and a history of wetting among male siblings were independent risk factors for moderate to severe daytime wetting. Because this was a cross-sectional study recall bias may have resulted in an overestimate of risk of daytime wetting being caused by such factors as emotional stress and family history. In addition, urine cultures were not obtained so occult UTIs could not be identified. Chung comes to the same percentage of OAB (16.6%) in 19,240 Korean children. In this study OAB was differentiated in ‘dry’ OAB and ‘wet’ OAB: children with OAB do not always have incontinence [21].

In a questionnaire-based study, supplemented by telephone calls, Hellstrom assessed the prevalence of urinary incontinence in 7-year-old Swedish school entrants [22]. Diurnal incontinence was more frequent in girls than boys, 6.7% vs 3.8%, respectively. Wetting every week was reported in 3.1% girls and 2.1% of boys. The majority of children with diurnal incontinence had concomitant symptoms: urgency was reported in 4.7% girls and 1.3% boys. Nocturnal incontinence combined with daytime wetting was equally common in males versus females, 2.2% versus 2%, respectively. At the age of 17 years daytime wetting, at least once a week, was found in 0.2% of boys and 0.7% of girls. A limitation of this study is its dependency on re-call. Children with daytime or mixed wetting were found to suffer from urgency in 50.7%, with 79.1% wetting themselves at least once in 10 days [23]. Urgency symptoms seem to peak at age 6–9 years and diminish towards puberty, with an assumed spontaneous cure rate for daytime wetting of about 14% per year [24].

In a cross-sectional sample of 594 individuals 4 to 26 years old Kyrklund describes in 2012 4% of respondents with frequent UI, most < 12 years. Prevalence decreases enormously with age [25].

Most children are toilet-trained by the age of 3 years, although the mean age may range from 0.75 to 5.25 years, with girls being trained earlier [2.25 years] than boys [2.56 years] [26]. A 2008 Turkish study reported day dryness at a mean age of 28 months (27). This is confirmed by a 2015 Turkish study in 1500 children whose mean age of dryness was 29 months (28). The age of commencing toilet training has increased [29]. This is thought to be associated with higher education levels in parents and the popularity of the child-oriented approach rather than parent-initiated methods [26]. Children who exhibited elimination signals for voiding became dry sooner than those who did not show such signs. There is huge social and cultural variation in toilet training practices with some of the implicated issues being, availability of inside toilet, washable versus disposable diapers, working or home-based mothers, rural or urban location and use or not of punishment methods [22]. It appeared that initiating toilet training after 24 months of age may be associated with problems attaining and maintaining bladder control and that early training is not associated with bladder dysfunction (29,30). A prospective study in 112 patients published in 2014 however showed problems in early training (<2 years) and in late training (>3 years) alike [31]. Da Fonseca found no association between children with combined bladder and bowel dysfunction and the time of toilet training compared to healthy children [32].

Swithinbank et al. found a prevalence of day wetting [including also “occasional” wetting] in 12.5% in children age 10-11 years which decreases to 3.0% at age 15-16 years [33]. Based on these findings, it seems that the prevalence of all kinds of daytime incontinence diminishes by 1-2% per year from age 10-11 to age 15-16 years, while daytime incontinence, at least once a week, seems to diminish by 0.2% per year from age 7 to age 17 years. Because of treatment interventions the studies may not re-count the true natural history.

A cohort study of all school children in the first and fourth grades in the city of Eskilstuna (Sweden), published in 2004, daytime urinary incontinence (at least once a month) was reported in 6.3% of the first graders and 4.3% of the fourth graders, while bedwetting (at least once a month) was reported in 7.1% and 2.7% and faecal incontinence in 9.8% and 5.6%, respectively. This study demonstrates that soiling and daytime urinary incontinence often coexist [34].

The natural history of detrusor overactivity in children is not well understood. It is no longer held that detrusor overactivity in children is idiopathic or due to a maturational delay but more likely to be associated with feed forward loops from the generation of a high
pressure system during voiding or filling. Both the interplay of neural drive with motor control and the dynamic nature of the growing bladder could be causative. This is in contrast to the adult population, where detrusor overactivity is considered a chronic condition whose origin is unrelated to functional use. There is no long-term data to determine if childhood detrusor overactivity predicts detrusor overactivity as an adult. There is evidence that genetic influences affect adult urinary symptoms and that suffering lower urinary tract conditions in childhood increases the risk for these conditions in adult woman (35-39). Recent research points to a link between deficits in the brain and functional urinary problems (5).

By the age of 5 years, unless organic causes are present, the child is normally able to void at will and to postpone voiding in a socially acceptable manner. After this age, night-time and daytime involuntary wetting become a social problem and a cause for therapeutic intervention. In children who present with a change in voiding habits, such as a new onset of voiding dysfunction, one should consider the possibility of child sexual abuse [37]. A more recent study found no significant differences in the presence of lower urinary tract symptoms between children and adolescents who had experienced sexual abuse and controls [31]. Never-the-less this should be kept in mind, especially when invasive diagnostic and therapeutic procedures are contemplated. One may want to simply ask the parent or caregiver if there were any precipitating events or concerns that they feel may have led to the changes in the child’s voiding habits. The appropriate individuals should be contacted if there is a high index of suspicion. Of adult women with complex urinary symptoms, a significant proportion report sexual abuse as a child.

2. INTRODUCTION TO CLINICAL ASSESSMENT

The International Children’s Continence Society has published standardisation documents on the diagnostic evaluation of children with daytime incontinence as well as on the management of daytime urinary incontinence in general and dysfunctional voiding in children. They also assessed psychological and psychiatric issues in urinary and faecal incontinence (39-41).

The evaluation of daytime wetting is based on the medical and voiding history, a physical examination, a urinalysis, bladder diaries and uroflowmetry with post void residual. The upper urinary tract should be evaluated in children with recurrent infections and dysfunctional voiding. Uroflowmetry can be combined with pelvic floor electromyography to demonstrate overactivity of the pelvic floor muscles. Urodynamic studies are usually reserved for patients with therapy resistant dysfunctional voiding and those not responding to treatment who are being considered for invasive treatment [42-46].

Treatment is usually a combination of ‘standard therapy’ (see below), behaviour therapy, bladder training, physiotherapy and medical treatment. Surgery is rarely needed for the management of daytime wetting in the absence of a structural abnormality. The roles of neurostimulation, botulinum toxin and intravesical therapies in the management of paediatric urinary incontinence are less well-defined. Clean intermittent self-catheterisation is sometimes necessary in children with poor bladder emptying, due to underactivity of the detrusor and subsequent large residuals, who do not respond to a more conservative approach.

The importance of treatment during childhood was pointed out in a general population study of 1333 adult women. Fifty percent reported symptoms of stress incontinence and 22 percent reported symptoms of urgency incontinence. Eight percent noted severe symptoms. Women who at age six years had wet episodes during the day or were wet several nights per week, were more likely to suffer from severe incontinence and report urgency symptoms: occasional bedwetting was not associated with an increased risk in adult life [47].

3. CONFOUNDING FACTORS: LOWER URINARY TRACT DYSFUNCTION, RECURRENT URINARY TRACT INFECTION AND VESICOURETERIC REFUX (VUR)

The relationship between detrusor dysfunction and VUR associated with a urodynamic anomaly was first described by Allen and Koff and has been confirmed by several authors [48-51]. Koff demonstrated that treatment of detrusor overactivity reduced the incidence of infection and resulted in a 3 fold increase in the rate of reflux resolution. In a study by Sillen of children with gross bilateral reflux, extreme detrusor overactivity without signs of bladder outlet obstruction was found in boys. Infant girls with gross bilateral reflux, extreme detrusor overactivity without signs of bladder outlet obstruction was found in boys. Infant girls with gross bilateral reflux did not show the same degree of detrusor overactivity [51]. Other investigators assessing high grade VUR in newborns noted similar findings. Van Gool et al noted that 40% of 93 girls and boys evaluated for urgency incontinence and recurrent UTIs had reflux [52].

These studies in infants and the association of combined bladder and bowel dysfunction with reflux and infection in older children support the suggestion that in some individuals, vesicoureteral reflux is a secondary disorder related more to abnormal detrusor function than to a primary anatomic defect at the ureterovesical junction. It has been shown that increased intravesical pressure, without reflux, may be detrimental for the upper tracts: renal scarring without reflux was recently described by Vega et al [53].
In support of this concept is the common finding of vesicoureteral reflux in children with neuro-pathic bladders and detrusor-sphincter dysynergia. In such children, the institution of clean inter-mittent catheterisation and anticholinergic therapy leads to the resolution of VUR in a large number of cases. It is believed that the decrease of detrusor overactivity and restoration of functional capacity in combination with regular and complete empty-ing of the bladder are the responsible co-factors [54].

Koff et al. evaluated the effects of antimuscarinic therapy in 62 children with a history of recurrent UTIs, VUR and detrusor overactivity, and com-pared these children with an age-matched control group with a normal urodynamic study [55]. The overall small sample size and the small number of compliant patients limit the study, however, it did demonstrate a statistically significant difference in the resolution rate of VUR between the treated group and the control group. The overall infection rate was lower in the treated group [16%] compared to the non-medically treated group [63%] and the age-matched control group [71%]. Several authors have documented the relationship between detrusor overactivity and dys-functional voiding with recurrent UTIs.

Proposed aetiologies for the increased incidence of UTIs in these patient populations include a milk back phenomenon whereby bacteria in the proximal ure- tra are “milked back” into the bladder dur-ing con-traction of the pelvic floor muscles. Alterna-tively, decreased blood flow and relative hypoxia during peri- ods of increased detrusor pressure such as during in-voluntary detrusor contractions and voiding against functional obstruction, may induce transient bladder mucosal injury.

Constipation is prevalent among children with bladder symptoms, but often poorly identified by parents [56]. It is a risk factor for recurrent UTIs. Contrary to ex-pectations, findings from the Euro-pean Bladder Dys-function Study suggested that symptoms of disor-dered defaecation did not influ-ence the cure rate of treatment for bladder symp-toms [57]. In a prospective non-randomised clini-cal series of day wetting children, a strong correla-tion was found between recurrent urinary tract in-fections, detrusor overactivity and detrusor-sphincter dysfunction [58]. In a study by Hansson et al, symptoms of detrusor overactivity, such as urgency and daytime incontinence were found in a high percentage of girls with asymptomatic bacte-riuria [59].

In the majority of children with dysfunctional void-ing the recurrent infections disappeared following suc- cessful treatment of the voiding dysfunction. This finding confirms the hypothesis that dysfunctional voiding is the main factor responsible for the infec-tions [and to a lesser extent vice versa] [60,61]. Addi-tionally, since such children typically have coexistent constipation, attempts at restoring normal bowel hab-its will also contribute to decreas-ing the risk of UTIs.

At present, current opinion is that vesicoureteral re-flux as such does not predis-pose to UTI: however it may facilitate renal in-volvement [causing pyelonephritis] once bacteriu-ria has been established in the bladder. This con-cept has not been scientifically val-idated and the incidence of renal scars as a conse-quence of pyelonephritis is reportedly the same, regard-less of whether reflux has been documented or not [62]. Those children with VUR in association with de-trusor overactivity and/or voiding dysfunction may be at increased risk for upper tract damage given their increased risk of developing UTIs. With this in mind, aggressive treatment of the underlying filling/voiding disorder, the addition of prophylac-tic antibiotics, and attention to their bowel habits should be given in an effort to decrease the risk of UTIs in this higher risk group [63-66].

In a recent study evaluating retrospectively a large group of children with LUT conditions it was shown that in patients who had urinary tract infec-tion the presence of reflux increased the rate of renal cortical abnormalities. [67].

4. CLASSIFICATION

Numerous classifications have been used for chil-dren who present with varying degrees of ‘func-tional’ urinary symptoms, unrelated to apparent disease, injury or congenital malformation. In 2016, the Interna-tional Children’s Continence Society (ICCS) released a standardised terminology to provide guidelines for the classification and com-munication about LUTS in children [11].

Symptoms are classified according to their relation to the voiding and or storage phase of bladder function.

In addition to gaining a comprehensive history, ob-serving micturition and examining the child forms the basis of assessment: the information derived from a 48 hour bladder diary, stool record, voiding uroflow-metry and lower urinary tract ul-trasonography is also essential in making the ini-tial diagnostic classi-fication (39,68).

Screening for psychological symptoms with ques-tionnaires is recommended, as 30-40% of children with daytime urinary incontinence are affected by comorbid emotional of behavioural disorders [69].

Urodynamic investigations elucidate the basis of clin-ical findings but are first line evaluation tech-niques only in tertiary referral centres where chil-dren have responded to previous treatment or have symp-toms suggestive of neural involvement or anatomical anomalies.

The ICCS has classified daytime LUT conditions into groups that currently align with understanding of under-lying pathophysiology. The groups com-monly overlap and allocation is based on the 4 symptoms of urinary incontinence, frequency of volitional voiding, micturition volumes and fluid intake.
• Over active bladder (OAB) including urgency incontinence
• Dysfunctional voiding
• Underactive voiding
The symptom-specific bladder conditions of
• Voiding postponement
• Vaginal reflux
• Giggle incontinence
• Extraordinary daytime urinary frequency
• Elimination syndrome

The term ‘non-neurogenic dysfunction’ is commonly encountered in the literature and describes the whole spectrum, from simple bladder overactivity to severe cases with deterioration of the upper tracts. The fact that a neuropsychiatric deficit is not demonstrated at the time of evaluation, does not, however exclude the possibility that a neurological abnormality was present at the onset of the problem. It has been postulated that detrusor overactivity may eventually lead to poor bladder emptying due to underactivity of the detrusor or severe dyscoordination between detrusor, sphincter and pelvic floor. However, the natural history of many of these children does not confirm this hypothesis, nor the early onset of severe pathology in some of them. Hoebeke et al found no evidence for this dysfunctional voiding sequence: children with functional incontinence have different primary diseases, but all have a common risk of incontinence, UTI, VUR [15%] and constipation [17%] [12].

4.1. Overactive bladder in children

The term bladder overactivity is used to describe the symptom complex of urgency, which may or may not be associated with urgency incontinence and is not a direct result of known neurological damage. Recent suggestions describe OAB as a symptom of corticocentral dysfunction that affects multiple systems rather than a dysfunction isolated to the urinary bladder [70]. Urgency syndrome is characterised clinically by frequent episodes of an urgent need to void, countered by contraction of the pelvic floor muscles (guarding reflex) and holding manoeuvres, such as squatting and the Vincent curtsey sign. The term urgency refers to a sudden compelling desire to void that is often difficult to defer, unlike the need to void which is experienced by all individuals and may be intense if one holds one’s urine for a prolonged period. The symptoms are thought to arise from detrusor overactivity during the filling phase, causing urgency. These detrusor contractions are countered by voluntary contraction of the pelvic floor muscles to postpone voiding and minimise wetting. Where present, the detrusor contractions can be demon-strated urodynamically, as can the increased activity of the pelvic floor muscles during each contraction.

The voiding phase is essentially normal, but detrusor contraction during voiding may be extremely powerful. The flow rate reaches its maximum quickly and may level off (‘tower shape’). Such strong bladder and pelvic floor muscle contractions have been postulated to result in damage to the bladder mucosa increasing the risk of UTIs. In addition, these children may note suprapubic or perineal pain. A cohort of patients presenting with night-time pain syndromes based on pelvic floor spasms was described by Hoebeke et al. Good response to pelvic floor relaxation biofeedback is described in this study [71].

Overactive bladder (OAB) should also be considered in “continent” children with recurrent UTI and vesicoureteral reflux. Depending on fluid intake and urine production, the complaints of incontinence become worse towards the end of the day, due to loss of concentration and fatigue and may also occur during the night. Children usually diminish their fluid intake to minimise wetting, and therefore incontinence may not be the main com plaint or symptom, but on careful questioning urgency becomes apparent.

Frequent voluntary contractions of the pelvic floor muscles may also lead to postponement of defaecation. Constipation and faecal incontinence (soiling) are often found in children with detrusor overactivity [72]. The constipation is aggravated by the decreased fluid intake. Constipation contributes to an increased risk of UTIs and may exacerbate the detrusor overactivity. An investigation of the natural history of combined emptying dysfunction of bladder and bowel, using an elimination score in women with and without urogynaecological prob lems, demonstrated that childhood lower urinary tract dysfunction may have a negative impact on bladder and bowel function in later life [73]. Urinary symptoms and faecal problems often go hand in hand, epidemiological data show that urinary con tinence is found more often in girls, where defaecation problems are more often found in boys. A clear explanation is not yet found.

A careful history, physical examination and scrutiny of the child’s bladder diary will identify symptoms of detrusor overactivity. Urine flow rate registration and post-void residual urine measurement help to identify co-existing dysfunctional voiding. Thus, in most children, invasive studies such as urodynamic studies are not indicated as part of the initial evaluation. Such studies are reserved for those children with a question of an underlying neurological defect and those who fail to improve with medical and behavioural therapy, if invasive therapies are being considered. Those children with a history of recurrent UTIs should undergo assessment with a renal/bladder ultrasound and depending on the age of the child, and the severity of the UTI(s), a voiding cystourethrogram (VCUG) to assess reflux is occasionally performed [74,75]. By adopting a structured approach to history and physical examination, the diagnosis can be made in most children without the need for invasive diagnostic procedures.
Treatment:
Treatment involves a multimodal approach, involving strategies such as behavioural modification, antimuscarinic medication and neurostimulation. Underlying and potentially complicating conditions such as constipation and UTI are managed prior to intervention.

Level of evidence: 3
Grade of recommendation: C

4.2. Dysfunctional voiding

Dysfunctional voiding refers to an inability to fully relax the urinary sphincter or pelvic floor muscles during voiding. There is no identified underlying neurologic abnormality. Children with dysfunctional voiding usually present with incontinence, urinary tract infections and constipation and demonstrate an intermittent, or fluctuating pattern referred to as staccato flow (by ICCS definition) during repeated uroflowmetry.

No clear data are available on the possible causes of dysfunctional voiding. It may be that detrusor overactivity eventually leads to overactivity of the pelvic floor muscles, with subsequent insufficient relaxation during voiding [75]. Alternatively, poor relaxation of the pelvic floor muscles during voiding may be a learned condition during the toilet training years, adopted following episodes of dys-uria due to UTI, or constipation or occurring secondarily to sexual abuse [77]. The child’s environment, in particular toilet conditions and privacy issues, can trigger or exacerbate voiding anomalies [78]. In some girls, anatomical anomalies of the external urethral meatus seem to be associated with a higher incidence of dysfunctional voiding. The urine stream may be deflected anteriorly and cause stimulation of the clitoris with subsequent reflex activity of the bulbocavernous muscle causing intermittent voiding [78]. Since no true structural obstruction can be identified the intermittent incomplete pelvic floor relaxation that occurs during abnormal voiding is termed a functional disorder.

Abnormal flow patterns seen in children with dysfunctional voiding:

- Fluctuating (Staccato) voiding: continuous urine flow with periodic reductions in flow rate precipitated by bursts of pelvic floor activity. Voids are commonly prolonged and incomplete.

- Interrupted voiding: characterized by unsustainable detrusor contractions resulting in infrequent and incomplete voiding, with micturition in separate fractions. Bladder volume is usually larger than age-expected capacity. Residual urine is often present. Detrusor overactivity may be seen but it may also be absent [61, 73, 80].

Sustained alteration of voiding is associated with subsequent filling phase anomalies such as phasic detrusor overactivity and inappropriate urethral relaxation [81]. Urinary tract infections and kidney damage are common sequelae [82]. Over time, routine incomplete bladder emptying may possibly progress to detrusor over-distension associated with chronic urinary retention and poor bladder emptying due to detrusor underactivity.

Urinary symptoms associated with dysfunctional voiding range from urgency to complex incontinence patterns during the day and night [78]. Child with dysfunctional voiding have a higher rate of recurrent urinary tract infections than children with no voiding abnormality and demonstrate increased incidence of higher grades of VUR [67, 84]. Symptoms are significantly more common in children with Attention Deficit Disorder than in ‘normal’ children [85].

Signs of dysfunctional voiding reflect initial “compensatory” overactivity of the detrusor along with poor emptying ability. They may include small bladder capacity, increased detrusor thickness, decreased detrusor contractility, impaired relaxa- tion of the external urinary sphincter/pelvic floor during voiding, weak or interrupted urinary stream and large post-void residual volumes of urine. There may also be ultrasound abnormalities, secondary vesicoureteric reflux, faecal incontinence or constipation [67, 86, 87].

Treatment:

Symptoms are often refractory to standard therapy of hydration, bowel management, timed voiding and basic relaxed voiding education. Effective interven- tion requires combination therapy, generally with a sizeable investment of time over a long period. Treatment is aimed at optimising bladder emptying and inducing full relaxation of the urinary sphincter or pelvic floor prior to and during voiding.

Specific goals are:
- consistent relaxation of the pelvic floor throughout voiding,
- normal flow pattern,
- no residual urine and
- resolution of both storage and voiding symptoms.

Strategies to achieve these goals include pelvic floor muscle awareness and timing training, repeated sessions of biofeedback visualisation of uroflow curves and/or pelvic floor activity and relaxation, clean intermittent self-catheterisation for large post-void residual volumes of urine, and antimuscarinic drug therapy if detrusor overactivity is present. If the bladder neck is implicated in increased resistance to voiding, alpha-blocker drugs may be introduced. Recurrent urinary infections and constipation should be treated and prevented during the treatment period.

Treatment efficacy can be evaluated by improvement in bladder emptying and resolution of associated symptoms [88]. Controlled studies of the various interventions are needed. As with detrusor overactivity, the natural history of untreated dys-functional voiding is not well delineated and optimum duration of therapy is poorly described.
Level of evidence: 4
Grade of recommendation: C

4.3. Detrusor underactivity

Children with detrusor underactivity may demonstrate low voiding frequency and an inability to void to completion using detrusor pressure alone. Voiding is of long duration, low pressure, intermittent and often augmented with abdominal straining.

Children with this condition usually present with urinary tract infections and incontinence. Urodynamically, the bladder has a larger than normal capacity, a normal compliance and reduced or no detrusor contraction during voiding. Abdominal pressure is the driving force for voiding. The pre-viiously used term ‘lazy bladder’ is incorrect and is no longer used.

A correct diagnosis can only be made by urodynamic evaluation. Renal function studies, renal ultrasound and VCUG should be performed to assess the extent of renal damage and reflux. Long-standing overactivity of the pelvic floor may in some children be responsible for decompensation of the detrusor, leading to an acontractile detrusor. However, no data are available to support this theory.

Treatment:

Treatment is aimed at optimising bladder emptying after each void. Clean intermittent (self) catheterisation is the procedure of choice to promote complete bladder emptying, in combination with treatment of infections and constipation (which may be extreme in these patients). Intravesical electrostimulation has been described, but now it is still not recommended as a routine procedure for children.

Level of evidence 4
Grade of recommendation C

4.4. Voiding postponement

Voiding postponement is a condition in which children habitually postpone imminent micturition until overwhelmed by urgency, resulting in urgency incontinence [88]. A study comparing children with typical OAB to those with voiding postponement revealed a significantly higher frequency of clinically relevant behavioural symptoms in postponers than in children with OAB, suggesting that voiding postponement is an acquired or behavioural disorder [88]. The rates of Oppositional Defiant Disorder (ODD) are especially high. Some children with voiding postponement have abnormal uroflow patterns (90).

Voiding postponement can develop out of previous OAB, but can represent a separate disorder. Also, voiding postponement can induce OAB. Therefore, different aetiologies need to be considered.

Only 20% exhibit a fluctuating voiding pattern. It remains to be determined whether voiding postponement can develop in the setting of a perfectly normal urinary tract or whether OAB is a necessary precursor.

Level of evidence 4
Grade of recommendation C

4.5. Giggle incontinence

In some children giggling can trigger partial to complete bladder emptying well into their teenage years, and intermittently into adulthood [91,92]. The condition occurs in girls and occasionally in boys and is generally self-limiting. The aetiology of giggle incontinence is not defined. Urodynamic studies fail to demonstrate any abnormalities, there is no anatomic dysfunction, the upper tracts appear normal on ultrasound, the urinalysis is normal and there are no neurological abnormalities [86,87]. It is postulated that laughter induces a generalised hypotonic state with urethral relaxation, thus predisposing an individual to incontinence, however the effect has not been demonstrated on either smooth or skeletal muscle. It has also been suggested that giggle incontinence is due to laughter triggering the micturition reflex and overriding central inhibitory mechanisms. One small study hinted at an association with cataplexy (associated involuntary truncal body movements) and narcolepsy (a state of excessive daytime sleepiness), suggesting involvement of central nervous structures, however with only 7 subjects further evidence is needed [94]. Since the aetiology of giggle incontinence is not known it is difficult to determine the appropriate form of treatment. Positive results have been reported with conditioning training, methylphenidate and imipramine [92-98]. Others have tried antimuscarinic agents and alpha-sympathomimetics. There is no acceptable evidence that any form of treatment is superior to no intervention.

Level of evidence 3
Grade of recommendation D

4.6. Vesicovaginal entrapment

Urinary leakage that occurs in girls a short time after voiding to completion, that is not associated with any strong desire to void, may be the result of vesicovaginal reflux [98]. Urine may become entrapped in the vagina during voiding due to labial adhesions, a funnel shaped hymen, or an inappropriate position on the toilet. The classic presentation is that of a girl who does not spread her legs apart during voiding and who is not sitting all the way back on the toilet seat, but who is rather sitting near the end of the toilet seat tilting forward. Obesity may be an associated risk factor. Changes in voiding position and treatment of labial adhesions will lead usually to resolution of the urine leakage.

Level of evidence 4
Grade of recommendation C
4.7. Bladder and bowel disorder

This is a term used to describe the association of any bowel and/or bladder disorder (11).

The genitourinary tract and the gastrointestinal system are interdependent, sharing the same embryologic origin, pelvic region and sacral innervation. Although children with voiding disturbances often present with bowel dysfunction, until recently this coexistence was considered coincidental. However, it is now accepted that dysfunction of both systems, in the absence of anatomical abnormality or neurological disease, is inter-related. The common neural pathways, or the mutual passage through the pelvic floor musculature, may provide a theoretical basis for this relationship, as may the acquisition of environmental and developmental learning. The latter can be influenced by episodes of urinary tract infection, constipation, anal pain or trauma, childhood stressors, reluctance to toilet and poor toilet facilities [69, 78, 100].

There is also evidence to suggest that in severe cases symptoms may have a neurological basis.

BBD is seen more frequently in girls than boys and is significantly associated with the presence of both VUR and UTI [101]. VUR is slower to resolve and breakthrough urinary tract infections are significantly more common in children with ES when compared to those without the diagnosis. Infections do not ameliorate with antibacterial prophylaxis. Age of first febrile UTI does not appear to be an aetiological factor [91], however, recurrence of UTI in children older than 5 years is associated with the presence of BBD [102-104].

Abnormal recruitment of the external anal sphincter during defection or at call to stool is considered causative, in that it elicits concomitant urethral sphincter and pelvic floor co-contractions. Thus, in both systems a functional obstruction to emptying is generated. In the case of the urinary system, high pressures generated by the detrusor muscle to overcome a decrease in urethral diameter can stimulate detrusor hypertrophy, detrusor overactivity, and lead to incompetence of the vesicoureteric junctions. In the early stages of defaecation disorders, bowel emptying is incomplete, infrequent and poorly executed. As the dysfunction progresses stool quality becomes abnormal, the child develops distension of the rectum and descending colon, seems to lose normal sensation and develops faecal retention incontinence. If constipation was not present as a predisposing factor, it rapidly develops [101].

Children with BBD commonly complain of daytime urinary incontinence, non-monosymptomatic nocturnal enuresis, recurrent urinary tract infections, imperative urgency to void (OAB) and exceptionally urinary frequency. On investigation, they are often noted to have poor voiding efficiency, vesicoureteric reflux, constipation, faecal incontinence, no regular bowel routine and infrequent toileting. The incidence of children with elimination syndrome and sub-clinical signs and symptoms is unknown.

It is important to differentiate between functional constipation and non-retentive faecal incontinence, as the treatment differs. The ICCS has provided documents for both disorders (105, 106).

Assessment follows the same process as for other aspects of paediatric bladder dysfunction, with the addition of a 2-week bowel diary and relevant symptom score. The inclusion of an ultrasound rectal diameter measure when assessing the bladder, has been shown to be discriminative for children with elimination syndrome. Urinary flow curve, perineal EMG and post void residual urine estimate, when considered in isolation, are not conclusive for the diagnosis of elimination syndrome. There is no evidence to suggest that anorectal manometry is warranted as a first line investigation in these children. Recently a symptom scale for BBD has been developed providing objective assessment for diagnosis and quantification of severity [107].

Treatment:

Treatment aims at assisting a child to become clean and dry in the short term, by retraining appropriate bladder and bowel awareness and teaching optimal toileting skills. As bowel dysfunction is more socially isolating than urinary incontinence, and in the light of evidence that amelioration of underlying constipation can relieve bladder symptoms, most clinicians begin with treatment of the bowel. Strategies include disimpaction [if needed], prevention of stool reaccumulation, and post-prandial efforts to empty the bowel while maintaining optimal defaecation dynamics (106). Once stools are being passed regularly, treatment focuses on teaching awareness of age appropriate fullness in the bladder, and training unopposed emptying (without straining or pelvic floor muscle recruitment), at pre-scheduled times. Pelvic floor awareness training and biofeedback therapy are integral.

There are few studies of the efficacy of treatment in children with BBD. Several authors have evaluated the outcome of constipation management on bladder symptoms, however the baseline characteristics of subjects were not described adequately enough to allow clear diagnosis of BBD [72, 107].

A review on the effectiveness of biofeedback for dysfunctional BBD reports that 80% of children benefited from biofeedback but that the level of evidence was low due to poor study designs (106, 109).

Grade of recommendation C
5. PRINCIPLES OF NON-PHARMACOLOGICAL TREATMENT OF ALL DIFFERENT STATES

Treatment of the overactive bladder focuses on both the involuntary detrusor contractions and the child’s awareness to these. The initial treatment of this and all other daytime urinary incontinence subtypes involves a behavioural and cognitive approach. Urotherapy is the umbrella term for all non-surgical and non-pharmacological interventions. The child and parent(s)/caregiver(s) are educated about normal bladder function and responses to urgency. Voiding regimens are instituted and any constipation managed. Additional treatment involves pharmacotherapy, pelvic floor muscle relaxation techniques and biofeedback, either alone or in combination.

Although there are many studies reported in the literature assessing the effects of various forms of therapy on daytime incontinence and urinary symptoms, many of these are case series rather than being randomised or controlled trials. The paucity of studies evaluating basic standard therapy initiatives has precluded double-blinded trials of novel and multimodal interventions. Whilst clinically important benefits are commonly described, patient numbers, objective outcome measures and length of follow-up are sub-optimal.

The main objectives of treatment are to normalise the micturition pattern, normalise bladder and pelvic floor overactivity and cure the incontinence, infections and constipation. Traditional therapy for day-wetting children is cognitive and behavioural. Children learn to recognise the desire to void and to suppress this by normal central inhibition instead of resorting to holding manoeuvres [i.e. immediate voiding without postponement] to generate urethral compression. Children with dysfunctional voiding learn to initiate voiding with a completely relaxed pelvic floor and to pass urine in association with a detrusor contraction rather than via generation of abdominal pressure. Dietary changes and bowel regimens are used to treat the constipation [108]. Antibiotic prophylaxis may prevent recurrent UTIs, however, data to support this is limited.

Some authors contend that in less severely affected children a thorough explanation of the underlying causes and the expected progress of resolution is sufficient treatment [52]. More active conventional management involves a combination of cognitive, behavioural, physical and pharmacological therapy. Common modes of treatment include parent and child reassurance, bladder retraining (including timed toileting), pharmacotherapy, pelvic floor muscle relaxation and the use of biofeedback to inhibit rises in detrusor pressure associated with urinary incontinence [33, 110-112]. Further treatment options include suggestive or hypnotic therapy and acupuncture. A combination of bladder training programmes and pharmacological treatment, aimed specifically at reducing detrusor contractions, is often useful and sometimes necessary.

5.1. Bladder rehabilitation and urotherapy

Initial intervention for OAB, voiding postponement and dysfunctional voiding uses a non-pharmacological approach. Despite the use of urotherapy for many years there is no set format and many clinical studies utilise differing combinations of therapies, which makes it difficult to evaluate the results [111,112]. The aim of urotherapy is to normalise the micturition pattern and to prevent further functional disturbances. This is achieved through a combination of patient education, cognitive, behavioural and physical therapy methods.

A Danish report of the outcome of standard urotherapy in 240 children with daytime incontinence noted achievement of dryness in 126 children (55%). Alarm therapy has traditionally been used for the treatment of nocturnal enuresis but was recently used in management of daytime wetting. When a time watch was utilised as a reminder to void at regular intervals 70% of children became dry. An earlier study of a contingent alarm [which sounded when the child wets] versus a noncontingent alarm system (which sounded at intermittent intervals to remind the child to void) over 3 months in 45 children [113] was equally successful for the achievement of continence. Predictors for dryness included a low voiding frequency, larger volumes voided in relation to age-expected storage and fewer incontinent episodes per week [114].

There is evidence that for children who are therapy-resistant, timed voiding assisted by a timer watch added to urotherapy is effective (115).

Following a 3-month training programme, 42.8% of day wetting children were cured at 1 month, 61.9% by 6 months, and 71.4% by 1 year (116). Allen et al [117] reported that urotherapy patients with good compliance with timed voiding were significantly more likely to improve their continence than those with poor compliance. It has recently been highlighted however, that there is frequently conflict between school rules, routines and toilet facilities and the urotherapy programme components. Adaptive coping techniques added to urotherapy training may enhanced gains in dryness.

In children with OAB and dysfunctional voiding the pelvic floor muscles relaxation is impaired during voiding. Physiotherapy is concerned with re-training of specific muscle groups. Adjunctive physiotherapeutic input offers children different strategies to achieve pelvic floor relaxation during micturition.

Several centres offer intensive urotherapy called voiding schools or even inpatient rehabilitation. A prospective evaluation of 38 Belgian children who underwent this approach showed improvement in 90% of the children with 42% becoming dry, whilst no child
on the waiting list improved during the 6 months (118). Long-term follow-up of 75 incontinent children who underwent intensive urotherapy 16-22 years later showed a good result in 84% and the authors concluded that if the original outcomes of paediatric intensive inpatient urotherapy were good, they tend to remain so over time in most patients (119).

**Level of evidence 3**

**Grade of recommendation C**

### 5.2. Adjunctive biofeedback

Biofeedback is a technique in which physiological activity is monitored, amplified and conveyed to the patient as visual or acoustic signals, thereby providing the patient with information about unconscious physiological processes. Biofeedback is mainly utilized for the management of voiding phase (dysfunctional voiding due to pelvic floor muscle overactivity) abnormalities (120).

Biofeedback can help children to identify how to relax their pelvic floor muscles or recognize involuntary detrusor contractions.

Training with biofeedback can be used as a single treatment [121,122], or in conjunction with a comprehensive rehabilitation program [123,124]. It may be performed by a cystometrogram during which the child is taught to recognize and inhibit involuntary detrusor contractions by watching the pressure curve during cystometry. This is invasive and a time-consuming process with limited application as a routine treatment.

More commonly pelvic floor muscle relaxation is taught using EMG biofeedback and/or real-time uroflow. The child sits on a toilet with a flow transducer, watching both the flow curve and EMG on a computer display, and attempts to empty completely in one relaxed void. Ultrasound may be used to determine the post void residual and demonstrate complete emptying. Interactive computer games are commonly used to make biofeedback training more attractive to children [125,126], however care should be taken that posture and muscle recruitment approximates that of the voiding position. Home training can be performed with success using pure EMG biofeedback.

The results of biofeedback are commonly reported as case series rather than RCTs. Results are generally positive but overall may not be superior to high quality standard urotherapy. The group receiving adjunctive biofeedback in the Vasconcelos study [116] did not achieve greater continence rates at the study end point, although a greater proportion of subjects achieved earlier dryness. Furthermore, the post void residual volumes were significantly reduced in the biofeedback group compared to the standard therapy only group.

Long duration follow-up, whilst desirable, confounds results of intervention in children who are continually growing and maturing. Hellstrom et al report results of a 6-week bladder rehabilitation programme inclusive of biofeedback [111] and note that at 3 years, 71% of the children with detrusor overactivity, 70% of those with dysfunctional voiding and 73% of those with a combined disturbance had a normal micturition pattern. The potential for bias from intercurrent events and interventions precludes statements about the efficacy of biofeedback alone.

**Level of evidence: 3**

**Grade of recommendation C**

### 5.3. Clean intermittent (self) catheterisation

In children with an underactive detrusor, bladder emptying may be achieved with timed and double voiding. If this does not adequately empty the bladder clean intermittent self-catheterisation (CISC) may be tried [127-129]. This requires careful guidance for both the child and the parents. Sometimes it is necessary to give the child a suprapubic catheter for a while and gradually prepare him/her to accept CISC. Once the infections have cleared and the child is continent it will become easier for both the parents and the child to accept. The frequency of CISC depends on the severity of the problem and may vary between four times a day and once a day before going to bed.

**Level of evidence 4**

**Grade of recommendation C**

### 5.4. Neurostimulation

Neurostimulation has been used in adults for a variety of lower urinary tract symptoms and has been applied in children. The main indication is OAB or urge incontinence with good success rates. The use of transcutaneous stimulation with surface electrodes stimulating the sacral root (S3) has shown promising results, especially when tested as part of a randomised controlled trial [130]. Transcutaneous and percutaneous neurostimulation delivered over either the sacral outflow or perineal region of the ankle at a frequency between 10-25 Hz, has proven a useful adjunctive treatment in children with detrusor overactivity. Intravesical stimulation is rarely indicated and can affect the function of an underactive detrusor and potentially improve detrusor contractile function and enhance bladder emptying [131,132]).

Electrical current directly affects the central nervous system by activating CNS centres facilitating both neural plasticity and normative afferent and efferent activity of the lower urinary tract. For children with structural abnormalities, for example imperforate anus, electrostimulation is one method of facilitating strength gains in the skeletal muscle and its fascial attachments. Treatment is particularly useful in patients with very little pelvic floor awareness to stimulate muscle recruitment. Once neural efficiency has improved, training is augmented by active pelvic floor contractions.
In 2011 three papers were published reviewing the use of neurostimulation in children (133-135). This highlights the level of interest in this modality for treating LUTD and bowel dysfunction. A literature search revealed 27 reports of the use of neurostimulation in children with non-neurogenic bladder dysfunction. Only five of these studies were randomised controlled or randomised cross-over studies whilst the rest were case series. However, parasacral Tens has been shown to be more effective than sham in randomised trials in treating OAB. Use of neurostimulation in children with neurogenic LUT dysfunction has been reported in 12 studies, 5 of which were randomised controlled trials.

Previously most studies have looked at the use of electrical neurostimulation in children whose symptoms have been refractory to all other interventions, whereas it is becoming apparent that sacral neurostimulation, especially TENS as first-line treatment is beneficial.

A recent prospective study in 69 children where neurostimulation was used as first-line treatment, a complete resolution of symptoms was seen in more than half of them (55.1%), after 20 sessions (136).

Also, studies using intravesical, transcutaneous and implantable electrodes have noted improved bowel function. One randomised placebo-controlled trial using interferential current transcutaneously showed significant improvements in colonic transit times, decreased soiling and abdominal pain and increased quality of life in children with severe constipation (137). Following up on these children for an average of 3.5 years has shown that these improvements were maintained (145).

From Table 1 and 2 different modes of application have been trialled in mostly small series of children. There is minimal standardisation of populations, application parameters or outcome measures. Thus, evidence is largely drawn from low quality studies. Clearly neurostimulation in children warrants larger, controlled and randomised studies, including its use as first-line intervention and in children with combined bladder and bowel dysfunction. Despite the slow pace of research the reviewers of the articles mentioned above agree that there is a positive role for neurostimulation in children with LUTD, and that it is adjunctive to other interventions, with no known predictors of efficacy now, but also rare and minor adverse events. Neurostimulation of the bowel shows promise.

Reported changes on bladder function with neurostimulation include: significantly increased bladder capacity, decreased severity of urgency, improved continence, and decreased frequency of urinary tract infection. Significant improvement in urodynamic parameters of bladder compliance, number of involuntary contractions, and bladder volume at first detrusor contraction have also been noted.

</table>
More recently the first reports on sacral nerve stimulation with implantable electrodes have been published. In a group of 20 patients between 8 and 17 years old followed prospectively, urinary incontinence, urgency and frequency, nocturnal enuresis and constipation were improved or resolved in 88% (14 of 16), 69% (9 of 13), 89% (8 of 9), 69% (11 of 16) and 71% (12 of 17) of subjects, respectively. Complications were seen in 20% of patients [138]. Different neuroanatomical pathways have been described as targets for invasive sacral neurostimulation. The third sacral (S3) nerve root remains the main access point used for neurostimulation treatment. A retrospective study of Luitzen-Albert Groen et al included 18 patients, of which 5 with neurogenic bladder showed a good short term (78%) and long term (73%) response (73%) (139). These results are similar to those of Hadad (140).

General limits of the evaluation of results for invasive SNS are the small number of patients in all series, the general absence of RCT, the different way to evaluate results and different clinical protocols, including implant techniques, furthermore in some countries as in the United States, SNS and PTNS have been approved by FDA for the treatment of urology diseases but SNS is not approved in children younger than 16 yrs. In Europe, the age limit is not so strictly defined as in the USA but the majority of experiences are mainly referred to postpuberal patients. Implantations of very young patient are generally avoided for a risk of electrode dislocation with statural growth during time, reduced collaboration and limitation for MRI studies. For all these reasons SNM in children still needs further studies (controlled and randomised). Evaluating SNM as first-line treatment in children with combined bladder and bowel dysfunction also depends on defining the criteria for optimal indications and predicting efficacy (149).

Due to the uncontrolled design the level of evidence is low. Experience from adults offered this treatment modality suggests future positive development in children to be likely.

**Level of evidence: 3**

**Grade of recommendation C**

### 5.5. Alarm therapy

Alarm therapy has traditionally been used for the treatment of nocturnal enuresis and has rarely been used for daytime wetting. Only one randomised clinical trial has been published to establish the efficacy of this form of treatment. Halliday et al compared a contingent alarm which sounded when the child wets with a noncontingent alarm system (which sounded at intermittent intervals to remind the child to void) [113]. Forty-four children participated in the study, 50% were assigned to each form of therapy for a 3-month period. Success was measured as 6 consecutive weeks without daytime wetting. Nine children in the non-contingent group and 6 children in the contingent group had persistent wetting. Although the risk of persistent wetting with the contingent alarm was 67% of the risk of persistent wetting with the noncontingent alarm, the difference in the reduction in wetting between the groups was not significant (RR 0.67, 95% CI 0.29 to 1.56). In a retrospective review by Van Laecke et al, a cure rate of 35% after the use of a daytime alarm was described [150]. Due to the retrospective design of the study the level of evidence is low.

**Level of evidence: 3**

**Grade of recommendation C**

### 5.6. Group training

Group training programmes have been developed for children with treatment-resistant incontinence. The program includes provision of information, coaching regarding drinking and voiding habits, relaxation and stress-reduction techniques, as well as cognitive-behavioural therapy (CBT). The training proved to be effective in pre-post analyses (151).

**5.7. Conclusion**

Many clinical studies describe combinations of therapies rather than single interventions, which makes it difficult to evaluate the results. Physiotherapy and biofeedback both focus on the pelvic floor. Relaxation of the pelvic floor during voiding is essential for normal voiding and most of these patients are unable to relax their pelvic floor muscles. Biofeedback is important for showing the children the effect of their relaxation efforts. Most studies only state the clinical responses, and do not provide information on urodynamic parameters before and after treatment. A ‘normal’ flow curve may not mean normal voiding if no information is provided on post-void residual urine. In most papers the inclusion and exclusion criteria are not clearly documented, and it may very well be that the more difficult patients with both storage and voiding dysfunction were included in the study population. Furthermore, different series may describe different groups of patients due to poor definitions and an inadequate classification system. In children with a suspected bladder outlet obstruction, endoscopic investigations should be performed. Most often the anatomic abnormality causing obstruction can be treated at the same time. In girls, a meatal web may cause a deflection of the stream upwards [causing stimulation of the clitoris and bulbocavernosus reflex]. A meatal web may cure this problem, though no information on the long-term effects is available [79].

### 6. PHARMACOLOGICAL TREATMENT

#### 6.1. Antimuscarinergic therapy

Antimuscarinic therapy remains one of the common forms of therapy for overactive bladder / detrusor overactivity. Its use is predicated on the concept that parasympathetic mediated stimulation of muscarinic
receptors in the bladder causes detrusor overactivity, which is responsible for the symptoms of detrusor overactivity. Antimuscarinic agents have been demonstrated to increase bladder capacity, increase bladder compliance and decrease detrusor contractions in neurogenic detrusor overactivity. Detrusor overactivity is believed to play a role in many children with functional incontinence, vesicoureteral reflux and urinary tract infections [152]. More commonly, pharmacotherapy is instituted when behavioural therapy has failed to achieve a satisfactory outcome. Some clinicians use pharmacological therapy as first line in children with moderate to severe daytime incontinence [66].

Despite the frequent use of anticholinergic therapy, often in conjunction with a behavioural therapy regimen, the outcome of pharmacological therapy for daytime urinary incontinence is "unpredictable and inconsistent" and there are few randomised studies available to assess drug safety and efficacy.

The following antimuscarinics are briefly discussed:

Oxybutynin: approved for use in children FDA EMA
Propiverine: approved for use in children EMA
Tolterodine: tested phase 3 clinical trials, not approved for use in children
Solifenacin: tested phase 3 clinical trials, awaiting approval for use in children
Terodiline: investigated in a randomised placebo controlled trial, withdrawn because of serious cardiac side effects.
Trospium chloride: used in small series in children
Fesoterodine: used in small series in children

**Oxybutynin**

Currently the pharmacological therapy most widely used in children with detrusor overactivity is oxybutynin [153]. In 2002, a long-acting formulation, Oxybutynin- XL, has been approved by the FDA for use in children [154]. Historically, oxybutynin use has been limited by its adverse effect profile with such side effects as dry mouth, constipation, facial flushing and CNS effects. The incidence of side effects seems to be dose-related, both for oral and intravesical administration [155]. The CNS effects are related to the ability for oxybutynin to cross the blood brain barrier. Oxybutynin- XL utilises a novel delivery system, which results in absorption in the large intestine, thereby bypassing the first pass metabolism in the liver. This leads to a decrease in the amount of active metabolite [produced in the liver]: resulting in a more favourable tolerability profile. The delivery system requires an intact tablet and thus it cannot be cut or crushed to facilitate swallowing. Another method of delivery of oxybutynin is intravesical therapy. This method of delivery also avoids the first pass effect and leads to increased amounts of oxybutynin available compared to immediate release oxybutynin. Its use in the neurologically intact patient is limited by the need for catheterisation [155].

There are only a few studies and only one randomised and double blinded, assessing the efficacy of oxybutynin in detrusor overactivity in children. In the European Bladder Dysfunction study, 97 children with DO on cystometrogram, received oxybutynin or placebo: the placebo effect of 45% was equal to the effect of oxybutynin chloride [156].

Curran et al, in a retrospective review of 60 patients assessed the efficacy of several agents, primarily oxybutynin in children with non-neurogenic detrusor overactivity, confirmed by urodynamics, who were refractory to behavioural therapy. Some children were treated with combination therapy. Eighty percent had complete resolution or a significant improvement in their urinary symptoms. The authors noted an average time to resolution of symptoms of 2.7 years [range 0.2 to 6.6], however patients were not followed frequently [157]. In a study by Van Hoeck et al, holding exercises with and without oxybutynin showed no beneficial effect on bladder volume. [158].

**Level of evidence: 3**

**Grade of recommendation C**

**Propiverine**

Propiverine is the second antimuscarinic drug approved by the EMA for use in children. A randomised, double-blind, placebo-controlled phase 3 trial with propiverine in children aged 5-10 yr. was reported in 2008. Of 171 randomised children, 87 were treated with propiverine and 84 with placebo. The primary efficacy outcome, decrease in voiding frequency, was -2.0 episodes for propiverine versus -1.2 for placebo; p=0.0007. Superiority could also be demonstrated for increase in voided volume (31.4 vs. 5.1ml; p=0.0001) and reduction in incontinence episodes (-0.5 vs. -0.2 episodes per d; p=0.0005. This clinical trial showed superior efficacy of propiverine over placebo and good tolerability for the treatment of children suffering from DO and urinary incontinence. [159,160] This is the first study with level of evidence 1 that shows beneficial effect of anticholinergic therapy.

A retrospective study published in 2012 on 68 children with OAB, reports a response rate of 86.8% (161).

**Level of evidence: 1**

**Grade of recommendation B/C (only single study)**

The following antimuscarinics are not approved for use in children, and may only be used off-label.

**Tolterodine**

Tolterodine, a non-selective antimuscarinic used for the treatment of overactive bladder and detrusor overactivity in adults. It is the first antimuscarinic agent designed specifically for use in detrusor overactivity and is felt to be "bladder selective". It’s affinity for the bladder compared to other organ systems
leads to an improved tolerability profile. The chemical nature of tolterodine makes it less likely to penetrate the blood brain barrier, which is supported by EEG studies [162]. The delivery system of the long acting preparation is such that the capsule may be cracked and “sprinkled” on food. Tolterodine has not been approved for use in children but there are several studies, which evaluate its safety and efficacy in children with detrusor overactivity. Hjälmas reported the results of an open label, dose escalation study using immediate release tolterodine in 33 children [163]. Doses ranged from 0.5 mg po BID to 2 mg po BID for 14 days. The results demonstrated a 21% (23% with 2 mg po BID) mean decrease from baseline in micturition frequency and a 44% mean decrease from baseline for the number of incontinence episodes in children treated with 1 mg and 2 mg po BID. Bolduc et al reported on a prospective crossover study of 34 children followed for > 1 year who were crossed over from oxybutynin to tolterodine because of adverse effects with oxybutynin [164]. Detrusor overactivity was confirmed in 19/20 who had urodynamic studies performed prior to therapy. Children received either 1 mg or 2 mg po BID and the median treatment period was 11.5 months. Efficacy was assessed by a questionnaire and was comparable for oxybutynin and tolterodine. Sixty-eight percent noted a > 90% reduction in wetting episodes at 1 year and an additional 15% noted a > 50% reduction in wetting episodes. Fifty nine percent reported no side effects with tolterodine and 18% reported the same side effect as with oxybutynin, but felt it was less severe. Eight patients [24%] discontinued tolterodine.

Munding et al reported on the use of tolterodine in children with “dysfunctional voiding” manifested as daytime wetting, frequency or urgency [165]. There was no documentation of uroflow studies to make the diagnosis of “dysfunctional voiding” and from the symptoms these children appeared to have detrusor overactivity. Children were started on behavioural modification for 4-6 weeks and pharmacological therapy was instituted if they failed or had only slight improvement with behavioural therapy. A minimum of 1 month’s follow-up was needed for inclusion, but the mean follow-up was only 5.2 months. Doses ranged from 1 mg po BID to 4 mg po BID. Assessment of results was made by telephone survey. Thirty three percent had > 90% reduction in daytime and nighttime wetting episodes and 60% had > 50% reduction. Four patients [13.3%] had side effects, constipation in 2, dry mouth in 1 and diarrhoea in 1.

Reinberg et al performed an open label parallel group retrospective study of the efficacy and safety of immediate release and long acting tolterodine and extended release oxybutynin [166]. Children started out with the lowest possible dose, 2 mg tolterodine and 5 mg oxybutynin and titrated up according to response and side effects. Children were arbitrarily assigned to therapy based on the formulary restrictions of the health plan and there was an uneven distribution of patients in the treatment groups. Final dose and duration of treatment were not noted. Study nurses asked about side effects and a voiding diary was used to assess efficacy. The authors concluded that extended release tolterodine [p<0.05] and oxybutynin [p<0.01] were more effective than immediate release tolterodine in improving urinary incontinence symptoms and that extended release oxybutynin was more effective than extended release tolterodine in resolving diurnal incontinence (p<0.05) Long term tolerability of tolterodine extended release in a large paediatric population has been shown. [167]

**Level of evidence:** 3

**Grade of recommendation C**

**Solifenacin**

Solifenacn is an antimuscarinic agent used in children with OAB: Hoebeke et al published results on 139 children with therapy resistant OAB, with favourable results, and few side effects, in 2009 (168).

Bolduc et al conducted a prospective, open label study, and published their results in 2009: 72 children enrolled, 45 with non-neurogenic DO. Continence improved in all patients, including 24 who were dry, and 42 and 6 who were significantly and moderately improved, respectively (169).

Long term use showed that high subjective and objective success rates were maintained over a longer follow-up (170).

Phase 3 clinical studies in neurogenic children as well as in non- neurogenic children are being conducted.

**Level of evidence:** 2

**Grade of recommendation 3**

**Terodiline**

One of the drugs which has been investigated in a randomised placebo controlled trial was terodiline [171,172]. Because of serious cardiac side effects terodiline has been withdrawn from the market and is of only historical interest.

**Trospium chloride**

Trospium chloride has been used in small series in children. It is currently available in a twice a day dosing formulation. In the adult population, there is a 16% intra-individual variability in bioavailability and 36% inter-individual variability. Absorption is affected by food intake. Trospium’s chemical structure make it unlikely to penetrate the blood brain barrier as supported by EEG studies. Lopez Periera et al evaluated the use of trospium in 62 children with documented detrusor overactivity and absence of ‘detrusor sphincter dyssynergia’ [173]. Children were randomly assigned to 10, 15, 20 or 25 mg of trospium administered in 2 divided doses or placebo. Fifty-eight children were evaluated. Response rates were assessed by incontinence episodes and urodynamic parameters. Overall, 32% had an excellent response, 42% a good response and 8% a fair response. Detrusor
overactivity completely resolved in 35%. Four children had medication related adverse effects including headache, dizziness, abdominal cramps and dry mouth.

Level of evidence: 3

Grade of recommendation C

**Fesoterodine**

Fesoterodine is approved for adults, and is reportedly safe and effective. A post marketing surveillance study with 2978 adults with OAB scored on efficacy in Korea showed amelioration in 91% (174).

Comparison with solifenacin showed no difference in efficacy, but more side effects with fesoterodine (175).

Expert opinion is that fesoterodine has a similar tolerability and side effect profile to other antimuscarinics and is, therefore, unlikely to revolutionise the treatment of the overactive bladder (176).

In children, the only study done is a Dose-escalating study of the pharmacokinetics and tolerability, showing steady-state plasma 5-hydroxy-methyltolterodine exposures similar to those in adults. The doses given were well tolerated. Only 10 children with non-neurogenic bladder and OAB were included (177).

**Darifenacin**

Darifenacin is approved for use in adults too. Although already mentioned in 2004 to be promising, in children, up to date no studies have published (178).

Some authors try combinations of anticholinergics for refractory OAB: Bolduc et al treated 33 children with a combination of oxybutynin and solifenacin or tolterodine with good success (179, 180).

Fahmy et al enrolled 72 children in a prospective study where tropism chloride was added to oxybutynin in refractory OAB: 68% showed improvement, 22.2% was completely dry (181).

6.2. Beta3-adrenoceptor agonists

Mirabegron is the first of a new class of drugs for the treatment of OAB. Stimulation of β3-adrenoreceptors results in relaxation of the detrusor smooth muscle and improves bladder compliance and bladder capacity. Randomised controlled trials in adults show that mirabegron decreased the number of micturitions and incontinence episodes in a 24-hour period compared with placebo. Mirabegron is approved for use in adults (182,183).

There is only one study published in children. A prospective off-label study in 58 children with refractory OAB or with significant side effects with at least two different antimuscarinic agents were recruited. Continence improved in 52 of 58, with 13 being completely dry. Eight patients reported mild or moderate side effects. Absence of a placebo group is a limitation of the study (184).

Phase 3 studies with mirabegron are currently running in children with neurogenic bladder, but not yet in neurologically normal children.

6.3. Botulinum Toxin

Botulinum toxin is used in children, mainly with neurogenic detrusor overactivity. Initial results are promising, but more studies need to be done. In children 100-200 Units on average, are injected in 30-40 spots [185]. The trigone should not be injected, as there is an increased risk of vesico-ureteric reflux. The results last about 6-9 months. Botulinum toxin is not registered for injection in the detrusor or the sphincter in children. It is used off-label and further prospective studies are needed before a general recommendation can be made (186).

One prospective uncontrolled study by Hoebeke et al in 21 children shows beneficial effects of botulinum toxin in 70% of children with therapy resistant detrusor overactivity [187].

Urodynamic assessment proves amelioration after botulinum toxin A in detrusor contractions and bladder capacity in a prospective study with 13 children included (188). Leon et al published an even smaller prospective uncontrolled series in 2014 on 8 children with favourable results (189). Other published studies are all retrospective: A retrospective study in 30 patients by Blackburn et al published in 2013 and a retrospective study in 57 patients by Mc Dowell published in 2012 demonstrates good response (190, 191). Injection of botulinum toxin into the external sphincter is also possible, but the results are more variable and last only 3-4 months [192]. Radijci et al describe excellent results in the treatment of dysfunctional voiding. In 20 children, good results are described for 17 patients [193]. In a retrospective study by Franco et al, similar results are described in 16 children, however using a higher dosage [194].

These results are confirmed by ’t Hoen et al, and by Vricella et al, but the effect in their series is longer: they report safe and persistent satisfactory results during an average of 13-months in 18 of 20 patients and 15 months in 8 of 12 patients respectively with therapy-refractory dysfunctional voiding (195,196).

Less invasively, botulinum toxin can be administered electromotively: a small study in 15 children shows the administration is feasible, safe, and results in considerable improvement on urinary incontinence (197).

Level of evidence: 3

Grade of recommendation C

6.4. Alpha-adrenergic blockers

Treatment of the overactive pelvic floor and sphincter is much more difficult. Treatment with alpha-adrenergic blockade seems promising, but from the presented studies it is difficult to draw firm conclusions:
as most series are small, not randomised and de-
scribe a mixed patient population [198-200].

In a more recent uncontrolled study by Donohoe et al
a total of 26 patients with Primary Bladder Neck Dys-
function (20 males, 6 females, mean age 12.8 years)
were treated with alpha-blockers. Mean average and
maximum uroflow rates improved from 5.5 to 12.6 cc
per second and from 10.3 to 19.7 cc per second, re-
spectively, while mean EMG lag time decreased from
24.4 to 5.7 seconds and post-void residual urine vol-
ume from 98.9 to 8.9 cc (all p <0.001). Mean follow-
up was 31 months and no major adverse side effects
were observed [201]. Further randomised controlled
studies are needed to define the place of alpha-block-
ers.

Level of evidence: 3

Grade of recommendation C

Because there is much variability in presenting symp-
toms as well as the underlying pathology an individual
approach is advisable: a step by step algorithm has
been developed by Marschall-Kehrel, which seems to
deal with many of these variables [202].

Level of evidence 3.

Grade of recommendation B/C

The limited number of identified randomised con-
trolled trials does not allow a reliable assessment of
the benefits and harms of different methods of man-
agement in children. Further work is required in this
difficult clinical area. The establishment of outcome
measures is needed, to facilitate randomised con-
trolled trials of routine therapy. Interventions that
would benefit from further investigations include:
bladder and voiding education, bladder retention
training, bowel management, hypnotherapy and alter-
native therapies, psychology, prophylactic antibiotic
medication, neuromodulation, biofeedback therapy
and pelvic floor muscle awareness and specific relax-
ation. Only then can the efficacy of new interventions
be measured in children with detrusor overactivity or
dysfunctional voiding.

6.5. Conclusion

A wide therapeutic choice available to clinicians,
many of the commonly used treatments are of dubi-
ouso value and have not been rigorously evaluated in
careful clinical trials with an appropriate study design.
Children who suffer this distressing condition, and
their families, and those who care for them clinically,
need clear guidance as to which treatments are of
proven value. They need access to treatments which
work, and they need protection from treatments which
do not work.

Children who present with urinary symptoms may
have been victims of sexual abuse. In these cases,
the use of invasive diagnostic procedures (VCUG and
urodynamic studies) must be regarded as contraindi-
cated, as must the use of invasive intra-anal treat-
ment devices. Development of less invasive methods

of diagnosis and treatment should therefore be en-
couraged.

V. NEUROGENIC DETRUSOR-
SPHINCTER DYSFUNCTION

1. INTRODUCTION

Neurogenic detrusor-sphincter dysfunction (NDSD)
can develop because of a lesion at any level in the
nervous system. This condition contributes to various
forms of lower urinary tract dysfunction which may
lead to incontinence, urinary tract infections (UTIs),
vesicoureteral reflux (VUR), and renal scarring. Sur-
gery may be required to establish adequate bladder
drainage, and potentially, if not managed properly,
NDSD can cause renal failure, requiring dialysis or
transplantation.

Management of neurogenic detrusor sphincter dys-
function in children has undergone major changes
over the years. While the use of diapers, permanent
catheters, external appliances and various forms of
urinary diversion were acceptable treatment modal-
ties; these are now reserved for only a small number
of resistant patients (1). Initially, long-term renal
preservation was the only aim of therapy and early
diversion had the best long term results for preserving
renal function. Despite some of the complications of
ileal conduits and cutaneous urostomies requiring
secondary surgery, this form of treatment offered the
best outcome for renal preservation with socially ac-
ceptable continence (2).

Introduction of clean (self) intermittent catheterisation
revolutionised the management of children with
NDSD. It, not only made conservative management a
very successful treatment option, but also made sur-
gical creation of continent reservoirs a very effective
alternative with a good quality of life (3).

The causes and presentation of a neurogenic bladder
in a child is different from adult forms. In most cases,
the paediatric neurologic bladder is caused by con-
genital problems, and many investigators differentiate
between a neurologic and a neuropathic bladder. A
neurogenic bladder is one from a true neurologic def-
cit like spina bifida (SB), and a neuropathic bladder
is one that acts like a neurogenic bladder but is not
caued by an innervation problem like valve bladder
syndrome. Acquired forms caused by trauma, infec-
tion, or behavioural issues are more comparable with
adult clinical pictures (4).

The most common cause of NDSD in children is neu-
rospinal dysraphism and this condition presents with
various patterns of detrusor-sphincter dysfunction
within a wide range of severity. About 15 % of neo-
ates with myelodysplasia have no signs of lower uri-
inary tract dysfunction (LUTD) when initially studied
(5). However, there is a high risk of progressive
changes in the dynamics of the neurological lesion in
time and even babies with normal LUT function at birth have a 1 in 3 risk of developing either detrusor sphincter dyssynergia or acontractile detrusors by the time they reach puberty (6). Nearly 60% of the neonates with neurospinal dysraphism may develop upper tract deterioration due to increased detrusor filling pressures and infections, with or without reflux (7,8).

As our understanding of urodynamic studies has evolved it allowed us to understand the nature and severity of the problems and administer management in a more rational manner differing according to the functional characteristics of each detrusor sphincter unit. Although the last quarter century has witnessed a remarkable progress in understanding pathophysiology, pathogenesis and the management of these children, the main goals of treatment remained the same i.e. the prevention of urinary tract deterioration and the achievement of continence at an appropriate age.

<table>
<thead>
<tr>
<th>2. PRESENTATION OF NEUROGENIC DETRUSOR-SPHINCTER DYSFUNCTION IN CHILDREN</th>
</tr>
</thead>
</table>

Neurogenic detrusor sphincter dysfunction can develop because of a lesion at any level in the nervous system, including the cerebral cortex, spinal cord or the peripheral nervous system. The level of the defect on the spine is strongly associated with survival and the development of cognitive and motor skills, with cervico-thoracic levels performing significantly lower in comparison with lumbosacral defects.

The type and degree of detrusor sphincter dysfunction is poorly correlated with the type and spinal level of the neurologic lesion.

The closure of spinal canal in utero takes place in caudad direction from cephalic end and is completed around 35 days of gestation. The failure of mesodermal in-growth over the developing spinal canal results in an open lesion most commonly seen in the lumbosacral area. The degree of this closure deficiency contributes to a variable presentation of neural injury with varying degrees of LUTD and lower extremity problems.

**Myelodysplasia**, also commonly known as **spina bifida** (SB), is a general term that describes incomplete closure of the vertebral column and malformation of the embryonic neural tube. This term includes a group of lesions like spina bifida occulta, meningocoele, lipomyelomeningocoele, or myelomeningocoele. Myelomeningocoele is by far the most common defect seen and the most detrimental. Traumatic and neoplastic spinal lesions of the cord are less frequent in children (9).

In **meningocele**, the meninges protrude through a vertebral canal defect but the neural elements of the cord remain confined within the canal.

In **myelomeningocoele**, the neural roots or segments of the spinal cord herniate through the incompletely closed vertebrae.

The neurological lesions produced by myelodysplasia are variable and contingent on the neural elements that protrude within the meningocele sac. The bony vertebral level correlates poorly with the neurologic lesions produced. Additionally, different growth rates between the vertebral bodies and the elongating spinal cord can introduce a dynamic factor to the lesion, and scar tissue surrounding the cord at the site of meningocoele closure can tether the cord during growth (11).

In **occult myelodysplasia**, the lesions are not overt and often with no obvious signs of neurological lesion. The diagnosis of this condition has increased since the advent of spinal ultrasonography and magnetic resonance imaging. Yet, in nearly 90% of patients, a cutaneous abnormality overlies the lower back. These cutaneous lesions can vary from a dimple or a skin tag to a tuft of hair, a dermal vascular malformation, or an obvious subdermal lipoma. (9) Alterations may be found in the arrangement or configuration of the toes, along with discrepancies in lower extremity muscle size and strength with weakness or abnormal gait. Back pain and an absence of perineal sensation are common symptoms in older children. Incidence of abnormal lower urinary tract function in patients with spina bifida occulta is as high as 40%. Occult lesions may also become manifest with tethering of the cord later in life. This can lead to changes in bowel, bladder, sexual and lower extremity function.

**Sacral agenesis** is a rare congenital anomaly that involves absence of part or all of one or more sacral vertebrae. Perineal sensation is usually intact and lower extremity function is usually normal and the diagnosis is made when a flattened buttock and a short gluteal cleft is seen on physical examination. This lesion may produce variable degrees and patterns of LUTD.

**Cerebral palsy** patients may also present with varying degrees of LUTD usually in the form of overactive detrusor and wetting.

**Imperforate anus** is a rare anomaly and presents with a closed rectum that does not open onto anal skin verge. These children may present with accompanying spinal cord pathology. This is more common when the rectum ends above the pelvic floor muscles and they should undergo a MR imaging for detection. Early detection of this problem in imperforate anus patients is important to improve the child’s chance of maintaining healthy kidneys and becoming continent.
3. CLASSIFICATION: PATTERN RECOGNITION

The purpose of any classification system is to facilitate the understanding and management of the underlying pathology. There are various systems of classification of the neurogenic bladder.

Most systems of classification were formulated primarily to describe those types of dysfunction secondary to neurologic disease or injury. Such systems are based on the localisation of the neurological lesion and findings of the neuro-urologic examination. These classifications have been of more value in adults as neurogenic lesions are usually due to trauma and more readily identified.

In children, the spinal level and extent of congenital lesion is poorly correlated with the clinical outcome. Indeed, severe detrusor sphincter dysfunction has been associated with minimal bony defects. Various possible neuropathological lesions of the spinal cord including syringomyelia, hydromyelia, tethering of the cord and dysplasia of the spinal cord are the causes of these disparities and they may extend several segments above and below the actual site of the myelomeningocele. Therefore, urodynamic and functional classifications have been more practical for defining the extent of the pathology and planning treatment in children.

The detrusor and sphincter are two units working in harmony to make a single functional unit. The initial approach should be to evaluate the state of each unit and define the pattern of bladder and sphincter dysfunction. Determined by the nature of the neurologic deficit, they may be either in an overactive or in an inactive state. The detrusor may be overactive with increased contractions during filling, with a diminished bladder capacity and compliance or be underactive with no effective contractions during voiding; the bladder outlet (urethra and sphincter) may be independently overactive causing functional obstruction or paralysed with no resistance to urinary flow leading stress incontinence.

These conditions may exist in any combination (10-15).

Urodynamic evaluation (preferably in combination with fluoroscopy) makes pattern recognition possible. Four major types are usually used to describe the detrusor-sphincter dysfunction:

1. Detrusor overactivity with overactivity of the sphincter (mostly dyssynergia),
2. Detrusor overactivity with normal or underactivity of the sphincter,
3. Detrusor underactivity with sphincter overactivity and
4. Detrusor underactivity with sphincter underactivity.

Besides these 4 patterns, one can use the ICS classification: overactive detrusor, underactive detrusor, overactive sphincter and underactive sphincter. Sometimes this is more helpful, as the detrusor may be overactive during filling, but underactive during ‘voiding’.

The urodynamic investigation is considered normal when there is suitable age appropriate capacity, good compliant bladder with no overactivity and normal innervation of the sphincter with normal sacral reflexes and an increase in pelvic floor activity during filling and no activity during voiding. Presence of detrusor overactivity during filling with or without decreased capacity and compliance, is usually seen when there is upper motor neuron lesion and this is usually accompanied by overactivity of the sphincter and failure to relax during voiding. A lower motor neuron lesion is considered when the voiding detrusor contractions are weak or lost and the sphincter is underactive. Urodynamic investigations make it possible to establish a management plan for each individual patient.

Level of evidence: 3
Grade of recommendation B

For the very young child the combination of an overactive detrusor and sphincter is potentially dangerous because of the high intravesical filling pressures, which will put the upper tract at risk (vesicoureteral reflux and hydronephrosis), whereas an underactive detrusor and a paralysed sphincter is relatively safe, providing a low-pressure reservoir (16-19).

Level of evidence: 2

4. PRENATAL DIAGNOSIS AND FETAL SURGERY

In utero intervention holds the promise of reversing some of the sequelae and improving outcome in SB patients. To prospectively evaluate the value of intrauterine surgery, a randomised controlled trial was established in 3 centres. The endpoints of this Management of Myelomeningocele Study (MOMS) included fetal and infant mortality, the need for a ventriculoperitoneal shunt at 1 year of age, and the evaluation of mental and motor development at 30 months of age. There were no maternal deaths and the rates of adverse neonatal outcomes were generally similar between the two groups (20). Long-term (5-year) follow-up has occurred in this cohort of patients. Previous reports have documented decreased incidence of ventriculoperitoneal shunting and neuromotor functioning, showing improved outcomes (less trabeculation and open bladder neck) compared with historical controls (21). The evidence to suggest prenatal surgery is still low and it should only be done in designated centres.
5. MANAGEMENT

The main aim in management of NDSD in children is to ensure and maintain a reservoir with normal age-matched capacity and good compliance that can be emptied completely at low pressures and at regular intervals. Urological care is initiated soon after a child with SB is born and is maintained throughout childhood. In the first years of life, the kidneys are highly susceptible to backpressure and infection. Bladder drainage is essential during and after the closure of the spinal defect in early in life. Following the closure within a few weeks emphasis will be on documenting the pattern of neurogenic detrusor-sphincter dysfunction and assessing the potential for functional obstruction and whether there is vesicoureteral reflux (19,22). Ultrasound studies and a VCUG or videouro Dynamics to exclude reflux must be performed soon after birth. Measurement of residual urine during both ultrasound and cystography should also be done. These studies provide a baseline for the appearance of the upper and lower urinary tracts, can facilitate the diagnosis of hydronephrosis or vesicoureteral reflux and can help identify children at risk for upper urinary tract deterioration and impairment of renal function.

Concerning the bladder function, 2 general scenarios are common. One group of patients will have an over-active sphincter and develop high detrusor leak point pressures greater than 40 cm H2O and are, therefore, active sphincter and develop high detrusor leak point pressures due to detrusor-sphincter dyssynergia cause secondary changes to the bladder wall. These fibro-proliferative changes may cause loss of elasticity resulting in a small non-compliant bladder with progressively elevated pressures. It is believed that early institution of intermittent catheterisation and anticholinergic drugs may prevent this in some patients (33-35).

**Level of evidence 3**

Retrospective evaluation of patients has also shown that significantly fewer bladder augmentations were required in patients with early start of CIC (30,31).

**Level of evidence 4**

The main disadvantage of CIC is bacteriuria which is found in 60% of the patients, but symptomatic UTI are less common (20%) with CIC when compared to the group without CIC (40%). Since the risk of reflux is similarly low with CIC, the renal scar rates are lower. CIC alone, when begun in infancy can achieve continence at a rate of 60 %. When combined with newer and more potent antimuscarinic drugs continence rates approach 75-80%. (36-39)

Due to high risk of latex sensitivity in the NDSD population, non-latex catheters are recommended. Hydrophilic-coated catheters have become more popular as they are more practical to use and are associated with less pain in use. In a randomised trial comparing hydrophilic-coated catheters to uncoated catheters, there was a reduction in microscopic haematuria and better overall satisfaction with the hydrophilic-coated catheters (40).

A Cochrane review examined sterile versus clean catheterisation technique, coated (pre-lubricated) versus uncoated (separate lubricant) catheters, single (sterile) or multiple use (clean) catheters, self-catheterisation versus catheterisation by others, and any other strategies designed to reduce UTIs with respect to incidence of symptomatic UTI, haematuria, other infections, and user preference, in adults and children using CIC (41). This review found a lack of evidence to state that the incidence of UTI is affected by any parameter. Another recent review failed to show that single use hydrophilic-coated catheters decrease the incidence of symptomatic urinary tract infection, when compared to clean multiple use polyvinylchloride catheters (42). The evidence to suggest one specific catheter type, technique, or strategy is weak and choice of catheters and regimens should be made on an individual basis.

**Level of evidence 3**

At present oxybutynin, tolterodine, trosplum, propiverine and solifenacin are the most frequently used anticholinergic drugs to treat detrusor overactivity in children.
The clinical efficacy and side effects from anticholinergics is related to the receptor subtype present in the target organ. There are several muscarinic receptor subtypes throughout the body named as M1, M2, M3, M4, and M5. The predominant muscarinic subtype in the bladder is the M2 receptor (66%); however, it is the M3 receptor subtype (33%) that is more important for detrusor activity (43).

Some clinical studies are available, but not many randomised placebo controlled studies have been performed (35,44-46).

Oxybutynin is the first anticholinergic agent which has undergone a broad investigation in children with NDSD. It is the only FDA approved anticholinergic for paediatric use in NDSD. The dosing of oral and intravesical oxybutynin is 0.2 mg/kg/dose every 8 hr. Despite its high efficacy, oxybutynin has major side effects, which include: dry mouth, constipation, blurred vision, headache, somnolence, learning disability, flushing, constipation and dry itchy skin.

If children are unable to tolerate oral oxybutynin, other modes of delivery can help reduce side effects. The intravesical route does not rely on gastrointestinal absorption and therefore largely avoids hepatic N-desethyloxybutynin, that is generated. It is an active metabolite with similar pharmacological properties to oxybutynin, increasing the potential for adverse effects. A meta-analysis involving intravesical oxybutynin in children with NBD supports its efficacy in lowering the mean maximum detrusor pressure while increasing bladder capacity, but side effects are nevertheless present, although fewer than with oral oxybutynin. Incontinence has been shown to be improved significantly in most studies, with "dry and improved" rates ranging from 61% to 83% (47,48). The transdermal route is an alternative treatment with similar benefits as intravesical treatment. It circumvents the production of N-desethyloxybutynin (49). The main limitations with transdermal delivery are local skin site irritation and the necessity for continual skin adherence.

A prospective controlled trial evaluating trospium in children reports that trospium is effective and safe in correcting detrusor overactivity in children but this study did not include patients with a neurogenic bladder (50). Tolterodine has undergone a trial in children with NDSD by the FDA. Study design limitations, however, prevent therapeutic labelling for tolterodine with NDSD by the FDA. Study design limitations, however, prevent therapeutic labelling for tolterodine with NDSD by the FDA. Study design limitations, however, prevent therapeutic labelling for tolterodine with NDSD by the FDA. Initial promising results in adults have initiated its use in children. So far paediatric studies have been open-label and prospective controlled trials are lacking (61-63). A recent study with selective α1-blockers (doxazosin) in children with NDSD and increased leak point pressure (LPP) did not show any evident efficacy (58).

Level of evidence 4

In neurogenic bladders that are refractory to antimuscarinics and remain in a low capacity and high-pressure state, injection of onabotulinumtoxinA (BTX) into the detrusor has been introduced as a new treatment alternative (59-60). Initial promising results in adults have initiated its use in children. So far paediatric studies have been open-label and prospective controlled trials are lacking (61-63). A recent systematic review examining 12 series (all non-randomised and only 2 with control group) injection of BTX A in therapy resistant bladders causes a significant improvement in terms of continence, maximum detrusor pressure, maximum cystometric capacity, and bladder compliance. This treatment seems to be more effective in bladders with evidence of detrusor overactivity, while non-compliant bladders without obvious detrusor contractions are unlikely to respond to this treatment (64).
In a report of a prospective study, sacral nerve modulation has been found to be effective in treating overactive bladder in chronic pelvic pain/painful bladder syndrome and in children with non-neurogenic lower urinary tract disorders; its effectiveness has not been established for most treatment centres. The nature of this type of treatment (time consuming and very dedicated personnel) renders it unattractive for most treatment centres.

Level of evidence 2

Grade of recommendation C

Nerve stimulation via the sacral or transcutaneous route has been also studied in the treatment of patients with a non-neuropathic bladder. Although transcutaneous nerve stimulation has been found to be effective in treating overactive bladder disorders in chronic pelvic pain/painful bladder syndrome and in children with non-neurogenic lower urinary tract disorders; its effectiveness has not been established for children with NDSD (78).

In a report of a prospective study, sacral nerve modulation conducted in children with NDSD, comparison of urodynamic variables revealed no statistically significant difference except that functional bladder capacity was better in the oxybutynin group and leak point pressure was better in the sacral neuromodulation group (79).

Although nerve stimulation has good evidence for its efficacy in non-neurogenic bladder overactivity, both in children and adults, there is no evidence for its effectiveness in neurogenic overactivity. Its use remains investigational (80).

Children with neurogenic bladder also have disturbances of bowel function. Faecal incontinence in these children is frequently unpredictable; it is related to the loss of lower bowel sensation and function, altered reflex activity of the external sphincter and the consequent failure to fully empty the rectum (81).

Most children with a neurogenic bladder also have constipation and this is managed most commonly with laxatives, such as mineral oil, combined with enemata to facilitate removal of bowel contents. A regular and efficient bowel emptying regimen is often necessary to maintain faecal continence and this may have to be started even at a very young age. With antegrade or retrograde enemata, most of these children’s constipation can be managed and they may attain some degree of faecal continence (82-86).

With availability of retrograde enemata devices with a balloon on the rectal catheter to prevent leakage of solution, retrograde enemata have become more efficient and more popular in comparison to antegrade enemata (87).

Level of evidence 3

Grade of recommendation C

Biofeedback training programmes to strengthen the external anal sphincter have not been shown to be more effective than a conventional bowel management programme in achieving faecal continence (88). Electrostimulation of the bowel may also offer a variable improvement in some patients (89).

Level of evidence 3

Grade of recommendation D

Urinary tract infections are common in children with neurogenic bladders. In the absence of reflux, patients with urinary tract infections should be treated if symptomatic. There is strong evidence not to prescribe antibiotics to patients with asymptomatic bacteriuria (90-93). Bacteriuria is seen in more than half of the children using clean intermittent catheterisation (CIC), but this is not an indication for treatment.

Level of evidence 3

Grade of recommendation B

Patients with vesicoureteral reflux and frequent urinary tract infection require prophylactic antibiotics to reduce the incidence of pyelonephritis, which can potentially lead to renal damage (94).

Sexuality, while not an issue in early childhood, becomes progressively more important as the patient ages. This issue has historically been overlooked. Patients with myelodysplasia have sexual encounters, and studies indicate that at least 15-20% of males are capable of fathering children and 70% of females can conceive and carry a pregnancy to term. Therefore, counselling patients regarding sexual development is important in early adolescence.

Children with a good response to antimuscarinic treatment and an overactive sphincter may be continent between catheterisations. Bladder pressure and (normal) development of the upper tracts will deter- mine whether additional treatment is necessary.
Children with therapy resistant overactivity of the detrusor, or small bladder capacity and poor compliance will usually need additional surgical treatment such as bladder augmentation.

Children with detrusor overactivity but with underactive sphincters will be in a better shape in terms of protecting their upper tracts, but they may be severely handicapped because of their incontinence. Initial treatment will be intermittent catheterisation (as it may reduce the degree of incontinence and offers a much better control over urinary infections) in combination with antimuscarinic drugs. At a later age the outlet resistance must be increased to render them continent (95). There is no medical treatment of proven efficacy that increases bladder outlet resistance. Alpha-receptor stimulation of the bladder neck has not been very effective. Surgical procedures need to be considered for maintaining continence (96-98).

It is important to establish adequate bowel emptying before attempting to correct bladder dysfunction surgically or medically.

Patients with a neurogenic bladder require lifelong supervision; monitoring of renal function is extremely important. Periodic investigation for upper tract changes, renal function and bladder status is mandatory. Therefore, repeat urodynamic studies are needed more frequently at younger ages and less frequently as time progresses. A repeat urodynamic study is warranted when the patient has a change in symptoms or undergoes any neurosurgical procedure. In case of any apparent changes both in the upper and lower urinary tract or any changes of neurological symptoms, a more detailed examination including urodynamics and MRI of the spine is indicated. Renal failure usually progresses slowly but may occur with startling rapidity.

Surgical intervention is required for congenital and acquired diseases interfering with the function of the storage function of the bladder, the sphincter mechanisms or which bypass normal sphincter mechanisms. A plethora of different surgical procedures has been proposed to maintain continence by using different mechanisms. Various procedures using different mechanisms for maintaining continence may be used in the same patient.

In many cases measures such as intermittent catheterisation and drug therapy are needed in addition to surgery since most of the surgical procedures can achieve ‘dryness’, but rarely restore normal voiding.

Patients with bladder neck incompetence pose a real challenge and require a different approach. All surgical procedures to "reconstruct" the bladder neck have one thing in common; an obstruction is created to enhance bladder outlet resistance. Even if successful, normal spontaneous voiding with low pressures without external help is not possible in most patients. Considering the long-term outcome, it may be better not to void spontaneously when bladder outlet resistance is increased because longstanding outlet resistance may cause secondary changes of the bladder wall.

The rarity and complexity of the conditions associated with congenital incontinence in children precludes the establishment of higher levels of evidence because of the rarity and spectrum of the pathology. Choice of surgical treatment depends on the need of each patient and there is never one surgical protocol that is good for everyone. The results are highly dependent on the skills and experience of the individual surgeon. Therefore, graded recommendations for specific procedures cannot be provided. There are no randomised controlled trials (level 1 and 2 evidence). Based on the available literature most studies have a level of evidence 3-4 and grade of recommendation C or D.

1.1. Abnormalities of storage

Bladder Exstrophy: The incidence of bladder exstrophy is 1 per 30,000 live births. (male to female ratio 2.3:1-6.1). Closure of the bladder is generally performed within the first days of life; pelvic osteotomies facilitate reconstruction of the abdominal wall and may improve ultimate continence (1,2,3). Some children will develop more or less normal capacities. Even after successful closure there will be some children who end up with poorly compliant small bladders, requiring later bladder enlargement or urinary diversion (ureterosigmoidostomy) (4,5,6,7). Patients with a good bladder template who develop sufficient bladder capacity after successful primary closure and epispadias repair can achieve acceptable continence without bladder augmentation and intermittent catheterisation (8,9,10).

Reconstruction of the bladder neck can either be done at the time of bladder closure or at a later stage. Early reconstruction may facilitate normal bladder function and preserve upper tracts.

VI. SURGICAL MANAGEMENT OF URINARY INCONTINENCE IN CHILDREN

1. INTRODUCTION

The core of current NDSD management is non-surgical. Intermittent catheterisation and drug therapy are usually sufficient in most cases for maintaining continence and preserving upper tracts. Surgical procedures should be considered if conservative measures fail to achieve continence between catheterisations or preserve upper tracts.

There is no particular surgical procedure which is suitable for everyone. Surgical management must be tailored to each individual case, based on careful consideration of urodynamic findings, medical history, age and presence of other disability.
function, but should be attempted only at centres experienced with such surgery (11,12). Continence rates vary from centre to centre and may range between 43 to 87% (13,14).

**Cloacal Exstrophy**: The incidence of cloacal exstrophy is 1 per 200,000 live births. This is a much more complex deformity that requires an individual approach. Most of these children have anomalies of the nervous system, upper urinary tract and gastrointestinal tract that can adversely affect urinary tract reconstruction. Before reconstructive procedures are considered, an extensive evaluation must be carried out.

**Agenesis and duplication of the bladder** are both extremely rare. Agenesis is rarely compatible with life. In bladder duplication, other associated congenital anomalies are often observed such as duplication of external genitalia or lower gastrointestinal tract.

Abnormal storage function in combination with other anomalies is usually caused by a neurological deficit or is secondary to bladder outlet obstruction. Sacral anomalies are frequently seen with cloacal malformations and imperforate anus (15, 16, 17,18).

Posterior urethral valves may cause severe hypertrophy of the detrusor with a small poorly compliant bladder (19,20). Unfortunately, following valve ablation, these bladders may not return to normal function (21,22).

### 1.2. Abnormalities of sphincteric function

**Epispadias (without exstrophy)**: incidence 1 in 60,000 live births, male to female ratio: 3-5:1. All patients with bladder exstrophy also have complete epispadias.

In male patients with complete epispadias and in all females, the sphincteric mechanism is deficient and the child has complete incontinence. Reconstruction of the bladder neck is either performed at the time of epispadias repair or at a later stage. The bladder function may or may not be normal in these patients (23,24).

**Malformation of the Urogenital Sinus** occurs exclusively in phenotypic females. The incidence is 1 in 50,000 live births. In patients with classical urogenital sinus or cloaca, the sphincteric mechanism is insufficient and due to associated neurological abnormalities the bladder function may be abnormal.

**Ectopic ureterocele** protruding into the urethra may be responsible for a partial defect of the bladder neck. In these rare cases, sphincteric incontinence may be the result.

**Sphincter abnormalities** secondary to spina bifida and other neurological disorders are of importance. The sphincter may be overactive (like in detrusor-sphincter dyssynergia) or underactive. Overactivity of the sphincter causes secondary changes of the bladder wall (increased collagen type III with decreased elasticity and compliance). Continence is usually achieved with antimuscarinic drug treatment or bladder augmentation (using the overactivity of the sphincter for continence). In cases of incompetence of the sphincter, different types of surgical intervention are possible to enhance the sphincteric mechanism. In general, all patients with a neurogenic bladder need Clean Intermittent Catheterisation (CIC). In patients reliant upon wheelchair mobility a suprapubic channel can be created (Mitrofanoff) to facilitate CIC.

### Bypass of sphincteric mechanism

**Ectopic Ureter** is an abnormally located terminal portion of the ureter. Instead of the ureter opening in the bladder, it opens in the urethra, vagina, or uterus. Ectopic ureters occur more frequently in girls and are commonly part of a duplex system: in girls, the ectopic orifice of the upper pole moiety drains into the urethra below sphincteric level or vaginal vestibule, thus causing incontinence (25).

When the ectopic ureter represents a single system, the trigone is usually asymmetrical and not well developed. These children may suffer from continuous incontinence as well as a deficient sphincteric mechanism: this is particularly true in bilateral ectopia of single systems. In these patients, the trigone and bladder neck are functionally abnormal and treatment includes surgical reconstruction of the bladder neck. When the upper pole ureter opens in the mid or distal female urethra or outside the urinary tract (i.e. vulva or vagina) incontinence results. Upper pole nephrectomy or ipsilateral uretero-ureterostomy solves the problem.

A rare and a challenging condition is when there are bilateral ectopic ureters. Since the bladder is hypoplastic, in these children achieving normal bladder capacity and function may require additional procedures to ureteric reimplantation (26,27,28).

**Urethral duplication**. Most patients with urethral duplication will leak urine from the abnormal meatus during voiding. In rare cases, when the urethra bypasses the sphincteric mechanisms, continuous leakage may be present (29).

**Vesicovaginal fistulae**. Acquired fistulae may be traumatic or iatrogenic, following procedures on the bladder neck.

### 1.3. Evaluation and diagnosis

A detailed history and physical examination in combination with imaging studies and urodynamic evaluation are the corner stones for successful management. Imaging studies are essential to define the anatomical abnormalities responsible for and associated with incontinence. Ultrasonography of bladder and kidneys as well as a voiding cystourethrogram are the basic studies. In infants and small children sacral ultrasonography can demonstrate normal position and mobility of the spinal cord. The scout film of the contrast voiding cystourethrogram (VCUG) assesses the lower spine and sacrum, intersymphysial distance, and faecal retention. The contrast films will show bladder configuration, presence of
vesicoureteral reflux, incomplete voiding, bladder neck competence, urethral anatomy, and vaginal reflux. Occasionally, an intravenous urogram will provide the clearest assessment of the urinary tract. MRI and CT scanning can be helpful in defining spinal abnormalities as well as congenital abnormalities in the urinary tract.

In addition to imaging studies, urodynamic studies (cystometrography, and when needed, electromyography of the sphincters and urinary flow studies) are useful for all patients with neurogenic incontinence, and after surgery in some cases of bladder extrophy and after posterior urethral valves resection to help define the mechanism of any continued incontinence. However, in many patients much useful information on the function of the lower urinary tract can be obtained with very basic studies including ultrasound and cystometry.

### 2. INDICATIONS FOR SURGICAL PROCEDURES TO CORRECT URINARY INCONTINENCE

#### 2.1. Storage function

Reduced bladder capacity is the main indication for simple bladder augmentation. Reduced capacity can be congenital (bilateral single ectopic ureters, bladder extrophy) or caused by previous surgery e.g. bladder neck reconstruction in extrophy patients, where a part of the bladder is used to create an outlet resistance. Other indications are low functional bladder capacity as it may be present in neurogenic detrusor overactivity, or poor bladder compliance (meningo-myelocoele), or bladder scarring from previous surgery or obstruction. Bladder scarring from bilharzia remains common in areas where this is endemic and is increasingly common with immigration to the developed world. In all such cases surgery is indicated when conservative treatment has failed.

Several studies suggest that aggressive early intervention with CIC and anticholinergic therapy improves bladder compliance and may protect children from augmentation surgery (30,31).

A survey has reported that there has been no change in augmentation rates during the last 5 years: rates demonstrate significant inter-institutional variability (32).

#### 2.2. Sphincter function during storage

Most of the diseases in childhood requiring surgical repair for incontinence not only have an influence on bladder capacity but also on sphincter function. Conservative measures to improve sphincter function have limited value and surgery is required in many cases. There are different surgical options; either to increase outlet resistance or to create or implant a new sphincter mechanism. In neurologically normal patients such as classic extrophy patients, early anatomic reconstruction may allow ‘normal’ bladder and sphincter function. Sling procedures are indicated when the residual sphincter function is not sufficient to avoid incontinence. This may be the case in patients with neurogenic bladder disturbances and urethral incontinence. If there is no residual sphincter function or outlet resistance, an autologous tape or artificial sphincter in boys, may be required. Primary urinary diversion (rectal reservoirs / continent stoma) offers an alternative solution to this problem.

#### 2.3. Procedures to bypass the sphincter

If bladder outlet surgery fails or urethral catheterisation is not possible, a continent stoma may be constructed. Some patients prefer catheterising through a continent stoma rather than through the sensitive urethra. The continent stoma (Mitrofanoff principle) may be combined with bladder augmentation and/or bladder neck reconstruction or closure. An alternative to such procedures would be the use of the anal sphincter for urinary continence with the use of colon as the storage reservoir.

### 3. BLADDER RESERVOIR CONSTRUCTION

#### 3.1. Ureterosigmoidostomy

This type of continent urinary reconstruction may be utilised in reconstruction for bladder extrophy, an incontinent urogenital sinus or the traumatic loss of the urethral sphincter. As this reconstruction is totally dependent on the normal function of the anal sphincter, contraindications include incompetence of the anal sphincter, anal prolapse, previous anal surgery, and irradiation. Because of the potential for electrolyte reabsorption, renal insufficiency is also a contraindication.

Low pressure rectal reservoirs are superior to simple ureterosigmoidostomy because the augmented or reconfigured rectal bladder achieves lower pressure storage and accordingly, enhances continence.

There are two techniques which have been utilised:

a) The augmented rectal bladder in which the rectosigmoid is opened on its antimesenteric border and augmented by an ileal segment. The sigmoid may be invaginated to form a nipple valve to avoid reflux of urine into the descending colon and thus to minimise metabolic complications.

b) The sigma-rectum pouch (Mainz pouch II) in which there is an antimesenteric opening of the recto-sigmoid and a side to side detubularisation anastomosis. Ureteral reimplantation of normal sized ureters is by a standard submucosal tunnel (Goodwin, Leadbetter). If the ureter is dilated the technique utilizing a serosa lined extramural tunnel may be more appropriate (33,34).
As reported by D’elia et al, the results of these low-pressure rectal reservoirs are excellent with day and night continence better than 95% and complications related to the surgical procedure range from 0 -10% with the sigma-rectum pouch to 34% for the augmented rectal bladder (35). Late complications for the sigma-rectum pouch range from 6-12.5% and the late complications for the augmented rectal bladder are 17%. Early complications include pouch leakage while late complications are mainly related to the ureteral implantation into the bowel and pyelonephritis. Metabolic acidosis also occurs (69% of the patients had a capillary base excess of –2.5 mmol/L and used oral alkalinizing drugs to prevent hyperchloremic acidosis). Periodic follow-up is important to check the upper urinary tract and prevent metabolic acidosis. Due to the risk of malignancy at the ureterointestinal anastomosis, colonoscopy should be performed annually beginning at postoperative year 10 (30,36,37,38,39).

Level of evidence: 3
Grade of recommendation: B

3.2. Bladder augmentation, bladder replacement and continent urinary diversion, using intestine

The indication for bladder augmentation, replacement of the bladder, or the creation of a continent urinary diversion, is either the morphological or functional loss of normal bladder function. The main goal of this surgery is to relieve high pressure and low capacity of the urinary bladder and create a new reservoir with low storage pressures that can be emptied periodically. It is particularly important that the patients understand that spontaneous voiding will not be possible after such surgery and lifelong intermittent catheterisation will be required.

Before deciding on what type of procedure can be performed some significant factors must be addressed. These are

3. Physical and mental capacity of the patient to do intermittent catheterisation.
4. Previous surgery (on urinary tract and bowel)
5. Renal function status (including acid base state)
6. Absence or presence of reflux
7. Outlet resistance
8. The need for a catheterisable channel

The different technical approaches to bladder augmentation or replacement are dependent on the clinical presentation of the patient:

- a simple bladder augmentation using intestine may be carried out if there is any bladder tissue, a competent sphincter and/or bladder neck, and a catheterisable urethra,
- an augmentation with additional bladder outlet procedures such as bladder neck reconstruction or other forms of urethral reconstruction are required when both the bladder and outlet are deficient. This occurs most commonly in spina bifida or bladder extrophy. It must be appreciated that bladder outlet procedures may complicate transurethral catheterisation.
- augmentation with surgical closure of the bladder neck may be required primarily, or as a secondary procedure in certain rare clinical situations. In this situation, a continent stoma will be required. However, most urologists prefer to leave the bladder neck and urethra patent as a safety precaution: when the bladder is very full leakage will occur and it allows transurethral manipulations such as catheterisation if the continent reservoir cannot be emptied through the suprapubic catheterisable channel.
- an augmentation with formation of an additional continent stoma is utilised primarily following failure of previous bladder outlet surgery. It is advisable also when an inability to catheterise transurethrally can be anticipated. An abdominal wall continent stoma may be particularly beneficial to the wheelchair bound spina bifida patient who often can have difficulty with urethral catheterisation or who is dependent on others to catheterise the bladder. For continence with augmentation and an abdominal wall stoma, it is essential that there be an adequate bladder outlet mechanism to maintain continence.
- total bladder replacement in anticipation of normal voiding in children is very rare, as there are infrequent indications for a total cystectomy, with preservation of the bladder outlet and a competent urethral sphincter. This type of bladder replacement is much more common in adult urological reconstruction.

The main contraindications are the inability of the patient to be catheterised, or perform CIC him or herself and the anticipation of poor patient compliance. When there is reduced renal function generally with a creatinine above 2 mg/dl or a creatinine clearance below 40 ml./min/1.73 m², there is a relative contraindication to the use of ileum or colon because of metabolic acidosis secondary to resorption. The stomach with its excretion of acid may be used with a low creatinine clearance possibly in preparation for transplantation. It is, however, not wise to use stomach in any voiding patient or one with any questions of an incompetent bladder outlet because of the severe skin irritation that the acid urine may produce (haematuria-dysuria syndrome).

3.3. Which intestinal segment should be utilized?

a) Stomach
Stomach has limited indications primarily because of the complications that have been seen. It is the only intestinal segment suitable in patients with significantly reduced renal function (40,41,42).

Additionally, when no other bowel may be available, such as after irradiation or in the presence of a short bowel syndrome, as in cloacal exstrophy, this may be the only remaining alternative.

b) Ileum / Colon

Clinically these two intestinal segments appear to be equally useful. In children, sigmoid colon is widely used except in those who have been treated for imperforate anus. Use of the ileocaeecal region can be associated with transient and sometimes prolonged diarrhoea. Use of this segment should be avoided in patients with a neurogenic bowel such as in myelomeningocele or who have been subject to previous pelvic irradiation. If the ileocaeal valve must be used, it can easily be reconstructed at the time of performing the ileo-colonic anastomosis. The ileum can be satisfactorily used for bladder augmentation: however, because of its smaller diameter a longer segment of ileum is required to create a comparable reservoir to that created from colon. Colon has greater flexibility for ureteral implantation and construction of a continent catheterisable channel.

c) General principles

There are several important principles for bladder augmentation and replacement that should be respected:

- use the minimal amount of bowel and, if available, use hindgut segments or conduits from previous surgical procedures,
- a low-pressure large capacity reservoir is essential. This requires detubularisation of any intestinal segment used.
- for colonic reservoirs, a sigmoid segment of 20-30 cm is generally satisfactory. A slightly longer segment of ileum is generally used. The length of the segments can be scaled down in smaller children. Care should be taken not to use more than 50 to 60 cm of ileum in adolescents and comparable lengths in younger children because of reduction of the intestinal resorptive surface.
- the jejunum is contraindicated in intestinal reconstruction of the urinary tract because of its metabolic consequences (hyponatraemia, hypercalcaemia, and acidosis).
- it is wise to strive to achieve an anti-reflux ureteral anastomosis into the reservoir to avoid the potential for reflux and consequently ascending infection; in high pressure bladders with reflux the reflux usually disappears spontaneously following augmentation (43,44).
- a reliable continence mechanism (continent urinary outlet) must be assured.
- because of the risk of stone formation only resorbable sutures and staples should be used in bladder augmentation and reservoir construction.

d) Bladder augmentation techniques

1. In gastric augmentation, a 10-15 cm wedge-shaped segment of stomach is resected. Most commonly this is based on the right gastroepiploic artery but can be based on the left artery as an alternative. The segment is brought down to the bladder easily in the retroperitoneal space along the great vessels.

2. When using large or small bowel the segment to be utilised is opened on the antimesenteric border and detubularised prior to anastomosis to the bladder remnant. The anastomosis of the intestinal segment to the bladder remnant and to itself is usually carried out in one running layer of inverting absorbable sutures.

3. The techniques for urinary diversion with continent stoma (Mainz pouch, Indiana pouch, Kock pouch) are covered in the chapter on urinary diversion in adults (45,46,47).

Currently, augmentation cystoplasty is the standard treatment for low capacity and/or low compliance bladders secondary to neurogenic, congenital and inflammatory disorders. Due to the relatively high morbidity of conventional augmentation there is renewed interest in alternative methods (48, 49,50,51,52,53). These alternative techniques try to avoid the contact between urine and intestinal mucosa and include gastrocystoplasty, bladder auto-augmentation, seromuscular augmentation, alloplastic or biodegradable scaffolds grafted with autologous urothelium developed in cell culture, and ureterocystoplasty.

e) Auto-augmentation

The principle of auto-augmentation of the bladder is the excision of a great portion of the detrusor while leaving the urothelium intact, creating a large diverticulum for the storage of urine at lower pressures. This urine stored at a low pressure can be drained by intermittent catheterisation. The theoretical advantages of this procedure are the low complication rates of the surgery, reduced operative morbidity with shorter stay in the hospital, absence of urine salt resorption, less mucus production in the urine and possibly absence of potential carcinogenesis. Although some series showed good results with this procedure (54,55,56,57), most authors have been unable to achieve the early reported rates of success (58). Long-term results have been rather disappointing: MacNeil et al concluded that of 17 patients with neurogenic bladder following auto-augmentation, 71% were clinical failures and 14 out of 15 were urodynamical failures (59). Similar findings have been reported by others (60,61). The inability of this procedure to achieve long-term good results may be due to the regeneration of nerve fibres divided during the
surgery as well as the ischaemic atrophy of the mucosa.

Although there are many potential advantages to this approach to a small poorly compliant bladder the inconsistency of success make it a less favourable option. It is generally felt that pressures can be lowered but that capacity remains unchanged.

More recently, some authors have proposed the laparoscopic auto-augmentation as a minimally invasive procedure for the treatment of a low capacity/low compliance bladder. (62,63). Despite the indifferent results, some still suggest its consideration before a standard augmentation because of the reasons listed above (64,65,66).

Level of evidence 4
Grade of recommendation C

f) Seromuscular patch

To overcome one of the major disadvantages of a conventional augmentation, that is mucus formation, several techniques have been developed to use intestinal segments free of mucosa. The first attempts resulted in viable seromuscular segments covered with urothelial mucosa (67,68). The intense inflammatory response and shrinkage observed in the intestinal segment discouraged its use in humans (69).

Further attempts consisted of using the association between demucosalised intestinal segments and auto-augmentation. In the initial model using sheep, the animals tolerated the procedure poorly, reflected by inflamed, haemorrhagic colonic segments in the animals sacrificed within one month. In addition, colonic mucosa regrowth occurred in one third of the animals (70). Follow-up studies in a dog model with seromuscular intestinal segments free of mucosa. The first attempts resulted in viable seromuscular segments covered with urothelial mucosa (67,68). The intense inflammatory response and shrinkage observed in the intestinal segment discouraged its use in humans (69).

Further attempts consisted of using the association between demucosalised intestinal segments and auto-augmentation. In the initial model using sheep, the animals tolerated the procedure poorly, reflected by inflamed, haemorrhagic colonic segments in the animals sacrificed within one month. In addition, colonic mucosa regrowth occurred in one third of the animals (70). Follow-up studies in a dog model with seromuscular intestinal segments free of mucosa. The first attempts resulted in viable seromuscular segments covered with urothelial mucosa (67,68). The intense inflammatory response and shrinkage observed in the intestinal segment discouraged its use in humans (69).

The initial experience in treating humans with colocoloplasty lined with urothelium were reported by Gonzales and Lima who independently developed a slightly different technique (75,76). Bladder capacity increased significantly while bladder pressures decreased. Biopsies demonstrated urothelium covering the augmented portion of the bladder in the majority of cases. Longer term follow-up is now available and although the results are very encouraging, they seem to be highly operator dependent and the way in which the mucosa is removed seems to be crucial. Lima et al no longer preserve the bladder urothelium and use a silicone balloon to prevent the augmented segment from contracting (they remove the balloon after 2 weeks: urine is diverted using ureteral stents): in 123 patients, no ruptures were found and only 10% were regarded as failures (77).

Gonzalez et al found seromuscular colocoloplasty in combination with an artificial urinary sphincter successful in 89% of their patients and that it effectively achieved continence with no upper tract deterioration, they concluded that this is their preferred method of augmentation when adverse bladder changes occur after implanting the AUS (78).

Although more authors have now reported their results this procedure remains a more complex form of augmenting the bladder and has not received general acceptance among the paediatric urological community. It is being done in some designated centres (79,80,81,82). A recent comparison of the long-term outcome of this technique with standard intestinocystoplasty has indicated that most of the risks and benefits of augmentation cystoplasty performed using intestine and seromuscular patch appear similar.

Level of evidence 3
Grade of recommendation C

g) Ureteral bladder augmentation

Another alternative to avoid the morbidity of intestinal bladder augmentation is the use of ureteral segments to improve bladder capacity and/or compliance. Megaureters associated with poorly or non-functioning kidneys provide an excellent augmentation material with urothelium and muscular backing, free of potential electrolyte and acid base disturbance, and mucous production (83,84).

An alternative in patients with ureteral dilation and good ipsilateral renal function, is to combine transureteroureterostomy with ureterocystoplasty (85). An additional option in patients with bilateral dilated ureters with preserved renal function is bilateral reimplantation and the use of the distal ends for detubularised bladder augmentation (86,87).

Bladder augmentation with ureter may be effective in a small sub group of patients with ureteral dilatation and poor bladder capacity. Overall long-term results are good and remain so over a longer period (88,89,90,91,92,93).

In a recent evaluation of the long term functional outcome of this technique, ureterocystoplasty provided durable functional urodynamic improvement, yet some patients (4 out of 17 in this series) eventually needed a standard intestinal cystoplasty (94).

Level of evidence 3
Grade of recommendation B

This type of augmentation can also be employed in children who require a kidney transplantation (95,96,97).

h) Experimental Methods
The artificial bladder has been the topic of speculation and experiment that remains outside the bounds of clinical application. Somewhat nearer to clinical application may be engineered autologous urothelium and bladder muscle cells. These cells may be grown on biodegradable scaffolds—both naturally derived and synthetic—for the temporary support of growing tissues which can then be used for augmenting the bladder. Several synthetic materials and natural matrices have been used in experimental and clinical settings and major improvement has been made in techniques of cell harvest, culture, and expansion as well as polymer design.

A range of applications of engineered bladder tissues are at different stages of development. There have been a few in preclinical trials, recent progress suggests that engineered bladder tissues may have an expanded clinical applicability in the future. Clinical trials with these methods are not far away (98-110). Although this field of research may represent the future of bladder reconstructive surgery, currently only experimental studies are available and it may be some time before clinical use becomes a practical reality. We strongly encourage further research in this field.

4. BLADDER OUTLET SURGERY

4.1. Urethral enhancement

In those children where sphincteric incompetence is the only cause of incontinence or plays a major role in association with decreased bladder capacity or compliance, surgical procedures to enhance outlet resistance should be considered. In many cases bladder outlet surgery needs to be combined with other procedures aimed at creating a large low pressure storage reservoir.

4.2. Bulking agents

The injection of bulking substances in the tissues around the urethra and bladder neck to increase outlet resistance in children has been at least 1985. However, concern about distant migration of the injected substance and risk of granuloma formation prevented this technique from gaining widespread acceptance (111,112).

The search for safer, biocompatible substances to create periurethral compression has first led to the use of cross-linked bovine collagen, with initially reported success in about 20-50% of children (113,114,115). Collagen injection appeared to effectively improve urethral resistance, but this did not always translate into satisfactory dryness, besides, the effect of the injection is of short duration and repeated injections were often necessary (116,117). Because of this collagen is no longer recommended for this indication.

Currently, the following substances are available and have been tested in children with incontinence: dextranomer / hyaluronic acid copolymer (a nontoxic, nonimmunogenic, non-migrant synthetic substance) and polydimethylsiloxane.

Usually the substance is injected endoscopically in the bladder neck area (finding the best spot is often the most difficult part of the procedure): more than one procedure may be necessary. On average 2.8 – 3.9 ml is injected. More than 50% of patients need more than one injection. Initial results of 75% success have been reported, but after 7 years there is a gradual decrease and only 40% remained dry (118,119,120). Others have reported success rates of 0 - 70% (121-128). Despite limited success bulking agents remain an option for all patients who are poor surgical candidates and those who want to avoid extensive bladder neck reconstruction. An alternative route may be the injection around the urethra using laparoscopy (129).

Grade of recommendation C

4.3. Artificial urinary sphincter (AUS)

Since its introduction in 1973, the AUS has undergone major transformations over the years. Different devices are currently in use: one of the most frequently used devices is the AS800-T that has been in use for almost 20 years (130). It consists of an inflatable cuff, a pressure regulating balloon and a unit containing a pump and control mechanisms. The inflatable cuff can only be implanted around the bladder neck in females and pre-pubertal males. In post-pubertal males, bulbar urethral placement is possible but not recommended for patients either requiring a wheelchair or those who perform intermittent catheterisation (131). In patients who have had extensive urethral surgery (exstrophy and epispadias) placement may not be technically feasible.

Implantation of an AUS requires special training and difficulties may be encountered in the dissection of the space around the bladder neck in obese, post-pubertal males or in patients with a history of previous bladder neck procedures. A 61-70 cm H2O pressure balloon is used exclusively when the cuff is around the bladder neck and a lower pressure balloon when it is around the bulbous urethra. Although high in cost, the artificial sphincter remains the most effective means or increasing urethral resistance and preserving the potential for voiding. The ideal candidate for AUS implantation is a patient with pure sphincteric incompetence who voids spontaneously and has good bladder capacity and compliance. Unfortunately, only a small proportion of children with sphincteric incontinence meet these criteria. The AUS may also be used in those dependent on clean intermittent catheterisation. The compatibility of the AUS with intermittent catheterisation and enterocystoplasty is well documented (132,133,134).
Another interesting aspect of the AUS is that in some patients require a bladder augmentation concomitantly or subsequently to the AUS implantation (133,136,137,138). The continence rate ranges from 63 to 97% (139-146). Herndon et al reported a success rate of 86% (of 134 patients); 22% voided, 11% had to perform CIC after voiding, 46% only performed CIC through the urethra, 16% performed CIC through a continent channel and 3% used diversion (147). Mechanical problems occurred in 30% of patients who had an 800-model implanted (versus 64% in the old model). Revisions (in 16%) were significantly less in the 800 model. Erosion occurred in both groups (16%). A major complication was perforation of the augmented bladder in this group (occurring in 10 patients). In 28% a secondary bladder augmentation was necessary.

Another interesting aspect of the AUS is that in some children the device is either deactivated or no longer functions but they remain dry: others have reported that placing a cuff only without activation is all that is required to make them dry (148).

The complications most commonly encountered in patients with AUS are mechanical failures. The longevity of the present devices is expected to exceed 10 years, although Spiess et al reported a mean lifetime of only 4.7 years (149). The second most common problem is the development of reduced bladder compliance with time. This may result from an error in the preoperative evaluation or the reaction of the detrusor to obstruction (a reaction noted in some patients with spina bifida). These changes can be seen after many years of follow-up. The results of decreased capacity and compliance may be incontinence, upper tract deterioration, or the development of vesicoureteral reflux. Therefore, long term follow-up with ultrasound, renal scintigraphy and if indicated urodynamics is mandatory in all patients with an AUS.

Infection of the prostate should occur in no more than 15% of all cases. Erosions of the tissues in contact with the prosthesis are rather infrequent. Bladder neck erosions are practically non-existent when the sphencter is implanted around a "virgin" bladder neck. When the AUS is used as a salvage procedure following bladder neck reconstruction, the erosion rate may be as high as 30% (137). Despite the high complication and revision rate, AUS results show that acceptable continence rates can be achieved in the long-term. For this reason, AUS implantation may be better considered as the initial treatment in selected cases (150).

4.4. Fascial slings.

Fascial slings constructed with the fascia of the anterior rectus muscle have been used to increase outlet resistance in incontinent children, particularly those with neurogenic dysfunction since 1982 (151). The sling is used to elevate and compress the bladder neck and proximal urethra. The dissection around the urethra may be facilitated by a combined vaginal and abdominal approach, however, this option is limited to post-pubertal females (152). Several technical variations of the sling have been reported. The fascial strip may be a graft or a flap based on the rectus sheath on one side. The fascial strip can be crossed anteriorly or wrapped around the bladder neck to enhance urethral compression. Although the short-term success rate reported by most authors is encouraging, there are no series reporting detailed results at 5 years (153-154). Most authors report a greater success when fascial slings are used in conjunction with bladder augmentation and success seems more likely in females than in males (155-158). In patients with neurogenic incontinence postoperative CIC is recommended.

The pubovaginal sling in girls may also be placed through the vagina: in 24 girls with spina bifida this procedure was successful in 19, while another 3 became dry following additional injections with bulking agent around the bladder neck via a suprapubic needle introduction. CIC was possible in all patients. One patient developed a vesicovaginal fistula (159). Complications of sling procedures include difficulties with intermittent transurethral catheterisation, erosion of the urethra and persistent incontinence. Overall, the increase in outlet resistance provided by slings seems less than that provided by the artificial sphincter. Experience with these procedures suggests an overall success between 50 and 80% in females. Numerous alternatives are now being used; small intestinal submucosa has been used in 20 children and showed equivalent rates of continence. The advantage being that it is available off-the-shelf. Results were better in girls than in boys (85 vs 43% being dry) (160,161,162).

When combining bladder augmentation with a Gore-Tex sling in 19 children the results were poor: because of erosion the sling had to be removed in 14 patients, all except in one who also had a bladder stone. In this respect, this type of sling should not be used (163).

From the data published it presently seems that the AUS provides more consistent results in boys and for girls capable of spontaneous voiding who have not had previous bladder neck surgery. Bladder neck slings may be used for the enhancement of bladder outlet resistance in most patients with neurogenic bladder who need augmentation cystoplasty and whom we do not expect will be capable of voiding spontaneously. Sling procedures are probably equally effective for girls, dependant on intermittent catheterisation and in conjunction with bladder augmentation. At present, given the cost and lack of effectiveness of injection procedures, their use does not appear justified in incontinent children. The cost of the AUS may restrict its use.
Level of evidence 2.

Grade of recommendation B

It is important that one should know these patients who undergo bladder outlet surgery need long-term follow-up not only because of the complications but also, because their bladder behaviour may undergo unexpected clinically asymptomatic changes that could impair their upper tracts if augmentation is not performed at the same time (164).

4.5. Bladder neck closure

In ‘desperate’ cases the bladder neck may be closed, the indication for this being persistent leakage despite several attempts to enhance outlet resistance by bulking agents or other surgical procedures. Although initial results are acceptable, long-term results are usually disappointing; persistent urinary leakage, stenosis and leakage or stone formation (in up to 40%) (165,166). One of the most important factors seems to be compliance with intermittent catheterisation and bladder irrigation.

4.6. Bladder outlet reconstruction

Surgical procedures to achieve urinary continence are dictated by functional and anatomical deficiencies and by the goal of either continence (with normal voiding) or dryness (dependent on intermittent catheterisation).

Construction of a functional urethra for continence usually implies an anatomical defect without a neurogenic component (epispadias / exstrophy) and includes urethral and bladder neck narrowing and urethral lengthening (167-172).

Such procedures may initially require intermittent catheterisation or occasional post voiding catheterisation, but bladder emptying by voiding is anticipated.

Urethral reconstruction for dryness, however, mandates intermittent catheterisation. The goal in surgery to achieve dryness is to create a urethra suited to catheterisation, which has closure such that intraluminal pressures always exceed intravesical pressure. The most dependable procedures for dryness utilise a flap valve or tunnel to achieve urethral closure, although urethral slings, wraps and injections have also been used (173).

Level of evidence 3

Grade of recommendation C

Reconstruction to achieve continence is based on the principle that proximal reduction of the calibre of the urethra supports the inherent proximal sphincteric mechanism of the bladder neck and proximal urethra. The narrowing must be dynamic to permit closure for continence and yet permit opening with funnelling during voiding. Several techniques have been described to achieve this goal (3, 166-176). Young (1922) performed a “double sphincter technique” that involved the excision of a wedge of tissue at the anterior bladder neck, as well as removal of a wedge of tissue just proximal to the epispadiac meatus (external sphincter). Dees (1949) added the concept of lengthening the urethral tube to that of narrowing. In his procedure, parallel incisions were made through the existing bladder neck area which created a posterior urethral plate from what had previously been the trigone of the bladder. This was tubularised to give added length to the proximal urethra. The added length provides increased potential for urethral closure and moves the bladder neck and proximal urethra into the abdominal cavity. Leadbetter (1964) modified the Young-Dees procedure by creating muscular flaps from the area of the bladder neck and proximal urethra which were used to wrap the newly created proximal tube. This procedure was popularized by Jeffs (1983) who applied it to a staged repair of exstrophy. He supported a lengthened urethra by a suspension. They report their long-term continence rate with this procedure as greater than 80%, without the need for CIC or augmentation (177).

Presently, this represents the gold standard for reconstruction for continence, however, modifications of the technique have reported similar or improved results. Most urethral lengthening procedures utilising the posterior urethra and bladder neck require ureteral reimplantation and preservation of the posterior urethral plate. Because part of the bladder is used to create the functional lengthening of the urethra, bladder capacity decreases following the procedure. It also remains to be seen whether the created urethra is actually a functioning urethra: in many patients fibrosis around the urethra prevent it from being really ‘functional’: in these patients, it may act as an anatomical obstruction and long-term follow-up is necessary to follow not only the bladder but also the upper tracts.

In a study examining the long-term outcome of urethral lengthening procedures (Kropp and Salle procedures) nearly 80% dryness was achieved at 4 hourly intervals and 90% at 3-hourly intervals, but the need for additional procedures were high (catheterisable channel: 54%, delayed augmentation: 47%) (178).

Surgery for dryness is dependent on the effectiveness of intermittent catheterisation and is usually reserved for patients with neurogenic dysfunction or multiple previous surgeries. Procedures to achieve dryness usually create a urethral closure pressure that exceeds bladder pressure.

A flap valve can be constructed by using an anterior or posterior bladder flap (full thickness) to construct a tube that is placed in a submucosal tunnel (171,175,176).

The major disadvantage of these procedures (flap valves) is that the valve will not allow leakage with high intravesical pressures, potentiating renal damage. Therefore, these procedures can be dangerous to the patient who is not totally committed to follow catheterisation recommendations.
Bladder outlet procedures without augmentation cystoplasty remain controversial. It is generally advised to combine it with augmentation cystoplasty to avoid upper tract changes and continued incontinence. In a review of 109 patients who underwent bladder outlet procedures without augmentation cystoplasty the need of augmentation cystoplasty was 30% and additional continence procedures was 70%. There were upper tract changes in more than 50% and chronic kidney disease 20% in a cumulative 10-year follow-up (179-181).

Unfortunately, the ideal procedure for surgical reconstruction of the bladder neck does not exist. The surgical approach to urinary incontinence in the child must be multifaceted because of the inherent complexity and varied nature of the problem.

Recent data support the concept that very early reconstruction in the exstrophy / epispadias group may result in physiological bladder cycling which facilitates normal bladder and urethral development. This results in higher potential for continence without the need for bladder augmentation and bladder neck reconstruction (Level 3). More work and clinical experience in this area is strongly recommended.

**Grade of recommendation A**

### 4.7. Alternative continence channels

In the surgical treatment of incontinence in children every effort must be made to preserve the natural upper and lower urinary tract. The bladder is the best urinary reservoir, the urethra the best outlet and the urethral sphincters the best control mechanism. If the bladder is partly or wholly unusable it may be augmented or replaced by a variety of techniques.

Urethral failure may occur either because the sphincters are incompetent or because it is overactive and does not allow spontaneous voiding. It would be preferable for the former to be treated by one of the techniques described above and the latter by intermittent catheterisation (CIC). If these fail, continent supra pubic diversion is indicated.

#### a) The Mitrofanoff principle.

Mitrofanoff’s name is given to the technique of burying a narrow tube within the wall of the bladder or urinary reservoir whose distal end is brought to the abdominal wall to form a catheterisable stoma suitable for intermittent catheterisation (182). The technique is simple and familiar to all urologists who are accustomed to re-implanting ureters. Several narrow tubes are available for the Mitrofanoff conduit (183,184). In the original description, the appendix was used. However, even if the appendix is still present, it may be unusable in 31% of patients (184).

If no suitable tube is found, a good tube can be formed by tailoring ileum transversely so that only 2-3 cm of ileum can be made into a 7-8 cm conduit. This modification was originally described by Yang in humans and by Monti in experimental animals (185,186). It is increasingly used though great care must be taken in its construction to avoid an internal fistula (187). The ureter may be used but there may be some difficulty in achieving sufficient calibre with a previously normal ureter. Earlier reports that the Fallopian tube could be used have not stood the test of time.

The Mitrofanoff system achieves reliable continence, which is maintained in long-term follow-up, for a high proportion of patients. Long-term follow-up data show that in the original series of Paul Mitrofanoff of 23 patients after a mean follow-up of 20 years, 1 patient had died, but in the other 22 patients no metabolic changes were noted. The bladder neck was closed in 21 patients. Secondary bladder augmentation had to be performed in 8, while in 4 children a non-continent diversion was created. With time the need for additional surgery decreased and after 20 years 16 patients had a good and stable continent diversion (189). The pressure generated within the lumen of the conduit is 2 to 3 times higher than that within the reservoir so that continence is preserved even when the intra-abdominal pressure is raised by straining. Conversely, the pressure in the lumen of a Kock nipple is only slightly higher than that in the reservoir so that continence is less reliable (189,190). The conduit may be buried either between the mucosal and muscular layers of the reservoir, or it may be completely brocated in the full thickness of the reservoir wall. Any well supported tunnel of about 2-4 cm will suffice. The choice depends both on the nature of the reservoir and on the conduit (192). Continence rates of 90-100% with the Mitrofanoff Principle are reported, regardless of diagnosis, reservoir or conduit type (192,193). Follow-up for at least ten years has shown that the system is resilient (194-196). Retrospective review of short and long-term outcomes of patients with the Mitrofanoff procedure reveal that stoma stenosis and leakage are the most frequent complications (within wide ranges of 10 – 60 % each) and occur early during the first two years after creation. After the initial peak of complications, there is a relatively complication-free period. Yet late complications occur in long-term evaluations, probably because of wear and tear of the channels and to anatomical modifications at adolescence with commonly associated obesity (197-201).

A modified technique of vesicostomy is described using a gastrostomy button, which could be used as a continent urinary stoma in children with incomplete voiding. Button vesicostomy is a useful addition to the options available for a catheterisable continent urinary stoma in children in the short or medium term (202). Although perfect continence seems attractive, it may not be in the child’s best interests. A ‘pop-off’ valve may be in the interest of the child if catheterisation is impossible or forgotten.

#### b) The Ileo-caecal valve.

The ileo-caecal valve is an obvious sphincter to combine with cecum and ascending colon as the reservoir
and the terminal ileum as the conduit. The early continence rate of 94% was not sustained because of high pressures in the tubular reservoir and weakness of the valve (203-205). The Indiana system is based on the competence of the ileo-caecal valve but with a detubularised reservoir (206). The valve itself is reinforced with non-absorbable plicating sutures and the terminal ileum which forms the conduit is tailored. The best reported continence rate is 96% with a 2% rate of catheterisation difficulties.

In the complete Mainz I pouch a length of terminal ileum is intussuscepted through the ileo-caecal valve as a Kock nipple (207). It is impossible to say whether the nipple or the ileocecal valve (or both) produce the continence which is reported in 96% of patients. Both of these systems work well as complete reconstructions and are widely used as bladder replacements in children. The sacrifice of the ileo-caecal valve may cause gastro-intestinal complications.

c) Kock pouch

The first workable continent diversion was the Kock pouch (42). The reservoir is made from 40cm ileum reconfigured to reduce the intrinsic pressure. The continence mechanism is formed by intussusception of 12cm of ileum. In a complete form it requires 72cm of ileum which may be more than can be spared from the gastro-intestinal tract. Although first described as a mechanism for a continent ileostomy in children the Kock pouch is not commonly used in children because of the problem with large amount of bowel needed, stone formation and mediocre success with dryness of the catheterisable stoma (208,209).

d) Artificial Sphincter

As a last resort, the AUS may be considered to give continence to a reconstructed outlet. Experimental evidence suggests that AUS cuffs can be placed safely around intestine providing the cuff pressure is low (210). The AUS has been used successfully around large bowel, in three of four children with follow-up of 11 years (211).

e) Where to place the cutaneous stoma

In patients with spina bifida, particularly those unable to walk, the site must be chosen with care. The natural tendency is for the spine to collapse with time so that the lower half of the abdomen becomes more pendulous and beyond the range of vision. A low site may seem appropriate in the child, but will become unusable in the adult. It is best to use a high, midline site, preferably hidden in the umbilicus. The site should be determined in a sitting position and marked before surgery because in the supine position the position will change dramatically. In some patients, the best position may not be in the midline at all: special care must be taken that the patient can manage bladder emptying and irrigation him/herself.

For most other patients, the site of the stoma should be chosen by cosmetic criteria. The umbilicus can be made into a very discrete stoma; the risk of stenosis is low and it is a readily identifiable landmark. Otherwise, the stoma should be as low on the abdominal wall as possible and certainly below the top of the underpants. However, many surgeons find the best results by placing the catheterisable stoma in the umbilicus.

The problem of stomal stenosis remains ever present. It can occur at any time so that only follow up of many years could determine whether any system of anastomosis to the skin is better than any other. The published rate of stomal stenosis is between 10 and 20%. The multi-flap V.O.Z. stoma is claimed to have the lowest rate but follow up is short and it may well not pass the test of time (212).

5. COMPLICATIONS OF CONTINENCE SURGERY IN CHILDREN

5.1 Storage and emptying complications

In the short term, continent diversions can store urine and can be emptied by clean intermittent catheterisation (CIC). It is apparent that there is a constant need for review and surgical revision. This observation mirrors the late complications of augmentation cystoplasty for neuropathic bladder where the median time to revision surgery is as long as ten years (213,214).

In general, once continent, they remain continent, although there are occasional reports of late development of incontinence. The problem lies more in difficulties with catheterisation, particularly stenosis and false passages which may occur in up to 34% of patients (192). In a recent retrospective evaluation of 500 augmentations over 25 years with a median follow-up of 13.3 years, the cumulative risk of further surgery at the bladder level was 0.04 operations per patient per year of augmentation and 34% of the patients needed further surgery for complications. Bladder perforation occurred in 43 patients (8.6%) with a total of 53 events and 125 surgeries done for bladder stones in 75 cases (215). The principal complications arise because the reservoir is usually made from intestine. Ideally, urothelium should be used and preservation of the bladder epithelium gives fewer complications than enterocystoplasty (216). Combinations of detrusor myectomy and augmentation with de-mucosalised colon have given promising results in the short term. The surgery is difficult as the bladder epithelium must not be damaged and the intestinal mucosa must be removed completely. When achieved there are no metabolic problems and many patients can void (216).

When augmentation can be done with a dilated ureter, the results are good and the complication rate low even in children with compromised renal function or transplantation (217). All intestinal reservoirs produce mucus. The amount is difficult to measure and most...
estimates are subjective. No regime has been shown to dependably reduce mucus production (218).

5.2. Reservoir rupture
The most morbid and disastrous complication following bladder augmentation is perforation, which may lead to peritonitis, sepsis, and even death. Reported rates of bladder perforation following augmentation range between 6 and 13 % (219-222).

There may be delay in diagnosis although the history of sudden abdominal pain and diminished or absent urine drainage should make it obvious. The patient rapidly becomes very ill with symptoms of generalized peritonitis (223,224). A 'pouchogram' may not be sensitive enough to demonstrate a leak. Diagnosis is best made by history, physical examination, ultrasonography and a CT cystogram. If diagnosed early, catheterisation and broad spectrum antibiotics may sometimes lead to recovery. If the patient fails to respond within 12 hours on this regime or if the patient is ill, laparotomy should be performed at once. If there is any instability of the patient laparotomy should be considered as an immediate necessity as bladder rupture in this clinical situation can be lethal.

Level of evidence 2.

Grade of recommendation A

Figures are not available on the incidence of this complication in reservoirs made only of bowel but come from patients with intestinal segments in the urinary tract. Most papers report small numbers. In a multicentre review from Scandinavia an incidence of 1.5% was noted. There were eight patients with neurogenic bladder which was said to be disproportionately high (223). In a series of 264 children with any sort of bladder which was noted. There were eight patients with neurogenic centre review from Scandinavia an incidence of 1.5% was lower in reservoirs with ileum as the only bowel segment compared to those containing some colon (9% v 16%). When arterial blood gases were measured in 29 of these children a consistent pattern was not found (229). In a series of 23 patients, Di-tonno et al found that 52% of patients with a reservoir of right colon had hyperchloraemic acidosis (230). In ileal reservoirs, Poulsen et al found mild acidosis but no patients with bicarbonate results outside the reference range (231). Many authors do not distinguish between patients with normal and abnormal renal function. All of 12 patients in one series with a pre-operative serum creatinine above 2.0mg% developed hyperchloraemic acidosis within 6 months of enterocystoplasty (232). It is prudent to monitor patients for metabolic abnormalities, especially hyperchloraemic acidosis, and to treat them when found (233).

With increasing experience, it has become clear that there is a risk of developing vitamin B12 deficiency, sometimes after many years of follow up. It is likely that resection of ileum in children leads to an incomplete absorption defect. Stores of B12 may last for several years before the serum level becomes abnor-

5.3. Metabolic complications

Because enteric tissue, although incorporated into the bladder, retains its absorptive and secretory properties, there are potential serious consequences, especially for children with an expected longer life span than adults (226,227). Metabolic changes are common when urine is stored in intestinal reservoirs and must be carefully monitored. It is uncertain whether they are commoner in children or whether they just live longer and are more closely monitored. Nurse et al found that all patients absorbed sodium and potassium from the reservoirs but the extent was variable (228). A third of patients (but 50% of those with an ileocecal reservoir) had hyperchloraemia. All patients had abnormal blood gases, the majority having metabolic acidosis with respiratory compensation. The findings were unrelated to renal function or the time since the reservoir was constructed. In 183 patients of all ages at St Peter's Hospitals who had any form of enterocystoplasty, hyperchloraemic acidosis was found in 25 (14%) and borderline hyperchloraemic acidosis in an additional 40 (22%) patients. The incidence was lower in reservoirs with ileum as the only bowel segment compared to those containing some colon (9% v 16%). When arterial blood gases were measured in 29 of these children a consistent pattern was not found (229). In a series of 23 patients, Di-tonno et al found that 52% of patients with a reservoir of right colon had hyperchloraemic acidosis (230). In ileal reservoirs, Poulsen et al found mild acidosis but no patients with bicarbonate results outside the reference range (231). Many authors do not distinguish between patients with normal and abnormal renal function. All of 12 patients in one series with a pre-operative serum creatinine above 2.0mg% developed hyperchloraemic acidosis within 6 months of enterocystoplasty (232). It is prudent to monitor patients for metabolic abnormalities, especially hyperchloraemic acidosis, and to treat them when found (233).

With increasing experience, it has become clear that there is a risk of developing vitamin B12 deficiency, sometimes after many years of follow up. It is likely that resection of ileum in children leads to an incomplete absorption defect. Stores of B12 may last for several years before the serum level becomes abnormal. At a mean follow up of six years, low levels of B12 have been found in 14% of children. There was a corresponding rise in the serum methyl malonic acid which accumulates in B12 deficiency, suggesting that the finding was clinically significant. Similarly, in adults, 18.7% have B12 deficiency at five years. In the adults, the mean B12 level was significantly lower when the ileo-caecal segment as opposed to ileum alone had been used (413 ng/ml compared to 257 ng/ml) (234,235). To avoid the serious neurological complications, regular monitoring of B12 levels is essential. In a review of 500 augmentations starting at 7 years postoperatively, 6 of 29 patients (21%) had low B12 values, while 12 of 29 (41%) had low-normal values (236). Paediatric patients who have undergone ileal enterocystoplasty are at risk for development of vitamin B12 deficiency. These patients are at the highest risk beginning at 7 years postoperatively, and the risk increases with time. An annual serum B12 value in children beginning at 5 years following bladder augmentation is recommended.

Level of evidence 2

Grade of recommendation B
The stomach has had a chequered career as a urinary reservoir. Its non-absorptive role in the gastrointestinal tract has made it particularly useful in reconstruction of children with inadequate intestine, such as those with cloacal exstrophy. There is little effect on gastrointestinal function. Metabolically, the acid production leading to hyperchloraemic alkalosis may be positively beneficial in children with renal failure. It produces no mucus and the acidic urine is less easily infected and seldom grows stones. However, about a third of children have had serious long-term complications, often multiple. The quite severe dysuria / haematuria and the skin complications from the acidic urine, particularly, have limited its use (237,238).

5.4. Effects on the gastrointestinal tract

Little attention has been paid to the effects on gastrointestinal motility of removing segments of ileum or cecum for urinary reconstruction in children. In adults, disturbance of intestinal function has been found to be more frequent and more debilitating than might be expected. Disturbance of bowel habit does not mean diarrhoea alone. It also includes urgency, leakage and nocturnal bowel actions. Quality of life may be seriously undermined by changes in bowel habit (239). It is known that the bowel has a considerable ability to adapt, especially in young animals, when parts are removed. Nonetheless, reconstruction should be undertaken with the smallest length of bowel possible. Care should be taken in children with neurological abnormality in whom rectal control is already poor. Poorly controlled faecal incontinence may occur in a third of patients (240,241).

5.5. Renal function

Obstruction and high pressures in the bladder during storage have devastating effects on the upper urinary tract. Bladder augmentation eliminates these high pressures. Urinary diversion with recurrent urinary tract infections and stone formation also may have deleterious effects on renal function. It is therefore of utmost importance to evaluate renal function in young children who have undergone undiversion or continence surgery. In the follow-up so far available, these procedures do not seem to affect renal function. When function has improved after such surgery it is likely to be the result of eliminating obstruction or high bladder storage pressure. In rats with near complete nephrectomy the rate of progression of renal failure is no worse in those with ileocystoplasty compared to those with normal bladder (242). This suggests, experimentally, that storage of urine in small intestine is not, on its own, harmful to renal function.

Clinically, in the longer term, renal deterioration has been related to obstruction, reflux and stone formation. In one long-term study of Kock pouch patients, these complications occurred at the same rate as that found in patients with ileal conduits: 29% at five to 11 years (243). Similarly, in a prospective follow-up to a minimum of 10 years, it was found that the deterioration in glomerular filtration rate (GFR), that was found in 10 of 53 patients, was due to a ‘surgical’ cause in all but one (244).

Although a more complicated procedure, a renal transplant can be anastomosed to an intestinal reservoir with similar long term results as those using an ileal conduit (245,246).

5.6. Infections and stones

The incidence of bladder reservoir stones varies between 12 and 25%. This is higher in children compared to adults. Palmer et al reported an incidence of 52.5% during a follow-up of four years (247). Renal stones are uncommon, occurring in about 1.6% of patients, an incidence which would be expected in a group with congenital urinary tract anomalies.

In a series comparing the Kock pouch with the Indiana pouch (which does not have staples), 43.1% of 72 Kock reservoirs formed stones compared to 12.9% of 54 Indiana reservoirs (248). Furthermore, no patient with an Indiana pouch formed a stone after 4 years, but patients with Kock pouches continued to do so at a steady rate up to eight years.

Apart from the presence of a foreign body, several factors have been blamed for the high stone risk. Almost all reservoir stones are triple phosphate on analysis, though Terai et al found carbonate apatite, urate and calcium oxalate in up to 50% of stones from patients with an Indiana pouch (249). This suggests that infection rendering the urine alkaline is a key factor. Micro-organisms that produce urease and split urea to form ammonia are the main culprits. The incidence of infection in reservoirs is high, 95% in one series, and yet the majority of patients do not form stones, suggesting that there are predisposing factors other than infection and the anatomical abnormality of the urine reservoirs (250). It has been suggested that the immobility associated with spina bifida may be responsible, but this seems to have been in series with a predominance of such patients and was not confirmed in other studies (251). In intestinal augmentation, mucus formation is especially troublesome as it tends to block catheters and requires regular irrigation, and may predispose to stone formation. The finding of a spectrum of stone formation from mucus, through calcification to frank stone lends some support to this aetiology. However, it could be a secondary event, with mucus becoming adherent to a stone that has already formed. Many surgeons encourage patients to wash out their reservoirs vigorously with water two or three times a week. There seem to be fewer stones in those that claim to practice regular washing. In a prospective study a regime of weekly washouts did not improve the incidence of stones in 30 children compared to historical controls (252). Mathoera et al found an incidence of 16% during a follow-up of 4.9 years in 90 patients: girls were more frequently affected than boys and concomitant bladder neck reconstruction, recurrent infections and difficulties with CIC were other risk factors identified, while the frequency of irrigation did not appear to be a risk factor (253).
Mucins are an important component of the epithelial barrier and protect the epithelium from mechanical and chemical erosion. Mucins are known to act as important adhesion molecules for bacteria. Mucins may also enhance the formation of crystals (254). Mucin expression changes after incorporating the intestinal segment in the bladder. Upregulation of MUC1 and MUC4 expression occurs in transposed ileal segments resembling normal epithelium, whereas ileal segments in enterocystoplasty showed an upregulation of MUC2,3,4 and 5AC expression towards the site of anastomosis with the ileal segment. These changes which may be due to exposure to urine coincide with a change from ileal sialomucins to colonic sulfomucins by a change in glycosylation. The mucins bind calcium and may form a template resembling the crystal structure on which crystals are formed and grow. From these studies, it is concluded that inhibition of bacterial adhesion (by using different irrigation fluids based on sugars) could be of eminent importance in the prevention of certain types of infection stones. An interesting comparison has been made between children with a native bladder alone and those with an augmentation, all of whom were emptying by self-catheterisation. There was no significant difference in the incidence of stones with or without an augmentation (255).

Stones are associated with inadequate drainage in the sense that CIC through the urethra, the most dependent possible drainage, has the lowest stone rate. Patients with the most ‘uphill’ drainage, that is with a Mitrofanoff channel entering the upper part of an orthotopic reservoir have a higher incidence of stones (254). Kronner et al made the observation, that the incidence of stones was statistically associated with abdominal wall stomas and a bladder outlet tightening procedure (21.1% compared to 6% in patients with augmentation alone) (250). Once a bladder stone has been diagnosed it has to be removed: several methods are available, but ESWL should be avoided as it is difficult to remove all fragments (and small particles may get trapped in mucus and the pouch wall), which may form the focus of a new calculus. Because of the recurrent nature of these stones the least invasive method should be recommended (256,257). Because of the high incidence of stones following enterocystoplasty several measures should be recommended to the patients and their parents. Regular CIC under hygienic circumstances with adequate fluid intake and irrigation seem to be the most important (258). It is unclear whether prophylactic antibiotics are useful, but a clinical infection should be treated adequately. Maybe in the future different types of irrigation fluid may prove helpful.

5.7. Growth

The suggestion that enterocystoplasty delayed growth in height seems to have been ill founded. In a group of 60 children reported in 1992 it was stated that 20% had delayed growth (259). Current follow up of the same group has shown that all have caught up and achieved their final predicted height. Furthermore, measurements in a group of 123 children from the same unit have shown no significant delay in linear growth (260). Enterocystoplasty may have an effect on bone metabolism even if growth is not impaired. At least in rats with enterocystoplasty there is significant loss of bone mineral density especially in the cortical compartment where there is endosteal resorption. These changes are not associated with HCA and are lessened by continuous antibiotic administration (261,262). More recent follow-up data shows either no effect on growth or a decreased linear growth (263-266).

5.8. Pregnancy

When reconstructing girls it is essential to have a future pregnancy in mind. The reservoir and pedicles should be fixed on one side to allow enlargement of the uterus on the other. Pregnancy may be complicated and requires the joint care of obstetrician and urologist (267). Problems include upper tract obstruction and changes in continence as the uterus enlarges. Pregnancy with an orthotopic reconstruction appears to have a good outcome but chronic urinary infection is almost inevitable and occasionally an indwelling catheter is needed in the third trimester (268). With a suprapubic diversion, catheter drainage for incontinence or retention may be needed in the third trimester (269). Except in patients with an artificial urethral sphincter and extensive bladder outlet reconstruction, vaginal delivery is usual and caesarean section should generally be reserved for purely obstetric indications (distorted pelvis in spina bifida patients). During the delivery, the bladder reservoir should be empty and an artificial sphincter deactivated. The urologist should be present during Caesarean section to ensure protection for the reservoir, the continent channel and its pedicles.

5.9. Malignancy

The risk of malignancy in enteric augmentations has been reported to be higher than expected, and the risk increases with length of follow-up. Malignancy occurs in 0.6-2.8% of patients during median follow-up of 13-21 years. In a study including 153 patients with a median follow-up time of 28 years, malignancy was found in 4.5% (270). Animal data suggest that faecal and urinary streams must be mixed in bowel for neoplasia to occur. However, if it is chronic mixed bacterial infection, rather than the faeces per se, then all bowel urinary reservoirs are at risk. The malignancy seemed to be associated with coexisting carcinogenic stimuli or with the inherent risk present with bladder extrophy. In patients with colonic and ileal cystoplasties high levels of nitrosamines have been found in the urine of most of the patients examined (271). Clinically significant levels probably only occur in chronically infected reservoirs (272). Biopsies of the ileal and colonic segments showed changes like those that have been found in ileal and colonic conduits and in ureterosigmoidostomies. More severe
histological changes and higher levels of nitrosamines correlated with heavy mixed bacterial growth on urine culture (273). In a review by Filmer et al, 14 cases of pouch neoplasm were identified (274). Special features could be found in nearly all the cases. Ten patients had been reconstructed for tuberculosis; four tumours were not adenocarcinomas; one patient had a pre-existing carcinoma; six patients were over 50 years old. Cancer was found in bowel reservoirs at a mean of 18 years from formation. This is a few years earlier than the mean time at which malignant neoplasms are seen in ureterosigmoidostomies. In a review of 260 patients with a follow-up of more than 10 years, Soergel et al found 3 malignancies (all transitional cell carcinoma): 2 following ileocecral and 1 after caecal augmentation. The age at augmentation was 8, 20 and 24 years respectively: the tumours were found when they were 29, 37 and 44 years old. All had metastatic disease and died. The incidence of malignancy in this group was 1.2%: considering that the development of tumours usually takes 20-25 years the probable incidence of malignancy following enterocystoplasty may be as high as 3.8 % (275). Husssmann et al studied a group of 153 patients with a mean follow-up of 27 years (10-52 yrs,) after augmentation cystoplasty. In those with a neurogenic bladder (n=97) they found 2 patients with transitional cell carcinoma (both smokers), in 38 patients with bladder exstrophy 3 multifocal adenocarcinomas in the augmented segment were found and in 2 of 18 patients with urethral valves an adenocarcinoma was discovered. The overall risk of cancer was 4.5% after a median period of 32 years. Of the 7 patients 5 died suggesting that these tumours are very aggressive and metastasised early (270). This level of carcinogenesis was also confirmed by Sung (276).

Patients who undergo bladder augmentation with a gastric remnant are at increased risk for malignancy, probably similar to that in patients with enterocystoplasty. In a review of 119 patients underwent augmentation cystoplasty with stomach in 2 institutions, three patients had gastric adenocarcinoma, while the other had poorly differentiated transitional cell carcinoma. Each case progressed to malignancy more than 10 years after augmentation (277-279). It has also been shown that patients with neurogenic bladder managed solely with clean intermittent catheterisation have an increased risk of bladder cancer, and this risk may be increased following bladder augmentation (280). If cancer is going to be a common problem, there will be some difficulty in monitoring the patients at risk (281). Endoscopy with a small instrument through a stoma may not be sufficient. Ultrasound may not be able to distinguish between tumours and folds of mucosa. Three-dimensional reconstruction of computerised tomography may be helpful, though the equipment is expensive and not widely available at present (282). Although many advise to perform an annual endoscopic evaluation in all patients following enterocystoplasty starting 10 years after surgery, some argue that yearly endoscopy is not cost-effective and the potential morbidity makes it an ineffective screening procedure (283).

5.10. Psychological consequences and quality of life

The main justification for performing a bladder reconstruction or continent diversion is to improve the individual’s Quality of Life (QoL). It would seem logical that continent urinary diversion would be better than a bag. This is not always the case. In adults, the only sure advantage is cosmetic. Validated QoL surveys in children have not been reported, primarily because of the lack of suitable instruments (284). Our prejudice is that reconstruction does, indeed, improve the lives of children although supporting evidence is very thin and based on experience in adults.

The ileal conduit has been a standard part of urological surgery for over 50 years. It has well known complications but few would seriously suggest that they were more troublesome than those of the complex operations for bladder replacement. In an early investigation into quality of life issues, Boyd et al investigated 200 patients, half with an ileal conduit and half with a Kock pouch: there was little difference between the groups except that those with a Kock pouch engaged in more physical and sexual contact. The only patients that were consistently ‘happier’ were those who had had a conduit and subsequently were converted to a Kock pouch (285).

In a recent QoL survey in adults, a wide range of complications were considered to be acceptable, although an ordinary urological clinic would be full of patients trying to get rid of such symptoms: mild incontinence (50%), nocturia (37%), bladder stones (12%), urinary infections (9%), hydronephrosis (5%). Nonetheless, their QOL was judged to be good, primarily because 70% had experienced no adverse effect on their normal daily lives (286).

Quality of life does not mean absence of disease or a level of complications acceptable to the reviewing clinician. It is a difficult concept to measure because lack of validated instruments, difficulties in translating from one culture or language to another, and the difficulties in selecting control groups and variations in clinical situations. Gerharz et al have constructed their own 102 item instrument and compared 61 patients with a continent diversion and 131 with an ileal conduit. Patients with a continent diversion did better in all stoma related items indicating that containment of urine within the body and voluntary emptying is of major importance. In addition, they had better physical strength, mental capacity, social competence and used their leisure time more actively. There was little difference in satisfaction with professional life, financial circumstances and in all interactions within the family including sexual activity (287).
Forms of urinary incontinence in children are diverse, however, a detailed history, physical examination and voiding diary obviate the need for further studies for the majority. This should identify that limited group that may require surgery. Many patients in this group will have obvious severe congenital abnormalities.

Because of the spectrum of problems, specific treatment is usually dictated by the expertise and training of the treating physician. The rarity of many of these problems precludes the likelihood of any surgeon having expertise in all areas. Furthermore, nuances in surgical procedures develop gradually and are often never systematically evaluated.

Nevertheless, it may be that newer forms of very early aggressive surgical approaches to severe complex anomalies such as extrophy, myelodysplasia and urethral valves may provide a successful model for significant impact on the ultimate continence in such patients. Ultimately these may provide a basis for randomised studies to determine the most specific and effective mode of therapy.

The committee would encourage vigorous research on the molecular basis of bladder development and support the development of surgical and treatment strategies which would utilise the natural ability of the bladder to transform in the early months of development and immediately after birth.

Furthermore, efforts to promote bladder healing, and to protect and achieve normal bladder function should be supported. Such studies and research may lead to earlier and more aggressive treatment of many of the complex anomalies now treated by the surgical procedures outlined in this report.

Comorbidity denotes the co-occurrence of two or more disorders at the same time (concurrent comorbidity) or in sequence (sequential comorbidity). The relevance of psychological factors for the different subtypes of incontinence will be considered. The terminology of the ICCS for enuresis and urinary incontinence as well as of the Rome-IV classification for faecal incontinence will be used (8,9).

2. CLINICAL BEHAVIOURAL DISORDERS

Worldwide, approximately 10 to 20% of children are affected by clinically relevant mental health disorder according to ICD-10 (10) or DSM-5 (11) criteria (12). Even under most conservative estimates, 15% of children and adolescents have psychological disturbances with daily incapacitation. But are these disorders increasing? Bor et al. tackled this question in their very carefully conducted review and found that for toddlers and children, there was no major increase of psychological disorders (13). However, adolescents show an increasing risk for internalising disorders such as anxiety and depression, especially girls. The rate of comorbid behavioural disorders is increased in children with all types of incontinence. Comorbidity denotes the co-occurrence of two or more disorders at the same time (concurrent comorbidity) or in sequence (sequential comorbidity). The focus on comorbidity allows a descriptive approach without referring to possible causal associations. Basically, four combinations are possible:

- A behavioural disorder can be a consequence of the wetting problem,
- A behavioural disorder can precede and induce a relapse when a genetic disposition for enuresis is present, for example in secondary nocturnal enuresis,
- Wetting and a behavioural disorder can both be due to a common neurobiological dysfunction (such as in nocturnal enuresis and ADHD),
- With such common disorders, no causal relationship can be present and the two may co-exist by chance.

A psychological disorder (synonyms: psychiatric, psychologic, mental disorder) “is a syndrome characterised by clinically significant disturbance in an individual’s cognition, emotion regulation, or behaviour that reflects a dysfunction in the psychological, biological, or developmental processes underlying mental functioning. Mental disorders are usually associated with significant distress or disability in social, occupational, or other important activities” (DSM-5) (11).

Clinically relevant disorders can be assessed by two basic methods: the categorical and the dimensional approach. The categorical method is based on a detailed diagnostic process (including history, observation, exploration, mental state examination, questionnaires, testing, physical examination and other procedures) and are professional diagnoses according to standardised classification schemes: ICD-10 (10) or DSM-5 (11). Dimensional assessment is based on symptom scores by questionnaires, but do not represent diagnoses. Cut-offs are defined to delineate a clinical (and sub-clinical) range.

One can differentiate three broad categories:

1. Externalising or behavioural disorders with outwardly-directed, visible behaviour (examples: conduct disorders and ADHD),
2. Internalising, i.e. inwardly-directed, intrapsychic disorders such as emotional disorders (examples: separation anxiety, social anxiety, phobias, sibling rivalry and depressive disorders),
3. Other disorders that do not fit into the two categories, such as anorexia nervosa, tic disorders and autism spectrum disorders.

Five of the most important disorders occurring in children and adolescents with NE, DUI and FI are summarised below:

- **Major depression** has a prevalence of 2-5%. The aetiology is multifactorial with a 40-50% contribution of genetic factors. Symptoms include sadness, unhappiness, loss of enjoyment, lack of energy and interest, negative thinking, sleep and appetite problems. Treatment includes counselling, cognitive-behavioural, interpersonal and psychodynamic psychotherapy which can be combined with antidepressant medication. A population-based study of 2079 6-year old children has shown that depressive and anxious symptoms are more common in children with NE and DUI, and especially high in FI (14).

- **Anxiety disorders** affect 5% of children. Again, aetiology is multifactorial, including family, temperament and to 40% genetic factors. Four subtypes predominate: separation anxiety disorder, characterised by fears associated with separation; generalised anxiety disorder with the main symptom of worrying; in social phobia avoidance of social situations is typical and in
phobia a fear of objects. Treatment consists of counselling, cognitive-behavioural therapy, relaxation, exposure and skills-based techniques, psychodynamic psychotherapy and medication in severe cases (antidepressants). Studies on anxiety in children with incontinence are still rare; exceptions are the study by Equit et al. (14).

Attention-deficit/hyperactivity disorder (ADHD) has a prevalence of 6% and a predominantly genetic aetiology (70-80%). The main symptoms are inattention, hyperactivity and impulsivity. Treatment includes counselling, parent training and cognitive-behavioural therapy. Medication plays a major role (mainly stimulants). In one population-based study of 1391 6-year old children, children with DUI had the highest rates of ADHD (15). Many studies have been conducted on the associations of ADHD and incontinence, which have been summarised in the systematic review of von Gontard and Equit (5).

Oppositional Defiant Disorder (ODD) is characterised by persistent hostile, provocative and noncompliant behaviour and affects 2-5% of children. The aetiology is best explained by a gene-environment interaction, including a genetic disposition and dysfunctional parenting practices. Treatment consists of counselling, parent training, cognitive-behavioural therapy, school-based interventions, but usually not medication. One population-based study on 718 6-year-old children showed a high rate of ODD, especially in children with DUI (16); and another study of 1676 6-year old children, especially those with FI were affected by ODD, ADHD or both (17).

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder, defined by persistent deficits in social communication and social interaction and restricted, repetitive patterns of behaviour, interests and activities (DSM-5) (11). These disorders are present from the early developmental period, cause clinically significant impairment and are associated with intellectual and language impairment, other disorders. The prevalence of ASD is 0.6-1%. The aetiology is mainly genetic, with up to 90% of the variance being due to genetic factors. 15% of ASD are syndromal forms, with the Fragile-X Syndrome, Tuberous Sclerosis being the most important syndromes. The diagnosis is based on a full child psychiatric, paediatric and genetic assessment. Treatment consists of parent training and counselling, autism-specific training programmes and behavioural therapy. Medication includes neuroleptics, stimulants, antidepressants (SSRI), which are not given routinely, but only when indicated. In a recent systematic review, the associations of ASD and incontinence were summarised, as well as the many open research questions (18).

3. CLINICAL BEHAVIOURAL DISORDERS IN CHILDREN WITH NOCTURNAL ENURESIS AND DAYTIME URINARY INCONTINENCE

Children with urinary incontinence show a higher rate of comorbid behavioural and emotional problems (16.5% to 51.9%) than non-wetting children (7.8% to 10.2%), in both epidemiological and in clinical studies. The overall relative risk is 1.4 – 4.5 times higher, based on early population-based studies (7). Epidemiological studies have the advantage of revealing representative associations. They often cannot differentiate well between subgroups. To date, the largest and best population-based studies are those of Joinson et al., based on the British ALSPAC birth cohort (19, 20, 21) (see table 2).

</table>
The only epidemiological study addressing monosymptomatic nocturnal enuresis included 8242 children aged 7 ½ years (25). Though not adhering to the ICCS criteria, children with monosymptomatic nocturnal enuresis showed fewer behavioural symptoms than those with daytime problems (i.e. the non-monosymptomatic forms), although the differences did not reach significance.

Regarding the types of behavioural and emotional disorders, externalising disorders such as ADHD and ODD predominate (5, 15,16,17, 26).

In a retrospective study of patients with ADHD, 20.9% wetted at night and 6.5% during the day. The odds-ratios were 2.7 and 4.5 times higher, respectively, which means that there is a nonspecific association of ADHD and both night and daytime wetting (27).

25% of 140 children with ADHD were affected by nocturnal enuresis compared to 10.8% of 120 controls (28). The highest comorbidity rates of 40% for ADHD and nocturnal enuresis were reported by Baeyens et al. (29), possibly due to selection bias: 15% had a combined, 22.5% an inattentive and only 2.5% a hyperactive type of ADHD. In a community based sample, the prevalence rate was much lower. ADHD continued to be present in 72.5% of children in a two-year follow-up indicating a high stability (37). Children with ADHD continued to wet at follow-up much more often (65%) than children without ADHD (37%): (Odds-ratio 3.17). At a 4-year follow-up, 64% still had ADHD: of these, 42% continued to wet at night (compared to 37% of the controls) (30).

In clinical practice, children with ADHD are more difficult to treat. In a retrospective study, 113 children with ADHD and nocturnal enuresis had a worse outcome on alarm treatment than controls (with nocturnal enuresis only): 43% (vs. 69%) were dry at 6 months and 19% (vs. 66%) at 12 months. There was no difference if they were treated with medication, which does not require active cooperation. Non-compliance was reported in 38% of children with ADHD, but only in 22% of the controls (31). This means that
children with both enuresis and ADHD require special attention – and both need to be treated separately.

3.2. Daytime urinary incontinence

Daytime wetting has been neglected in epidemiological research. The most important study is based on a cohort of 8213 children aged 7 ½ to 9 years (20). Children with daytime wetting had significantly increased rates of psychological problems, especially separation anxiety (11.4%), attention deficit (24.8%), oppositional behaviour (10.9%) and conduct problems (11.8%). Externalising disorders predominate in daytime wetting children, which, in turn, will interfere with treatment. In the same cohort, 10,000 children aged 4 to 9 years were analysed. Delayed development, difficult temperament and maternal depression/anxiety were associated with daytime wetting and soiling (32). In another population-based study, 36.7% of children with urinary incontinence had ADHD symptoms, in comparison to 3.4% of dry children (15).

ADHD is a common problem among day wetting children, as well. Compared to controls, children with ADHD had more symptoms of incontinence, constipation, infrequent voiding and dysuria (33). With ADHD, treatment outcome is worse. In a retrospective analysis, 68% of day wetting children with ADHD became dry compared to 91% of controls. Non-compliance was much higher for timed voiding (31).

Daytime wetting is a heterogeneous group of disorders. According to the ICCS terminology, following subgroups can be differentiated (8):

- Over-active bladder including urgency incontinence
- Voiding postponement
- Underactive detrusor
- Dysfunctional voiding
- Obstructive voiding
- Stress urinary incontinence
- Vaginal reflux
- Giggle incontinence
- Extraordinary daytime urinary frequency

Only some of these subgroups have been studied regarding comorbid psychological disorders.

Children with urgency incontinence have fewer behavioural problems than those with other types of DUI. 29% of children with urgency incontinence had an ICD-10 diagnosis and 14% had an internalising disorder. 13.5% had a clinical total problem score in the CBCL, again mainly internalising problems (34,35). The children are distressed by their wetting and family functioning is intact. In another study, 35% of children with urgency incontinence fulfilled the criteria for an ICD-10 diagnosis (36). Children with urgency incontinence have lower rates of comorbid disorders than those with voiding postponement (36% vs. 59%), but higher than controls (9%). Children with urgency incontinence predominantly have emotional, introverted disorders. In summary, children with urgency incontinence have only a slightly increased rate of comorbid psychiatric disorders. If they are affected, emotional, introverted symptoms predominate.

Children with voiding postponement, on the other hand, fall into two groups: in some it represents an acquired habit, in others, it is associated with externalising psychological disorders, especially oppositional defiant disorder (ODD). In a systematic study of children with voiding postponement in a paediatric and child psychiatric setting, 53.8% fulfilled the criteria for at least one ICD-10 diagnosis (34). These were mainly externalising disorders in a third children such as Oppositional Defiant Disorder (ODD). Also, 37.3% of children had a CBCL total score in the clinical range, again, with externalising symptoms predominating. In addition, family functioning was impaired (34,35). In another sample, 53% of children with voiding postponement had at least one ICD-10 diagnosis (37). In summary, children with voiding postponement have highly increased psychiatric risks. Voiding postponement as one of the most important subgroups of DUI was the topic of a recent review (38).

Studies on comorbid behavioural problems in children with underactive bladder have not been performed. Systematic investigations of psychological aspects of dysfunctional voiding are rare. In some children, it represents an acquired habit, in others severe psychological disturbances are present (39). Dysfunctional voiding following severe sexual abuse and deprivation as well as other familial stressors such as migration has been described in case reports (40). There have been no systematic investigations of children with giggle incontinence. From clinical experience, they are highly distressed by the symptom and try to avoid situations in which they might be forced to laugh. Social withdrawal, not going to parties and meeting with friends has been observed. It is not known if the rate of behavioural disorders is increased. Regarding the other subtypes of urinary incontinence, not even anecdotal data are available.

4. CLINICAL BEHAVIOURAL DISORDERS IN CHILDREN WITH FAECAL INCONTINENCE

According to the Rome-IV classification, two subtypes of faecal incontinence can be differentiated (9):

- Functional constipation (with or without incontinence)
- Non-retentive faecal incontinence.
4.1. Epidemiological Studies

In the large ALSPAC study of 8242 children aged 7-8 years, children with faecal incontinence had significantly increased rates of separation anxiety, specific phobias, generalised anxiety, ADHD and ODD (see table 2) (21). In other words, soiling children show a completely heterogeneous pattern of both internalising and externalising disorders. Again, these will require assessment in the individual child, as they will interfere with treatment of the incontinence.

In clinical studies, 35% to 50% of all children with faecal incontinence had a total behavioural score in the clinical range in this parental questionnaire. Compared to the normative population (10%), 3.5 to 5 times more children with faecal incontinence have total behaviour scores in the clinical range (7). Children with behavioural maladjustment are less compliant than children without psychological disorders (71% vs. 38% non-compliant) – so if these behavioural problems are not addressed treatment will be less successful (41).

Children with faecal incontinence and constipation have the same rate of behavioural scores in the clinical range as children without constipation (39% vs. 44%, (42) and 37% vs. 39%, (43)). This means that the two major types of faecal incontinence cannot be differentiated according to the behavioural comorbidity. More importantly, regarding the aetiology, there is no evidence that one type (i.e. with constipation) has more somatic aetiology, while the other type (i.e. without constipation) has a more psychogenic aetiology. There is no specific psychopathology typical for faecal incontinence: all types of behavioural and emotional disorders can co-exist.

4.2. Subclinical signs and symptoms

Subclinical behavioural signs and symptoms are common, understandable, adequate reactions towards the wetting problem and not disorders. Many studies have addressed the impact of wetting on children.

a) Impact on children

Most children are distressed by enuresis. For example, 35% said that they felt unhappy, 25% even very unhappy about wetting at night in one study (40 children aged 5-15 years) (44). In a Finnish population-based study, 156 day and night wetting children (from 3375 7-year olds) showed significant differences compared to 170 controls regarding following personality traits (45): they were more fitful (vs. peaceful), more fearful (vs. courageous), more impatient (vs. calm), more anxious (vs. does not worry) and had more inferiority feelings (vs. feels equal). In a large population-based British study of 8209 children aged 9 years, 36.7% of children consider bed-wetting to be “really difficult” – ranking 8th behind other stressful life-events (46).

One construct of special importance is that of self-esteem. In one study, lower self-esteem in children with enuresis disappeared upon attaining dryness (47). In another, global self-esteem was significantly lower in children with nocturnal enuresis than in controls (48) and in yet another, the self-esteem total score was higher among enuretics than norms (49). Therefore, it was concluded that there is no clear evidence that bedwetting leads to lower self-esteem (50) – but there can be no doubt that self-esteem can improve upon attaining dryness (49). Self-esteem increases even if treatment of enuresis is not successful (51), showing that care and “good doctoring” for children and parents is of great help – regardless of outcome. Recently, a focus has been on quality of life, which is reduced in children with urinary incontinence (52). Questionnaires to assess quality of life will be presented later.

Children with faecal incontinence tend to feel less in control of positive life events and had a lower sense of self-esteem than children with other chronic conditions (53). However, in a more recent study, self-esteem did not differ between children with faecal incontinence and controls (54).

b) Impact on parents

Enuresis and urinary incontinence may be just as distressing for parents as for children. Generally, parents are very concerned about the welfare of their child. In a population based study, 17% worried a great deal and 46% some or a little (55). In one study, the greatest maternal concerns were: emotional impact, social relationships, smell, extra washing and financial aspects (56). Mothers of children with nocturnal enuresis had a reduced quality of life scores (bodily pain and emotional role) and more depressive symptoms (57).

Parents also believe that their child should be dry at a very early age, which can induce anxiety and stress: the mean anticipated age of dryness was 3.18 years in one study (58) and 2.75 years in another (59). Also, many parents think that emotional factors are the cause of nocturnal enuresis and forget that they might be the effect of the wetting problem instead (58,59).

A minority of parents show an attitude that was described as “maternal intolerance” by Butler et al (60). Convinced that their child is wetting on purpose, the risk for punishment is increased. In some cultures, punishment is very more common: 42% of Turkish children were spanked and 13% beaten (61). Chinese parents show a high level of parenting stress associated with externalising behavioural problems or their child (62). These parental attributions and experiences must be considered in all treatment plans for enuresis, as they can decisively influence the outcome.

Parents of children with faecal incontinence are also stressed and worried about the problem (63). In one study, children with faecal incontinence had family environments with less expressiveness and poorer organisation than controls (54). In another study of 104 families, nearly half (51%) had no unusual family
problems; 23 had severe and widespread difficulties including sexual abuse; 11 families described moderate difficulties and 18 a single traumatic event (64). In other words, the atmosphere was warm and supportive without major difficulties in at least half of the families.

5. CHILDREN WITH SPECIAL NEEDS

Special needs is an umbrella term referring to individuals who require additional medical, psychiatric, psychological and educational assistance (6). Those with special needs comprise heterogeneous groups of physical and intellectual disability, as well as a wide variety of neurodevelopmental disorders. These disorders and disabilities continue to affect adults, i.e. they are life-long conditions. Incontinence is major, but often neglected disorder in people with special needs.

Studies have shown repeatedly that all types of incontinence are more common in children with special needs than in normally developing children, i.e. nocturnal enuresis (NE), daytime urinary incontinence (DUI) and faecal incontinence (FI). Also, incontinence has a higher likelihood of persisting into adolescence and adulthood, i.e. becoming a chronic condition. Incontinence can have an additive negative effect on the emotional state, self-esteem and quality of life of the child with special needs – and can affect his/her own daily school and family functioning.

Many children with intellectual disability have special needs. Intellectual disability (ID) is defined by an IQ < 70. Mild ID (IQ 50-69) and severe ID (IQ < 50) are the two broad categories. Many different syndromes and disorders are associated with ID, most with prenatal, genetic causes. Overall, incontinence is more common in children, adolescent and young adults with ID (65). Also, there is an inverse relationship between IQ and incontinence, i.e. the lower the IQ is, the more often incontinence occurs.

Incontinence has been studied only in some of the specific syndromes of ID, such as Fragile-X, Williams, Down and Angelman syndromes (66-69). In addition to the IQ-level, syndrome-specific risk factors for incontinence have been identified, such as epilepsy in Angelman syndrome and behavioural factors in other syndromes.

As many children with special needs do not receive standard assessment and adequate treatment. Professionals working with children with special needs should realise that incontinence is a major and common problem in their patients and should actively offer effective treatment based of incontinence, the underlying condition and associated, comorbid disorders. Daily distress will be reduced for patients, as well as parents and caregivers.

6. GENERAL PRINCIPLES: ASSESSMENT

6.1. Screening Questionnaires

Due to the high rate of comorbid behavioural disorders, the ICCS recommends screening with a broad-band, validated questionnaire (7,8). Broad-band means that a wide range of psychological symptoms are assessed. Narrow-band questionnaires are less useful as screening instruments, but are valuable in the diagnosis of specific disorders. Narrow-band questionnaires include those for depression, anxiety, ADHD, obsessive-compulsive behaviour, tics and autism spectrum disorders. If a manifest psychological disorder is suspected by history, clinical observation, exploration and broad-band questionnaires, a child psychological or psychiatric assessment is recommended. Short, medium and long screening questionnaires are available.

a) Short broad-band screening questionnaires

The ‘Parental Questionnaire – Enuresis/Urinary Incontinence (PQ-EnU)’, a parental questionnaire which has been used widely in clinical care and research, has recently been validated (3, 70). It contains yes/no questions regarding nocturnal enuresis (NE) (12 items), daytime urinary incontinence (DUI) (10 items), voiding and stool habits (19 items), as well as behavioural problems (10 items). In the validation sample of 496 patients, a high correlation of .723 to .778 with diagnoses of incontinence (NE, DUI and faecal incontinence -FI) could be demonstrated. A factor analysis of the Behavioural Problem Scale (BP) revealed three factors: “attention and school deficits” (Cronbach’s α = .665), “impulsive-aggressive behaviour” (Cronbach’s α = .731) and “internalising problems” (Cronbach’s α = .409). These factors showed significant correlations with Child Behaviour Checklist (CBCL – see below) total, internalising and externalising scales (.351 to .608). In summary, the PQ-EnU is a valid questionnaire to examine children with incontinence and can be used as a screening for psychological symptoms. It can be downloaded without charge (3).

The ‘Short Screening Instrument for Psychological Problems in Enuresis (SSIPPE)’ is a comparable instrument available in appendix of Van Hoecke et al. (71). It is a validated parental questionnaire, based on the Child Behaviour Checklist (CBCL) (72). It has three scales including 7 items for emotional problems, 3 items for attention symptoms and 3 items for hyperactivity/impulsivity symptoms. The authors recommend that if more than two yes answers are given for any of the 3 problem areas (emotional, attention, hyperactivity/impulsivity), this should be followed by a more detailed questionnaire such as the CBCL. If the CBCL T-scores are in clinical range (or many problem items are answered with a “2”), then a detailed child psychiatric assessment should follow.

PSYCHOLOGICAL ASPECTS OF URINARY INCONTINENCE, ENURESIS AND FAECAL INCONTINENCE | 1037
b) **Medium-length broad-band screening questionnaire**

The Strengths and Difficulties Questionnaire (SDQ) is a medium-length behavioural screening questionnaire about 3-17 year olds (73). Parent and teacher versions are available, as well as self-reports for 11-17-year-old children and adolescents. It exists in several versions to meet the needs of researchers, clinicians and educationalists. In addition to the standard version, one version additionally assesses impact and incapacitation, while another version is useful for follow-up. Official translations are available in 77 languages.

All versions of the SDQ ask about 25 attributes, some positive and others negative. The items are scored on a three-point scale: not, somewhat and certainly true. The 25 items are divided between 5 scales: emotional symptoms (5 items), conduct problems (5 items), hyperactivity/inattention (5 items) and peer relationship problems (5 items) – these 4 scales form the total difficulties score. A fifth scale measures prosocial behaviour (5 items).

The Strengths and Difficulties Questionnaires, whether in English or in translation, are copyrighted documents that may not be modified in any way. Paper versions may be downloaded and subsequently photocopied without charge by individuals or non-profit organizations provided they are not making any charge to families. The questionnaires, scoring instructions, norms and related articles can be downloaded free of charge at following website: www.sdqinfo.org

As the name implies, the CBCL/6-18 is a parental questionnaire for the age groups of 6 to 18 years. It consists of a 113 problem items, which are scored on a three-point scale: 0= not true; 1= somewhat or sometimes true; 2= very true or often true. Three composite scales can be calculated (total score, internalizing, externalising behaviour). For these composite scales, the clinical cut-off is at the 90th percentile and the borderline cut-off at the 85th percentile. In addition, 8 other syndrome scales can offer valuable information.

The CBCL is one of many questionnaires within the Achenbach family of instruments: these aim at the pre-schoolers (1 ½ - 5 years), school age children (6-18 years), young adults (18-30 years), adults (18-59 years) and older adults (60-90 years). Self-report, parent and teacher versions exist, so that behaviour can be assessed in different contexts. All Achenbach questionnaires (such as the CBCL), manuals and related materials can be ordered under: www.aseba.org

In the ICCS documents, a general screening for emotional and behavioural problems in all settings (paediatric, urologic, child psychiatric, etc.) with a validated and standardised parental behavioural questionnaire is recommended because of the high rate of comorbid disorders in 30-50% of children (8). This can be done in two steps: using a short screening questionnaire first, flowed by a long questionnaire; or in one step: using a validated, medium of long questionnaires. If many problem items are checked, a child psychological or psychiatric assessment should follow. If comorbid disorders are present, counselling or treatment, if necessary, is recommended (see figure 1).
One construct of special interest in children with incontinence is that of health-related quality of life (HRQOL). In their standardisation document, the ICCS recommends to screen for changes of health-related quality of life (HRQOL) and specifically recommends using the PinQ-questionnaire, which is by far the best condition-specific HRQOL for children with incontinence (8, 74).

Generic HRQOL questionnaires can be useful in research in comparison with healthy controls and with children affected by other chronic medical conditions (75-77). Self-report versions for different age-groups, as well as proxy-report versions exist. The youngest age for self-report is 4 to 6 years, with reliable results available from 8 years onwards. The most commonly used proxy report is by parents, but caregivers, nurses and doctors can fill out these questionnaires, as well. Parental and child appraisal of HRQOL can differ. In research, comparison of child and own parental QoL can be interesting (77,78), but is usually not feasible in clinical practice.

In general, as HRQOL is a multidimensional construct, different aspects are assessed such as physical functioning, psychological well-being, social relationships, everyday life activities, satisfaction, discomfort, etc. These questionnaires can also be useful in monitoring the effects of therapy – in research, as well as in clinical practice. HRQOL questionnaires are not useful in screening for psychological disorders, i.e. the information is not sufficient to decide if a disorder could be present or not.
6.2. Child psychiatric assessment

A child psychiatric assessment is a professional procedure with the goal of coming to a categorical decision: to see if a diagnosis, according to the standardised classification schemes (ICD-10 or DSM-5) is present in the child or not (10,11).

The first step is a detailed developmental, behavioural and family history in much greater detail than provided in the outline in the appendix. The next step is to observe the child as well as the parent-child-interaction, followed by an active exploration of the child. The information gained from history, observation and exploration forms the basis of the mental state examination. This is a descriptive, phenomenological assessment of mental and behavioural signs and symptoms (for example: CASCAP-D) (79).

Questionnaires are always an essential part of child psychiatric assessment. They are a time-efficient way to gather information from different informants. They can contribute towards but do not provide a diagnosis. Behavioural questionnaires can again be divided into general and specific questionnaires. The best known, most widely used general parental questionnaire is the Child Behaviour Check List, which has been translated into many languages (CBCL/6-18)(72). In the meantime, Achenbach and co-workers have produced a whole “family” of questionnaires for different age groups (infants, children – adolescents, young adults) and different informants (parents, teachers and for children themselves starting from age 11). In addition, other specific questionnaires address circumscribed areas such as depressive symptoms or ADHD problems.

An intelligence test is not routinely indicated in the assessment of children with elimination disorders, as the IQ is in the normal range for most children with wetting, as well as soiling problems. However, the rate of elimination disorders is clearly increased in children with general developmental disorders, including those with mental and physical handicap (6). If a lower intelligence is suspected, one-dimensional tests (such as the CFT or CPM/SPM tests) or multidimensional tests such as the Kaufman or the Wechsler tests can be performed. If specific developmental disorders such as dyslexia or dyscalculia are suspected, specific tests for these circumscribed disorders are indicated. Disorders of speech or language (such as articulation, expressive and receptive speech disorders) require a detailed assessment by an audiologist and speech therapist. Motor disorders can be assessed clinically by including soft neurological signs in the physical examination of children.

After the diagnostic process has been completed, the child’s disorder is diagnosed according to standardised classification schemes. The two standard classification systems are the ICD-10 (10), which is widely used in Europe and in other parts of the world and the DSM-5 (11) employed in the United States.

In child psychiatry, a multi-axial classification is used. Six different axes denoting different domains are used, including:

1. Axis: clinical psychiatric diagnosis (such as anorexia nervosa, depressive episodes, etc.)
2. Axis: specific developmental disorders (such as dyslexia)
3. Axis: intelligence (such as dyslexia, speech and motor disorders)
4. Axis: somatic diagnosis (such as epilepsy and other paediatric diagnoses)
5. Axis: psychosocial risks occurring within the last six months (such as distorted intra-familial interaction, isolated family and other stressful life events)
6. Axis: the global severity of a disorder (ranging from mild incapacitation to disorders requiring constant supervision and guidance)

Only after the diagnostic process has been completed and discussed with parents and children, should therapeutic interventions be planned.

6.3. General principles: treatment of psychological disorder

For most children with elimination disorders, a symptom-orientated approach is sufficient. If, however, another, co-occurring child psychiatric disorder is present, additional types of treatment will be necessary. In these cases, a differential indication for therapy is mandatory. The question is: which treatment is most effective for this child in this family at this moment?

For some disorders (such as ADHD), medication plays a major role. For most others, psycho-therapeutic interventions are the first-line treatment. There can be no doubt that psychotherapy in children is effective. In one of the best and largest meta-analysis of 150 studies, Weisz et al. (80) conclude that “psychotherapy with young people produces positive effects of respectable magnitude” (i.e. effect sizes in the medium to large range - 0.5 to 0.8). It has been estimated that over 500 different types of psychotherapies exist in the USA for children and adolescents alone (81). Of those which have been evaluated, four basic schools of psychotherapy can be differentiated:

1. Depth psychology (or psycho-analysis), which addresses and works with unconscious aspects of the psyche;
2. Client- (or child-) centred-psychotherapy, which focuses on the current conscious experience of the child and the healing aspects of their therapeutic relationship;
3. Family therapy, which focuses on the interaction between family members but not the individual person;

Before initiating any psychotherapy, a differential indication for therapy as to be made. The first basic question should be: is treatment needed at all? In many cases counselling of parents and child is all that is required. In other cases, changes in the child’s environment (such as changing school) or help from social services can be more useful than psychological treatment in the narrower sense.

The modality should be considered. Although parents are nearly always included, the focus can be on an individual, group or family therapy. The intensity and duration should be addressed: is a short focal therapy focused on one specific problem needed, or a longer more general treatment? The age of the patient plays an important role: while older children and adolescents can be reached verbally, younger children require play or other non-verbal media in their therapy.

Psychotherapies can be combined with other methods, such as pharmacotherapy, but also by using speech, occupational, physiotherapy, music and other types of therapies – if indicated. The decision should no longer be based on personal inclinations. Instead, empirically based “practice parameters” or “guidelines” have been developed in many countries. These interventions are usually performed on an outpatient basis. Day clinic treatment can be indicated in more severe disorders, which require a more intense approach and management. Finally, in-patient child psychiatric treatment is indicated in severe disorders, in which a more intense type of treatment is possible.

6.4. General principles

a) Urotherapy

A major part of therapy of incontinence in children is non-pharmacological and non-surgical. The term urotherapy is used in some countries. It is an umbrella term which has been defined as a “type of training which makes use of cortical control of the bladder, teaching children to recognise and employ conscious command over their lower urinary tract. Its main ingredients are information about normal lower urinary tract function and the specific dysfunction in the child, instruction about what to do about it and support and encouragement to go through with the training programme (82).

Although not a psychotherapy in a narrow sense, it employs many psycho-therapeutic techniques borrowed especially from counselling and cognitive-behavioural therapies. As these approaches have been shown to be most effective, basic principles and findings shall be outlined.

b) Non-specific approaches

The first step in any diagnostic and therapeutic process is to create a good relationship with both the child and the parent. One should enquire and talk about all relevant facts, signs and symptoms openly. It is also important to ask about the subjective meanings and connotations. Next, the provision of information is essential, because many facts are not known. It is often forgotten that not only parents but each child needs information, as well. This should be provided in words and concepts that a child understands and in a format that is attractive. Increasing motivation and alleviation of stress and guilt feelings are also part of all patient contacts.

c) Counselling

Counselling is already part of the treatment process, which has been defined as the provision of assistance and guidance in resolving personal, social, or psychological difficulties. For many children, even with psychological disorders, counselling is, in fact, sufficient. Sometimes, it can be helpful to enhance the verbal counselling by other techniques. One simple technique is that of “demonstration”, e.g. actively showing how an alarm works. In “coaching”, parents and children take an even more active role, e.g. they set and activate an alarm themselves. They can be observed and corrected. Other techniques might include “modelling” and “role-playing”. The learning effect is much greater in these active forms of teaching than in solely verbal counselling.

d) Cognitive-behavioural therapy

Cognitive-behavioural therapy (CBT) is a subtype of psychotherapy that has shown to be effective for many disorders. Cognitive therapy focuses on irrational, dysfunctional conditions, thoughts and beliefs. Cognitive therapy encompasses a whole variety of techniques such as “self-monitoring” (observation and registration), “activity scheduling” (organisation of activities) and “labelling” (using positive suggestive statements). Behavioural therapy concentrates on observable behaviour, which it aims to modify with a variety of techniques. These include “classical conditioning” and “operant conditioning”, which basically means learning by success, which can be achieved by different strategies using positive or negative reinforcement.

e) Baseline and observation

Baseline and observation are effective techniques used in cognitive-behavioural therapy. Children (and parents) are advised to observe a defined symptom. Different parameters such as frequency (how often it occurs), severity (how marked it is), symptomatology (in what form it occurs) and in which situation (associated factors) can be registered, e.g. in an observation chart. The mere observation and registration has a therapeutic effect and many symptoms diminish if they are simply observed.

In nocturnal enuresis, children are asked to fill out a calendar or chart depicting the wet and the dry nights symbolically for two to four weeks (3). These non-specific measures have been shown to be successful and are associated with fewer wet nights (3). In one clinical trial, for example, 18% became dry after an 8-week baseline (83).
In urgency incontinence, the cognitive aspects are stressed in treatment: children are asked to register feelings of urgency, refrain from using holding manoeuvres, to void and register the voiding (or any wetting) in a chart (3). For children with voiding postpone-ment, timed voiding 7 times a day and registration in a chart is recommended (3,38).

For all children with faecal incontinence, stool regulation is an essential part of treatment. Children are asked to sit on the toilet three times a day after meal-times in a relaxed mode for five to ten minutes (4). This is documented in a chart and can be reinforced positively. If constipation is present and a large amount of faecal mass has accumulated, disimpac-tion has to be performed at the beginning of treat-ment. Oral disimpaction is the preferred method. To avoid re-accumulation of faecal masses, mainte-nance therapy with oral laxatives, such as polyeth-ylene glycol (PEG) is recommended for at least six, and up to twenty-four months (84). The preferred oral lax-atives are osmotic laxatives such as PEG.

f) Biofeedback

Biofeedback has been shown to be effective in some elimination disorders such as dysfunctional voiding (85). It is defined as a variety of techniques, by which physiological activity is registered, enhanced and pre-sented to the patient in real time by visual and acous-tical signals). In faecal incontinence, biofeedback is no more effective than standard behavioural tech-niques in faecal incontinence both with (86) and with-out constipation (87).

g) Alarm treatment

Alarm treatment for nocturnal enuresis is also a type of cognitive behavioural therapy. It works by positive reinforcement, as well as aversive, negative experi-ences and has been shown to be highly effective and was introduced by Mowrer and Mowrer (88).

It is the most effective form of treatment of nocturnal enuresis with the best long-term results (grade I level of evidence according to reviews and meta-anal-yases). Houts et al. (89) compiled a systematic review and meta-analysis on 78 randomised studies on nocturnal enuresis. 62% were dry at the end of treatment and 47% at follow-up. The authors conclude that “urine alarm treatments should not only be consid-ered the treatment of choice, but the evidence from this review suggests that cure rather than manage-ment is a realistic goal for the majority of children suf-fering from nocturnal enuresis”. Therefore, when indi-cated, alarm has been endorsed as a first line cura-tive treatment by various guidelines and by the ICCS (90).

The effect of alarm treatment can be enhanced by adding additional behavioural components to the treatment. Programmes that include alarm in addition to other behavioural components showed following general effects: 72% of children became dry at the end of treatment, and 56% remained so at follow-up (meta-analysis) (89).

These specific programmes including alarm are all essentially cognitive-behavioural techniques. Arousal training is a simply and easily performed (91,92). Chil-dren are instructed to turn off the alarm within three minutes, go to the toilet and reset the alarm. This goal is reinforced positively with two tokens. If the goal is not reached, one token has to be returned. The initial success rate (89 %) and the rate of dryness after 2 ½ years (92 %) were higher than with alarm treatment alone (73 % and 72 % respectively).

Finally, alarm treatment can be combined with phar-macotherapy, although the evidence for combination treatment is conflicting. The combination of desmo-pressin and alarm treatment has been reported in several studies (92,93). The combination with anti-cholinergics plays an important part in clinical prac-tice, but has not been investigated systematically. However, when alarm treatment fails, the ICCS rec-ommends switching to desmopressin alone (90).

6.5. Conclusion and summary

This review summarised the most important psycho-logical aspects in children with enuresis, urinary in-convenience and faecal incontinence.

The rate of comorbid clinical behavioural disorders is increased. Children with DUI are more affected than those with NE. Children with secondary and non-monosymptomatic NE have especially high rates of comorbid psychological disorders. The most common single diagnosis is ADHD, but other disorders such as depression, anxiety disorders and autism spec-trum disorders can exist and must be considered.

Children with DUI have mainly externalising behav-ioural disorders. Children with urgency incontinence have a low comorbidity, those with voiding postpone-ment are characterised by oppositional behaviour. Children with FI have the highest rate of associated disorders – both internalising and externalising.

These disorders will not disappear upon attaining dry-ness. They must be addressed, as they will interfere with the incontinence therapy due to low compliance. Even if comorbid disorders are not present, children and parents are highly stressed by the incontinence. These subclinical symptoms will often recede upon successful treatment. Children with special needs, especially those with ID, have very high rates of in-convenience. Assessment and treatment of inconti-nence should be offered to all affected children.

Questionnaires are useful as screening instruments in the assessment process. It is recommended that questionnaires are used as a general screening pro-cedure for emotional and behavioural problems rou-tinely in all settings. If a psychological disorder is sus-pected, a full child psychiatric assessment and sub-sequent treatment is needed. The basic principles, in-cluding those of psychotherapy, are outlined. Psycho-therapeutic techniques are used in urotherapy, espe-cially cognitive-behavioural elements. Non-pharma-cological and non-surgical techniques are most effec-
tive for most forms of incontinence. Therefore, it is important that psychological aspects are integrated into the treatment of children with incontinence problems.

VIII. URINARY INCONTINENCE IN CHILDREN WITH SPECIAL NEEDS

1. INTRODUCTION

Children with special needs, i.e. intellectually and/or motor disabled, suffer lower urinary tract symptoms (LUTS) than the normal population. Several studies have shown that nocturnal enuresis, daytime urinary incontinence and faecal incontinence are more frequent in children with special needs. Moreover, incontinence has a higher likelihood to persist during adolescence and adulthood. Although LUTS are associated with poor quality of life and health status, they are often less important to parents and physicians who are mainly focusing on physical rehabilitation. Literature on this topic is limited, but illustrates that adequate treatment improves quality of life significantly.

2. CHILDREN WITH SPECIAL NEEDS: GENERAL INFORMATION

2.1. Intellectual disability

Intellectual disability, the former mental retardation, is defined by the American Association on Mental Retardation (AAMR) as a disability characterised by significant limitations both in intellectual functioning and in adaptive behaviour as expressed in conceptual, social and practical adaptive skills. The disability originates before 18 years of age. Limitations in intellectual ability correspond to an IQ less than 70 to 75.

According to DSM-V (Diagnostic and Statistical Manual of Mental Disorders 5th edition. American Psychiatric Association (2013) Washington, DC) intellectual disability involves impairments of general mental abilities that impact adaptive functioning in three domains, or areas. These domains determine how well an individual copes with everyday tasks:

- The conceptual domain includes skills in language, reading, writing, math, reasoning, knowledge, and memory.
- The social domain refers to empathy, social judgement, interpersonal communication skills, the ability to make and retain friendships, and similar capacities.
- The practical domain centres on self-management in areas such as personal care, job responsibilities, money management, recreation, and organizing school and work tasks.

In DSM-V intellectual disability is two standard deviations or more below the population mean, which equals an IQ score of 70.

Severity was defined in the DSM-IV (Diagnostic and Statistical Manual of Mental Disorders 4th edition. American Psychiatric Association (2000) Washington, DC) based on IQ ranges:

- Mild: 50-55 to 70
- Moderate: 35-40 to 50-55
- Severe: 20-25 to 35-40
- Profound: < 20-25

2.2. Motor disability:

Motor disabilities affect a person’s ability to learn motor tasks such as walking, running, skipping, sitting, handwriting and others. To be considered a disability, the problem must cause a person to have motor coordination that is significantly below what would be expected for age, and the problem must interfere with activities of learning and daily living.

Although Intellectual disabilities and motor disabilities can stand on their own, in a considerable number of patients, a combination of both is diagnosed.

Intellectual disability is a common problem. Up to 10% of the school-aged children are learning impaired and as many as 3% of children in the US manifest some degree of mental retardation. The prevalence of mild mental retardation is about 1/77 (1.2%) and that of severe mental retardation is 1/300 (0.33%). For the clear majority of individuals with mental retardation (45-63%) no aetiology is identifiable. More than 800 syndromes are associated with mental retardation, of which Trisomy 21 or Down syndrome is the best known. In addition, environmental factors, such as Foetal Alcohol Syndrome and peri- and postnatal conditions, such as CMV, rubella and hypo-ischemic encephalopathy, may also be responsible for mental retardation.

The second most important cause of developmental disability is cerebral palsy (CP). Cerebral palsy encompasses a group of disorders of the development of movement and posture, causing activity limitation, which are attributed to non-progressive disturbances occurring in the developing fetal or infant brain. [1] Often disturbances of sensation, cognition, communication, perception and/or behaviour, and/or seizure disorders accompany the motor disorders. CP is a non-progressive injury of the brain occurring in the perinatal period and persisting through the lifespan.

The incidence of cerebral palsy is about 1.5 per 1000 births.

Twenty percent of the intellectually disabled individuals suffer cerebral palsy and 50% of the cerebral palsy patients are intellectually disabled.
Von Wendt et al. published that 7-year-old children with mild intellectual disability differ relatively little from healthy children with respect to enuresis, (11.1% versus 9.8%), but suffered significantly more daytime urinary incontinence (16.7%) than the normal population (3.4%). The more severe the intellectual disability the higher the risk of persisting enuresis and daytime urinary incontinence. [2]

In children with CP 55.5% suffer LUTS, of which urinary incontinence is the most frequent with a prevalence rate ranging between 20% and 94%. Urgency and frequency, with a respective prevalence of 38.5% and 22.5%, are also very common in CP patients. Urinary incontinence, urgency and frequency are significantly more common in children with CP compared to a healthy population.

Storage symptoms are more prevalent than voiding symptoms, with a prevalence of hesitancy in children with CP of 16.5%. Urinary tract infections (UTI), with a prevalence rate of 8.5%, are also more common in CP children than in the normal population. [3]

Patients with Down’s syndrome also show an impaired ability to become continent. Several studies have illustrated that children with Down’s syndrome have a delay in toilet training and are more prone to incontinence afterward. One fifth of the children with Down’s syndrome are not toilet trained at the age of five and nearly 50% of the toilet trained children will have incontinence, that even can persist into adulthood. [4]

LUTS are also more common in children with Down’s syndrome, with a prevalence around 27%. The LUTS are more common in male (42.8%) than in female (19.6%) patients. These LUTS decrease with age, and patients with Down’s syndrome older than 10 years have a five times lower chance of LUTS compared to those who are ten years or younger. [5] Kitamura et al. found LUTS to be very common in children with Down’s syndrome, but remarkably neither the children nor their environment seemed to be aware of it. [6]

Von Gontard reviewed the association of nocturnal enuresis, daytime urinary incontinence and faecal incontinence in children with intellectual disability in general and in patients with specific syndromes of intellectual disability including Rett’s, Angelman’s, Fragile-X, Prader Willi, Noonan’s and Williams’ syndrome. He concluded that people with profound intellectual disability have the highest rate of incontinence, whereas syndromes with mild intellectual disability have much lower rates. [7-12]

Not only intellectual capacity, but also the motor capacity is correlated with the development of continence. The more immobile the higher the prevalence of urinary incontinence. Motor disability, especially the degree of mobility, rather than intellectual disability seems to be the dominant factor determining urinary continence. [13]
Kitamura et al. found in their study that a significant lower number of children with Down’s syndrome had a normal bell-shaped uroflow pattern (18%) than age-matched control children (60%). They concluded that the non-bell-shaped uroflow patterns are due to functional and not to anatomical or organic abnormalities [6].

b) Bladder capacity:
Reduced bladder capacity is a major factor in the pathophysiology of urinary incontinence in children with special needs. Several studies illustrated that 73.5% of the CP subjects have a too small bladder capacity compared to the expected bladder capacity for age (EBC). Mean bladder capacity is 58.5% of the EBC [3]. Bladder capacity can be negatively influenced by uninhibited bladder contractions, characteristic for NDO, inadequate fluid intake due to swallowing problems and inadequate hydration [13, 24-27]. Constipation, which can be due to restricted fluid intake, can negatively influence reduced bladder capacity [28].

c) Inadequate fluid intake
Van Laecke et al. found that only 9.9% of the children with a special need included in their study had a normal fluid intake. Although some of these children suffer swallowing problems, the major problem was found to be inadequate drinking. Increasing the fluid intake to a normal level of 1500ml/m² resulted in a significant increase in continence and maximum voided volume [13, 27].

d) Post-void residual
In CP patients, according to the low prevalence of DSD and hesitancy, prevalence of pathologically increased post-void residual is limited [14, 18, 19, 29, 30]. In Down’s syndrome patients post-void residual was demonstrated in 7% [6].

e) Intellectual disability and motor dysfunction.
LUTS are less influenced by intellectual disability than by moderate to severe motor dysfunction [13, 31, 32]. Concerning children with CP, continence is less often achieved in subjects with low intellectual capacity combined with spastic quadriplegia than in subjects with high intellectual capacity combined with hemi- or diplegia [33]. The combination of both intellectual disability and spasticity has a bigger influence than both factors independently. Bross et al. concluded that urinary symptoms and pathological urodynamic findings increase along with the degree of motor function impairment [14].

Involuntary spasticity of the pelvic floor, which may be part of a general spasticity, may cause LUT dysfunction [25, 28]. This can also explain the vulnerability to acquire pelvic floor hyperactivity in reaction to NDO in children with spasticity [14, 23].

In subjects with quadriplegia LUTS and abnormal urodynamic findings are found more often than in patients with diplegia, illustrating that not only lower limb impairment, but also upper limb impairment plays a role in achieving continence [33]. The plasticity of the central nervous system enables the unaffected side to assume more control over the bladder during development. This could explain the lower prevalence of LUTS and disturbed urodynamic findings in children with hemiplegia [32].

Poor mobility is an important factor in achieving continence. Inability to reach the toilet, to get adequate on the toilet and to drink enough will influence both urinary incontinence and constipation. Moderate to severe functional impairment (GMFCS III or higher) and the spastic subtype with quadriplegic distribution will negatively influence the ability to become continent [3].

5. COMORBIDITY

a) Constipation and faecal incontinence
Constipation is an important comorbidity in the process of urinary incontinence in children with special needs. There is a proven correlation between constipation and urinary incontinence, detrusor overactivity, dysfunctional voiding and UTI [34]. Intellectual disabled children are more prone to constipation and faecal incontinence. Up to 70% of these children suffer constipation [35]. Up to 90% of the children with CP suffer constipation and 47% faecal incontinence, though most of them to a minor degree [36].

b) Neuropsychiatric disorders
ADHD and autism are more frequent in intellectually disabled children and there is a proven correlation between ADHD and urinary incontinence [37, 38].

c) Sleep disorders
There is increasingly more evidence that there is a relationship between nocturnal enuresis and sleep disorders in otherwise healthy children [39-41]. Sleep is a complex neurological function. In children with brain damage, the autonomous nervous system, which is involved in pineal melatonin secretion and sleep regulation might be affected [42]. Sleep is also vulnerable to several other factors common in CP. Muscle spasms, decreased ability to change body position during sleep, epilepsy and glossoptosis, which can induce sleep disorder breathing, may be the cause of disturbed sleep in these children [43, 44]. Sleep disorders like delayed insomnia, disrupted sleep, early awake or a combination of these are frequently reported in patients with CP. Newman et al. found that 44% of the patients presented at least one clinically significant sleep disorder. Nearly 50% of the children with CP have some kind of sleep problem. These problems are more reported in non-walkers (72%) than in walkers (36%) [45]. Also in patients with Down’s syndrome sleep disturbances are more common [4].
6. EVALUATION OF THE SPECIAL NEED CHILD SUFFERING LUTS

a) History

History taking in children with special needs is often challenging, and mainly relies on hetero-anamnestic data. Important is that not only parental information but also information from the care givers should be considered, as many of these patients spend a lot of their time in specialised institutions. The questions should include items on nocturnal enuresis, urinary incontinence, lower urinary tract symptoms and bowel function. Attention should also be paid to intellectual and motor development, family disorders, the child’s psychosocial and familial situation, neurological and congenital anomalies, urinary tract infections, relevant medication and surgery. Special emphasis should be given to fluid intake and food habits.

A voiding and drinking diary, and a dry-wet calendar are essential to determine the child’s voiding frequency and voided volumes, to evaluate the number of enuresis and incontinence episodes, to determine the nocturnal diuresis and to evaluate the quantity and quality of fluid intake. The same should be done for stool, registering defaecation frequency, stool consistency and soiling.

b) Physical examination

Theoretically, physical examination should include the assessment of perineal sensation, the perineal reflexes supplied by the sacral segments S1-S4 and anal sphincter tone and control. Practically, as this is confronting for the child, this part of the physical examination is restricted to those where there is a suspicion of neuropathy.

Special attention should be paid to signs of neuropathy such as: spine deformity, abnormal gait, abnormal deep tendon reflexes, asymmetrical atrophy of the feet, high plantar arches, hammer toes, and signs of occult dysraphism, i.e. skin discolouration, dimples, hairy tufts, subcutaneous lipoma, asymmetrical buttock, legs or feet and oblique gluteal cleft [46]. The abdomen should be palpated to assess a full bladder, full sigmoid or descending colon and flank masses. The external genital region must be inspected for vaginosis and vulvitis, meatal web and a hymen that covers nearly the complete vaginal introitus in girls and for penile anomalies and meatal stenosis in boys. In motor disabled children the locomotor system has to be evaluated according to muscle power, mobility, stability and spasticity. Intellectual disabled children are often too anxious to perform a uroflowmetry and motor disabled children are often incapable to perform a non-disturbed micturition because of their instable position on the flow chair. Therefore uroflowmetry, especially in moderate and severe patients, should be preferably performed in their own environment on their personal adapted toilet chair.

c) Laboratory tests

Urine analysis to exclude pyuria, proteinuria, glycosuria, haematuria, calcium and bacteriuria should be done at the first office visit. Urine osmolality and electrolytes should be determined in case of monosymptomatic enuresis with persistent therapy resistant polyuria.

d) Uroflowmetry

Uroflowmetry in children with special needs is often a problem. Intellectual disabled children are often too anxious to perform a uroflowmetry and motor disabled children are often incapable to perform a non-disturbed micturition because of their instable position on the flow chair. Therefore uroflowmetry, especially in moderate and severe patients, should be preferably performed in their own environment on their personal adapted toilet chair.

e) Ultrasound

Ultrasound is used to evaluate the upper and lower urinary tract in children with LUTS especially when they are suffering UTI. It can also be used to measure the post-void residual.

f) (Video-) Urodynamic examination

These urodynamic investigations are invasive, especially in children with special needs who often lack the intellectual capacity to understand what is going to happen, or are physically unable to undergo the examination in a comfortable way. Although some authors are convinced that urodynamics should be performed in the majority of moderate and severe patients to rule out the silent bladder dysfunction or risk factors for UUTD, this examination should be reserved for those patients suffering therapy resistant urinary incontinence and/or recurrent UTI or when obstructive lower urinary tract problems are suspected.

7. TREATMENT OF URINARY INCONTINENCE IN CHILDREN WITH SPECIAL NEEDS

a) Urotherapy

Urotherapy in children with special needs does not differ fundamentally from that used in normally developing children. The aim is also to achieve normalisation of the micturition pattern by a combination of patient education and cognitive, behavioural and physical therapy methods.

The first cornerstone of this therapy is patience. Treating these children will certainly take more efforts and time, but even in severe patients it may lead to an important amelioration or cure of urinary incontinence.

The second is adequate fluid intake. Although often time-consuming, the results are remarkably positive as illustrated in the study of Van Laecke et al. [27]. Fluid intake does not only positively influence maximum voided volume and continence, but also contributes to an important amelioration of constipation.
The third cornerstone of urotherapy is correct toilet position. Adequate relaxation of the pelvic floor can only be achieved when sitting in a stable position. In many children with CP this can only be the case when using a personal adapted toilet chair.

b) Treatment of Bowel Dysfunction

Constipation and faecal incontinence are common comorbidities in children with special needs. LUT dysfunction and bowel dysfunction often occur concomitantly and have been labeled as BBD (Bladder and Bowel Disturbance) by the ICCS [47]. Adequate management of both constipation and faecal incontinence is essential for successful treatment of urinary incontinence in these patients.

Prevention and treatment of milder forms exist of optimisation of food and fluid intake (qualitative and quantitative) and of toilet habits (regular toileting after meals). In case of functional constipation stool masses need to be evacuated with laxatives or enemas. Afterwards laxatives should be continued together with behavioural therapy and dietary interventions for months or even years [48].

c) Alarm treatment

Just like in normally developing children, alarm therapy can be used to treat either nocturnal enuresis or daytime urinary incontinence in children with special needs [49-51]. In the treatment of daytime incontinence, it can be used to achieve active continence, but in some therapy resistant cases it can also be used to achieve passive continence by introducing timed voiding [52]. Again one should be aware of the fact that using an alarm in this population will be more challenging and time consuming.

8. PHARMACOLOGICAL TREATMENT

a) Antimuscarinics

If standard urotherapy fails to achieve urinary continence antimuscarinics are the mainstay of treatment in patients with overactive bladder (OAB). Oxybutynin remains the only FDA approved antimuscarinic for the treatment in children. The major problem with oxybutynin are the side effects; dry mouth, constipation, blurred vision, psychologic and personality changes are common side effects, causing up to 10% of the children to stop their treatment [53]. Especially in children with special needs these side effects are more problematic as tooth decay, constipation, mood disturbances and intellectual delay, which are already relatively common in this population, can get even worse. Therefore, newer, more bladder specific antimuscarinics, only approved for adults, like solifenacin and tolterodine are used off-label in these patients. Propiverine, which is suggested to be better tolerated than oxybutynin, has been approved in some countries for the use in children [54]. When using antimuscarinics strict follow-up, with special attention for side effects and post void residual is necessary.

b) Desmopressin

In case of monosymptomatic enuresis with proven nocturnal polyuria, as in normally developing children, desmopressin is the first line treatment [55]. This treatment should be used with care as excessive fluid intake shortly before or quickly after administration of desmopressin can cause a life threatening water intoxication with hyponatraemia and convulsions.

c) Botulinum toxin

Botulinum toxin has been used off-label successfully for the treatment of children with neuropathic bladder and non-neurogenic bladder dysfunction [50, 56-58]. In accordance with treatment in normally developing children, also in children with special needs it can only be considered in patients suffering OAB or urinary incontinence in whom other treatment options have failed.

9. SURGERY

Children with Down’s syndrome have a significantly increased risk of anterior urethral obstruction and posterior urethral valves [59]. In Down’s syndrome children, where there is suspicion of obstruction of the LUT, cystoscopy under general anaesthesia with possible incision of the obstructive element should be performed. In those patients with a neuropathic bladder, refractory to conventional therapy, bladderaugmentation, i.e. ileocystoplasty with or without continent catheterisable stoma (Appendicovesicostomy, Monty) can offer the final, non-reversible, solution to achieve continence and to protect the upper urinary tract.

10. CLEAN INTERMITTENT CATHETERISATION (CIC)

Some children do need intermittent catheterisation, especially those undergoing a bladder augmentation. Children with cerebral palsy treated with continuous Baclofen can also suffer urinary retention needing intermittent catheterisation. The problem with some of these children with special needs is that they have a normal genital sensation that makes catheterisation uncomfortable, or even painful. Combined with the reduced intellectual capacities of some this makes CIC nearly impossible. Therefore, incontinent stoma is sometimes the only solution.

11. CONCLUSION

Although often thought to be a minor problem urinary incontinence remains an important issue for every special needs child. Urinary incontinence can lead to limited self-esteem and independence, and may be
challenging health. Often it is a multifactorial problem, but with adequate therapy these children are amenable to continence rehabilitation. The majority can become continent, but some will only achieve a passive form of continence.

This chapter deals with neurologic urinary and faecal incontinence; it draws on previous ICI reports, and complements information in other ICI chapters. In developing the content, literature searches were undertaken with the keywords; “neurologic”, “neurogenic”, “bladder”, “bowel”, “lower urinary tract”, “ano-rectal”, “incontinence”, “continence”, “urinary”, “faecal”, “paralysis”, “dysfunction”, “retention”, “constipation”.

Searches for specific neurologic diseases (section E) were undertaken, looking into selected neurological diseases of particular relevance to neurourology, comprising the more prevalent or more challenging in terms of incontinence diagnosis and treatment.

Continence relates to reservoir functions of the bladder and rectum, and closure of their respective outlets by contraction of smooth muscle (bladder neck and internal bowel sphincter) and striated muscle urethral and anal sphincters. Expulsion requires relaxation of these latter structures, and contraction of the musculature of the respective reservoirs, to permit a physiological reflex evacuation of urine or faeces.

The lower urinary tract (LUT) and the lower bowel tract (LBT) are interrelated structures. Embryologically, bladder and rectum originate from the same basic structure, the cloaca [1]. Anatomically both viscera lie in close proximity to each other, and to the muscular structures of the pelvic floor. Both are innervated by autonomic and somatic nerves (table 1), and have similar principles of central control [2, 3]. The LBT differs from the bladder in having an enteric nervous system [4]. Interactions between the two organ systems are increasingly recognised, and their activity is co-ordinated. Voiding can occur without defecation [5], and the initiation of micturition often precedes that of defecation, even if both organs are considered equally full [6]. The filling status of the bladder influences sensation in the rectum and vice versa [7], and the potential for mutual influence in pathology is emerging [8]. Nonetheless, little information is available on co-ordination of both functions in patients with neurological pathology.
**Table 1:** Overview of function of the abdominal sympathetic, the pelvic parasympathetic and somatic nerves in the LUT and LBT.

**1. THE EVIDENCE BASE**

Neurogenic lower urinary tract dysfunction (NLUTD) is a term that applies to an extraordinarily diverse spectrum of clinical conditions. This heterogeneity can be appreciated by considering the different challenges faced by the infant born with myelomeningocele and the elderly patient with dementia-associated incontinence. Some order can be imposed by grouping conditions based on their cause and site of impact on the neuraxis (see table 2) [9].

Historical data demonstrates that the management of NLUTD has made huge advances over the last century, largely based on a trial and error approach and the dissemination of expert opinion [10]. Improved outcomes for patients were the result of the development of a urodynamic-based understanding of pathophysiology, the introduction of effective treatments to allow safe and reliable urine storage and intermittent catheterisation, the advent of more effective antibiotics and the development of better catheters and appliances. However, the historical approach is accompanied by significant problems. Dangerous or ineffective treatments can be trialled out-with an appropriate ethical framework and successful therapies can be slow to be introduced because their proponents may not convince their peers of the merits of the new treatment.

*Conditions that can arise in more than one region of the CNS.*

There is an inherent risk when an area of clinical practice has not been accompanied by a culture of high quality scientific research, and where the data which is available is used uncritically. For example, there has long been concern that management of NLUTD by indwelling catheter drainage results in excessive
morbidity and, at first glance, published data on complication rates between different bladder management systems would appear to confirm that catheters are damaging to upper urinary tract function. However, this is based on cross-sectional data; such studies do not effectively take into account the preceding bladder management methods, the inability to randomise to different management approaches, and that catheters are typically used as a last resort in patients who have already developed problems with their urinary tracts [11]. Prospective longitudinal evaluation accounting for antecedent bladder management actually indicates that indwelling catheterisation is protective for the upper urinary tract [12].

The extensive evidence base concerning NLUTD is clearly demonstrated by the content of this chapter, but much of the evidence is contained in reports of studies which fail to meet contemporary standards for high quality evidence. How then should the clinical community respond to the challenge of improving the scientific foundations of our care for patients with NLUTD?

There are many aspects of modern management of NLUTD which will never be tested in definitive clinical trials because they appear to be of self-evident value. As a result, no trial could be conducted because the hypothesis that was to be tested would lack equipoise. For example, it would be impossible to conduct a trial that randomised spinal cord-injured patients between urodynamic-led and clinical-led treatment planning. However, that does not preclude the need to question these standard approaches. For example, such a study could be conducted in the context of multiple sclerosis where different approaches have been advocated [13, 14].

Despite the difficulties of conducting high quality trials in the field of NLUTD, there are an increasing number of studies that demonstrate the feasibility of such studies. Large, industry-sponsored studies have been conducted and are capable of providing near-definitive data on important clinical questions [15, 16]. However, even where high-quality data exists for some patient groups, there may be little or no data for others; spinal cord-injured and multiple sclerosis patients have been shown to respond to intra-detrusor injections of botulinum neurotoxin A but there is a dearth of data on patients with neurogenic detrusor overactivity (DO) due to intracranial conditions. Extrapolation from one condition to another is inevitably going to be needed but would be aided by even small, well-conceived trials that looked at patients with less common conditions.

There are a large number of interventions that have only been assessed by low quality methodologies, typically uncontrolled case-series. In some cases, such as that of the artificial urinary sphincter, there is sufficient data on which to base an evaluation, whereas other procedures still await a more complete assessment; the majority of alternative operations used to treat neurogenic stress incontinence fall in this category.

Finally, there is the question of how to evaluate new investigative and treatment techniques. Drug therapies are tightly controlled by regulatory authorities but it is common for drugs to be extensively investigated in the non-neurogenic population but not in patients with NLUTD. It is to be hoped that tighter regulation and the demonstration that NLUTD trials are feasible will encourage drug evaluation in this patient group. For devices and surgical procedures, regulation is less tight and it is therefore for the clinical body to resist the premature introduction of techniques that lack an appropriate evidence base. There is a need for multi-centre cooperation in clinical trials that are designed to look, not only at short-term clinical efficacy, but also at long term results, complications and cost-effectiveness of new interventions.

II. PATHOPHYSIOLOGY

With a neurologic lesion the type of dysfunction that follows in LUT (and LBT) will depend on the site, the extent and the evolution of the deficit. Traditionally neuro-urological pathology has been divided into the upper motor neuron lesions (UMNL), comprising suprapontine (cerebral) and suprasacral (brainstem, and spinal cord); and lower motor neuron lesions (LMNL), comprising sacral and subsacral (cauda equina and peripheral nerve). Brainstem lesions are rarely compatible with more than short-term survival, so they are only infrequently encountered in neuro-urological practice.

Very recently Powell proposed a new step in classification of the neurogenic bladder: SALE (Stratify by Anatomic Location and Etiology). The classification is based on seven categories, each having a neurologic defect in a distinct anatomic location. In addition, the presence or absence of bowel dysfunction and autonomic dysreflexia is reported. In the future, as more definite prognostic information can be gleaned from biomarkers, urinary nerve growth factor (NGF) and urinary brain-derived neurotrophic factor (BDNF) levels can be added to the classification. The SALE system should efficiently describe a patient suffering from NGB and simultaneously inform the most appropriate treatment, follow-up regimen, and long-term prognosis. [1]

1. SUPRAPONTINE LESIONS

In suprapontine lesions a neurologic LUTD may be a direct consequence of the neurologic lesion, but may also be due to or changed by other conditions: e.g. motor and cognitive dysfunctions may lead to “functional” incontinence.

There is growing knowledge about how cerebral suprapontine regions are related to the LUT function. The location and extent of a suprapontine lesion will
determine the resulting symptoms and if they are reversible or not. While historically a close clinical observation, post-mortem or surgical evaluation were the main link between LUTD and brain lesions, the modern functional neuroimaging has illustrated such interaction better and has permitted to highlight smaller lesions. [2]

The current model of central LUT control consists of a network of interconnected brain regions involved in the switch between storage and voiding. A recent overview accepts functional roles of the supplementary motor area, dorsal anterior cingulate cortex, lateral prefrontal cortex, thalamus, insula. [3] It is important that there is laterality of cerebral control networks, which can influence the dysfunction in unilateral pathology. Speculations have been made regarding the role of neural circuits but, what is still lacking is a full understanding of connectivity of cerebral control networks.

The cerebral control of the urethral sphincter will depend on voluntary and involuntary control by different parts of the brain. [4]

Supra-Pontine neurologic lesions differ from other neurologic insults because they lead to loss of tonic inhibition of the pontine micturition center (PMC). This can lead to spontaneous involuntary DO, which is different from DO that occurs after supra-sacral SCI. The supra-pontine lesions are overall characterized by storage dysfunction. Normal uroflow and normal post voiding residual (PVR) can often be expected. In some cases detrusor underactivity (DU) has been reported, as well as DO with impaired contraction (DOIC). So it is important to acknowledge that DO is not the only finding in supra-pontine injury. [5] Moreover there may be loss of one or more of the cerebral functions, such as volitional control over timing of emptying, inhibition of bladder, conscious filling and emptying sensations and some integration functions with other organ systems and activities of daily life. One should not overlook the importance of the loss of mobility and of initiative /cognition. This is not seldom the case in such brain lesions as stroke or head injury, which mostly continue to have a synergic LUT function. In many cases there will be OAB syndrome, the patients may purposely increase sphincter activity during an overactive detrusor contraction to prevent urinary incontinence which would otherwise occur. [6] This has been termed “pseudo-dysynergia” because it is difficult to distinguish from true detrusor sphincter dysynergia (DSD) on an urodynamic record.

New knowledge is developing. The CNS, once considered to be an immune-privileged area may instead be an active surveillance site, with bi-directional communication with the immune system. This finding has led to a significant interest in neuro-immunological interactions and investigation into the role of the immune system in the pathology of various neurological disorders. The proposal has been made that the relationship between peripheral immune cells, the brain, and the urologic system should be considered as an additional possible mechanism in urologic diseases, and that immunotherapy might be an alternative therapeutic strategy in treating neurogenic bladder dysfunction. [7] [8]

A growing body of evidence suggests that 5-hydroxytryptamine (5-HT; serotonin) has both physiological and pathological functions in the LUT. In the central pathways controlling the micturition reflex, 5-HT1A, 5-HT2A, and 5-HT7 are involved in regulation of bladder and urethral sphincter activities. Their functions, especially that of 5-HT1A, vary in a species- and site (spinal or supraspinal)- dependent manner. [9]

A similar relationship between the bladder and mitochondrial function in the regulation of cellular energetics and metabolism was described as in heart failure. Though there are currently no pharmacologic agents that directly affect mitochondrial biogenesis in organ failure, current advances in the development of therapy including mitochondrial biogenesis, mitochondrial oxidative stress and mitochondrial pore transition proteins might become important in the future. [10]

### 2. PONTINE LESIONS

The dorsal pontine tegmentum has been established as the seat of the micturition centre. Lesions at that level are rare, but may lead to DO and DSD. This can occur in multiple system atrophy (MSA; formerly known as Shy-Drager syndrome). In view of the crucial role of the pons in key homeostatic and physiological functions, only a limited extent of pontine dysfunction is compatible with life.

### 3. SUPRASACRAL SPINAL CORD LESIONS

#### 3.1. Complete suprasacral lesions

A lesion resulting in a completely transected spinal cord which occurs above the level of the conus medularis (L1/L2), leads to a cranial cord segment and a caudal cord segment which cease to communicate (Fig 1). The caudal segment therefore becomes autonomous and is known as the **distal autonomous cord**. This leads to an upper motor neurone picture in the affected limbs with hypertonicity, spasticity, absent sensation and hyperreflexia. Occasionally, a lesion above the conus medularis may extend into the lumbar and sacral segments of the conus and lead to lower motor neurone effects in the affected limbs. The...
resulting LUT dysfunction in this case will follow a sacral pattern rather than a suprasacral pattern. Therefore it is not just the level of injury which is important but the extent of injury and whether it leads to a distal autonomous cord (Fig 1).

With complete suprasacral injury, micturition, which was once controlled by the pontine micturition centre becomes essentially an unmodulated spinal reflex. Previously quiescent, C fibre afferents become activated and the patient develops a reflex bladder. As the bladder fills and pressure rises it contracts automatically leading to involuntary urination, seen as neurogenic detrusor overactivity on a urodynamic study. The guarding reflex (which contracts the urethral sphincter on urine entering the bladder neck) is no longer synchronised with voiding (as this is co-ordinated by the pons). This leads to detrusor sphincter dyssynergia (DSD) i.e. concomitant contraction of the urethral sphincter during bladder contraction. [11]

Incontinence is caused by detrusor overactivity when the bladder pressure overcomes the sphincteric resistance or when the sphincter fatigues. The bladder also may not empty to completion as it is reliant on the neurogenic detrusor overactivity (reflex contractions) to empty and is impeded by the DSD.

Another feature of the distal autonomous cord is autonomic dysreflexia. This can only occur in the areas under suprapontine control i.e. those above the lesion. [12] This results in the visibly characteristic vasoconstriction in the skin below the level of SCI and vasodilation above.

A complete suprasacral cord injury results in a reflex bladder with DSD. The important aspects worth considering are that: [1] bladder contraction involves different afferent fibres (experiments in cats indicate that the relevant afferents are the C-fibres) [13] [2] bladder contractions are poorly sustained, [3] the urethra and bladder become dyssynergic, and [4] previously irrelevant stimuli influence the bladder and/or external sphincter activity. Also voluntary inhibition of the micturition reflex is lost, though some consciousness of bladder sensation may still be present.

Of 489 patients assessed by Kaplan et al. it was shown that all those with suprasacral cord lesions without sacral cord signs (complete SCI) had detrusor overactivity and DSD and in those with sacral cord signs (incomplete injury) 84% had an areflexic bladder. [14] Another study by Weld and Dmochowski of 196 veterans with suprasacral injuries revealed 95% had NDO and/or DSD. [15] Six patients (3%) all with lumbar injuries had bladder areflexia and fit the subsacral pattern described below.

Figure 1: Diagrammatic representation of complete spinal cord injury with a) distal autonomous cord present leads to spasticity, hypertonicity and hyperreflexia in limbs and reflex activity and DSD for the bladder and sphincter respectively, b) No distal autonomous cord/ sacral lesion leads to flaccidity and areflexia in limbs and an areflexic bladder with a flaccid sphincter.

DSD may cause incomplete emptying and with prolonged detrusor contractions structural bladder changes may occur resulting in bladder fibrosis and poor compliance with vesico-ureteric reflux. When combined with recurrent urinary tract infections, renal failure may result. This is more common with continuous than intermittent DSD although both require long term follow-up. [16] More than half of men develop urological complications and are considered to be at high risk of upper tract damage.
3.2. Incomplete suprasacral lesions

Incomplete suprasacral injuries can take many forms but four common patterns of injury have been described. Anterior cord syndrome, usually occurs due to disruption of the anterior spinal artery leading to reduced or absent motor activity and pain/temperature sensation but proprioception is retained. In contradistinction, posterior cord syndrome for example due to tabes dorsalis affects only proprioception. Lateral cord syndrome also known as Brown Sequeard leads to ipsilateral loss of power and proprioception and contralateral loss of pain and temperature sensation. The most common pattern however, is seen due to traumatic neck hyperextension during a fall and is termed central cord syndrome. Due to lamination in the spinal cord, the upper limbs are more affected than lower limbs (as they lie closer to the central canal) and the former are more likely to show lower motor neurone features compared to the latter which demonstrate spasticity. Sensation also disproportionately affects the upper limbs. Recovery is also more likely in the less affected lower limb.

Incomplete suprasacral lesions lead to variable bladder and sphincteric function. Anterior cord injury leads to detrusor overactivity in the majority of patients, and DSD is also a possibility dependent on how extensive the injury is and which parts of the cord are affected. The pathways co-ordinating the bladder and sphincter are located mostly in the lateral columns and if these are affected DSD may occur. If the dorsal columns are unaffected, bladder sensation but proprioception is retained. In contradistinction, posterior cord syndrome will be variable and the risk of upper tract damage is proportionately greater.

A urodynamic study of 22 veterans with central cord syndrome revealed normal findings in three men, detrusor areflexia in four, DSD in 11, detrusor overactivity without DSD in one and detrusor underactivity in one, also two men had BOO due to BPH. Therefore it is clear that the LUT function in central cord syndrome will be variable and the risk of upper tract damage due to DSD or poor compliance needs to be considered but is not common and also sensation is reported to be preserved.

With Brown Sequard syndrome, urodynamic studies in eight patients revealed detrusor overactivity in four, an areflexic detrusor in three and DSD in four patients. In a study of 269 patients with spinal cord lesions, those with unimpaired sensation and younger age were most likely to recover acceptable bladder function.

4. SACRAL AND SUBSACRAL LESIONS

Lesions of the conus medullaris and cauda equina are characterized by motor and sensory symptoms in the lower limbs, buttocks, perineum accompanying the dysfunctions of bladder, bowel and sexual activity: the "cauda equina syndrome". As the axons with roots from cauda equina extend into the spinal cord, dysfunctions caused by a lesion of conus or cauda are similar thus making distinction between them on clinical grounds difficult.

4.1. Sacral (conus medullaris) lesions

The intermediolateral nucleus contains the motor nuclei of the autonomic nervous system. In the sacral spinal cord, this region is parasympathetic, and damage to the nucleus renders the detrusor areflexic. Resulting retention of urine can cause incontinence (formerly termed overflow incontinence). Onuf’s nucleus, located medially in the ventral horn of the sacral spinal cord, is a mixed autonomic/somatic nucleus containing the motor nuclei for the LUT and LBT outlets. Damage to this structure affects sphincters (and some pelvic floor musculature), and thus stress incontinence may result. If the pudendal nerve is also impaired, there is an increased risk for incontinence.

The functioning of a sacral or areflexic bladder depends on the sphincteric resistance (detrusor leak point pressure). The bladder will fill up to the detrusor leak point pressure and empty by overflow. There will be no detrusor contraction. The bladder may develop poor compliance and pose some risk to the upper tracts. The symptoms can be acute with motor and sensory changes as when central large lumbar disc herniation occurs. Chronic symptoms may occur when degenerative disc disease and osteoarthritis of the spine create gradually narrowing of the spinal canal and/or foramina.

4.2. Subsacral lesions (cauda equina or peripheral nerves)

The same effects as seen with lesions of the conus medullaris can result from lesions of the subsacral nerves (the cauda equina, or the peripheral nerves-including the pudendal nerves). The main function of peripheral nerves is the communication between the CNS and peripheral effector organs. Lesions at that level can occur by different causes as infections (cytomegalovirus, herpes), fractures, surgery, radiotherapy and many more. Peripheral neuropathies are found in a long list of conditions as diabetes, alcohol abuse, Guillain-Barré et al. Both parasympathetic and somatic motor function will potentially be impaired; the detrusor can be underactive or areflexic and the external sphincter can be paralyzed. These lesions can also cause a variety of sensory deficits. Some pain and/or filling sensation can be retained because of intact sympathetic hypogastric nerves, which enter the spinal cord in thoracic roots. The bladder neck is predominantly innervated by sympathetic pathways, and so it can retain some function in sacral injury. If there is extensive autonomic damage, the bladder neck remains open.

Iatrogenic causes of focal pelvic nerve lesions have been described with abdominoperineal resection,
though these are probably less frequent with intraoperative neuro-monitoring. It has been studied in hysterectomy, where nerve sparing techniques offer a better outcome. [30] [31] Also in radical prostatectomy enhanced attention to the innervation at the time of surgery may result in improved preservation. [32] Complete lesions of all local innervation, are followed by a silent, painless distension of the bladder. Urinary retention follows, leading to incontinence by overfilling, though if the external urethral sphincter is also denervated stress urinary incontinence (SUI) and even continuous urine leakage may occur. When lesions are partial, sensory symptoms may predominate. But patients, especially women, can report “spontaneous voiding” with Valsalva. In patients with a presumed isolated PNS involvement (as in Guillain-Barré syndrome), DO with or without DSD has been described. [33] [34]

In patients with a complete cauda equina or a lower conus lesion, a sensory input from the bladder can be preserved and is possibly transferred through the intact hypogastric plexus to the thoracolumbar segments of the spinal cord. [35]

Conclusions (LOE = 1)

- With a neurologic lesion the type of dysfunction that follows in LUT (and LBT) will depend on the site, the extent and the evolution of the deficit.
- Distinction is made between suprapontine, pontine, suprasacral spinal cord, sacral and subsacral lesions.

Recommendations (grade A)

- It seems worthwhile to further evaluate the classification of the neurogenic bladder: stratified by Anatomic Location and Etiology (SALE). Beside classifying into seven categories, each corresponding with a neurologic defect in a distinct anatomic location, the presence or absence of bowel dysfunction and autonomic dysreflexia is reported.
- In the future, if further evaluation confirms their importance, prognostic information as from biomarkers, NGF and BDNF, can be added to the classification and will be an important avenue for further research.
- As such the classification describes a patient suffering from NGB and simultaneously informs about the most appropriate treatment, follow-up regimen, and long-term prognosis.

NLUTD may be caused by a variety of neurological diseases and/or events affecting the various parts of the nervous systems controlling the LUT. The resultant dysfunction depends grossly on the location, extent, and nature of the causative neurological lesion or lesions. Overall prevalence estimates for NLUTD in the general population are scarce, but data are available on the prevalence of the underlying conditions and, in some cases, the relative risk for the development of NLUTD. It is important to realise that most of these data show a very wide range of prevalence figures, due to low level of evidence in most published data and smaller sample sizes.

Nevertheless, worldwide estimates of the prevalence of spinal cord injury (SCI) are at over 2.5 million, multiple sclerosis (MS) considerably greater than 1.5 million and Parkinson’s disease (PD) approximately 3 million [1-3]. Spinal cord injuries are common, with an estimated 50 people per million sustaining a traumatic spinal injury every year in the Western world [4]. Non-traumatic injury (vascular, infection, tumour) is more common, and cancer alone is estimated to cause more SCI than trauma [5]. Traumatic injury mostly affects young men, and advances in rehabilitation medicine mean that the longevity of paraplegics is similar to the general population while that of tetraplegics is 10 years shorter [9]. The prevalence of MS is approximately 1 per 1 000 [2].

Mobility, pain and bladder dysfunction in neurological patients has been relatively well studied, while the bowel and pelvic floor dysfunction has been neglected by comparison. With rapid advances in rehabilitation medicine resulting in increased survival of patients, these individuals are experiencing bladder and bowel symptoms for ever-longer periods.

As in previous International Consultations on Incontinence reports published data on epidemiology were reported both in a separate section and in each specific neurological condition, it seemed more appropriate for the 2016 ICI report to present updates of epidemiology only with each specific neurological condition. The general conclusions and recommendations on epidemiology of the previous ICI report remain unchanged.

Conclusions

- Dysfunction of the LUT occurs in patients with a variety of neurologic diseases but precise epidemiological data is seldom available.
Common manifestations of NLUTD include urinary incontinence, voiding difficulties, and urinary retention.

Because neurological disease is often present in elderly populations, it is frequently difficult to discriminate if LUTS are due to aging alone, or due to the presence of neurological disease. This difficulty is reflected in widely varying prevalence estimates.

Recommendations

- Patients with neurologic disease known to be associated with NLUTD should be evaluated for the presence of lower urinary tract symptoms.

- In certain neurologic disease states, NLUTD may be relatively asymptomatic, yet represent a risk of upper urinary tract impairment.

- In the appropriate clinical setting, a neurological evaluation may be recommended in a patient with unexplained LUTS and no known neurological disturbance. This is particularly true in the case of a young patient with idiopathic severe LUTS after proper office evaluation for common etiologies.

- Prevalence estimates of NLUTD would be improved by multicenter co-operative studies from large tertiary centers utilizing established outcomes and evaluation tools.

2. SPECIFIC DIAGNOSTICS

Before any functional investigation is planned, all “basic” data should be gathered and used for further interpretation of the NLUTD [1,2]. Relevant investigations include; history and physical examination, questionnaires, urine tests, voiding diary, urodynamic studies (cystometry, electromyography (EMG), videourodynamic, uroflowmetry, pressure-flow study), diagnostic imaging with voiding cystourethrogram and ultrasonography. In this chapter are highlighted some data specially related to NLUTD. Some tests developed for the diagnosis of neurologic dysfunction are considered specifically; the bethanechol supersensitivity test, and the ice water or bladder cooling test. Neurophysiologic studies are discussed in the chapter “Clinical Neurophysiological testing”, and only some data for NLUTD is given here.

2.1. History

The general history aims at gathering information on the neurological and congenital abnormalities, previous urinary complications or treatments. The use of medication with known or possible effects on the LUT, menstrual, sexual and bowel function, and obstetric history are also important. Hereditary or familial risk factors, metabolic diseases and other must be known. Lifestyle factors such as smoking, alcohol, or addictive drug use should be assessed as well as an evaluation of Quality of Life. Social impact and the degree of disability have to be taken into consideration. Patients with a spinal cord lesion above Th6 may develop autonomic dysreflexia, so a history of severe headaches should be explored.

The signs and symptoms that bring the patient to consultation must be documented. Symptoms related to storage and voiding, continence and/or retention, as well as onset and nature of the NLUTD (acute or insidious) should be determined. If appropriate this information should be compared with the patient’s condition before the NLUTD developed. Bladder sensation and mode and type of voiding (catheterization) should be considered. Validated questionnaires are useful for recording symptoms, their frequency, severity and bother, and the impact of LUTS on QoL. Some instruments were not validated in NLUTD or are impossible to implement because of sensory or motor deficiency in NLUTD. An excellent review of available tools for neurological disease and urinary-specific instruments used to assess QOL associated to bladder symptoms has been written by Clark and Welk [3]. Results are summarized in Table 3 at the end of this paragraph. Warning signs and symptoms that warrant early further investigation include; fever, pain, hematuria, catheterization problems, clinical infections and signs of autonomic dysreflexia. Individuals with NLUTD may not be accurate at determining whether they have a UTI based on their symptoms [4]. UTI management is not standardised and clinical practice suffers from a weak evidence base [5].

**Table 3 abbreviations:** QOL, quality of life; MDC*, 1.96*[SD* √(1-ICC)]^\frac{1}{2}; SCI, spinal cord injury; MS, multiple sclerosis; α, Cronbach's alpha; ICC, interclass correlation coefficient; SQLP, Subjective Quality of Life Profile; SRM, standardized response mean; MDC, minimally detectable change; SCI-SCS, Spinal Cord Injury Secondary Conditions Scale; SCQ, Seekins Secondary Conditions Scale; R, Spearman correlational coefficient; NE, not established; NC, not calculable; SCI-QOL, Spinal Cord Injury Quality of Life; Neuro-QOL, Quality of Life in Neurological Disorders Measurement System; SCI-FI, Spinal Cord Injury Functional Index; I-QOL, Incontinence Quality of Life; SUI, stress urinary incontinence; SF-36, Short Form 36 Health Survey; MID, minimally important difference; NBSS, neurogenic bladder symptom score; SB, spina bifida; AUASS, American Urological Association Symptom Score; ICIQ-UI, International Consultation on Incontinence-Urinary Incontinence; GBA, Global Bladder Assessment; MSQOL-54, Multiple Sclerosis Quality of Life 54-item scale; MOS, medical outcomes study health distress measure; MSIS-29, Multiple Sclerosis Impact Scale 29-item; GHQ-12, General Health Questionnaire; FAMS, Functional Assessment of Multiple Sclerosis; MDI, multiscale depression inventory; PSR, Eastern cooperative oncology group performance status rating; MCSDS, Marlow Crowne social desirability scale; HAQUAMS, Hamburg Quality of Life Questionnaire in MS; EDSS, expanded disability status scale; T8, timed 8-minute walk; SDMT, symbol digit modalities test; 9HPT, nine hole peck test; HADS, hospital anxiety and depression scale; MSQLI, Multiple Sclerosis Quality of Life Index; ABSST, Actionable Bladder Symptom Screening Tool; SF, short form; OAB-q SF, Over Active Bladder Questionnaire; HRQOL, health related quality of life; QOLSB, Quality of Life in Spina Bifida scale; IIQ-7, Incontinence Impact Questionnaire 7-item; UI, urinary incontinence; IIQ, Incontinence Impact Questionnaire; EORTC QLQC30, EORTC Quality of Life Questionnaire; KHQ-LUTS, King's Health Questionnaire Lower Urinary Tract; ICIQ-OAB, International Consultation on Incontinence Questionnaire Overactive Bladder.
A urinary diary can be used to capture information on the number of voids (frequency and nocturia), the sensation at each void, volumes voided, incontinence, and volume/ time of fluid intake. Little information is available on optimal diary duration in NLUTD, considering information captured balanced against inconvenience to the patient [33]. However general recommendation is to do it at least for 3 days [34]. Some information could be difficult or impossible to collect because of sensory or motor deficiency in NLUTD. Nonetheless, such diaries deliver useful assessment for evaluating treatment outcomes [35].

A Urinary diary can be subdivided into:

1. Micturition Time Chart: this records only the times of micturitions, day and night, for at least 24 hours.

2. Frequency Volume Chart (FVC): It records the volumes voided as well as the time of each micturition, day and night, for at least 24 hours.

Bladder Diary: it records the times of micturitions and voided volumes, incontinence episodes, pad usage and other information such as fluid intake, the degree of urgency and the degree of incontinence.

2.2. Physical examination

A general impression of patient’s physical and mental possibilities is relevant to the choice of investigations and treatment. Severely impaired mobility, extreme spasticity, severe mental disorder and general weakness are all important in this respect. The physical examination evaluates the lower abdomen, external genital organs and perineal skin. Palpation per vagina or per rectum is done in search of pelvic organ descent, or cervix-uterus/ prostate disease. The strength of the pelvic floor muscles should be assessed. Cardiovascular function should be considered. Patients with very high neurological lesions may suffer from a significant drop in blood pressure when changing position.

Specific examination of the lumbo-sacral innervation includes: sensation of fine touch and pin-prick in the different perineal dermatomes (Figure 2), evaluation of bulbocavernous/ anal/ cremaster reflexes, tone of anal sphincter and voluntary contraction of the anal sphincter / pelvic floor muscles (Figure 3). Clinical neurological findings correlate well with NLUTD in some types of neuropathy such as single level traumatic spinal cord lesions [36] but less in other types like meningomyelocele or combined traumatic spinal cord lesions [37,38]. Urinary symptoms and pathological urodynamic findings increase along with the degree of motor function impairment in infantile cerebral palsy [39] The levels of vertebra lesions does not correspond to the level of nerve damage (Figure 4) [40]

2.3. Urine tests

Tests for bacteria or pyuria do not establish a diagnosis of urinary tract infection (UTI), but are helpful in

Figure 2: Dermatomes of spinal cord levels L2-S4

Figure 3: Urogenital and other reflexes in lower spinal cord

the context when symptoms are present. The urine sample should be collected with sterile catheter and taken to the laboratory immediately. Colony forming units ≥10^5 cfu/L in an intermittent catheter specimen with symptoms present, represents sufficient diagnosis of UTI’s. In clean-voided specimens from catheter-free men using condom catheters, ≥10^7 (cfu/L) is a sufficient level [41]. There is however lack of other high level evidence to define UTI’s in patients with NLUTD.

2.4. Urodynamic tests

Urodynamic techniques evaluate multiple functional parameters in NLUTD [42]. The International Urodynamic Basic Spinal Cord Injury (SCI) Data Set sets out data to be included in the urodynamic evaluation of patients with SCI. Variables included are; bladder sensation during filling cystometry, detrusor function
and compliance during filling cystometry, detrusor function during voiding, detrusor leak point pressure, maximum detrusor pressure, cystometric bladder capacity and post-void residual [16]. If the study is undertaken with video control then one has to look for reflux, bladder trabeculations and sphincter dyssynergia.

Often, the nature of NLUTD is impossible to anticipate from clinical assessment alone, exemplified by CNS tumours in children [43]. Likewise, severity of NLUTD does not necessarily correspond with severity of neurological lesion.

Electromyography (EMG) during cystogram and pressure flow studies

The basis of EMG has long been a question of debate [44, 45]. Sundin and Petersen [46] used cystometry (EMG) investigation in NLUTD for patients with an active detrusor contraction associated with impaired bladder emptying. A voluntary control of external urethral sphincter relaxation was found in most of the healthy volunteers, and cystometry-EMG gave reliable information on DSD in patients. On the other hand Kirby et al showed that perineal surface patch EMG did not measure expected pelvic floor and urethral sphincter relaxation during voiding [47]. De et al found significant disagreement between needle EMG and VCUG for a positive diagnosis of DESD and suggested a combination of EMG and VCUG for diagnosis of DESD [48]. Perkash [49] found rhythmic detrusor contractions on cystomanometry with associated marked increase in EMG activity on attempted voiding to be relevant characteristics of patients with DSD. Rodriguez et al. [50] used EMG-gas cystogram to select SCI patients for removal of a Foley catheter. Important factors governing success were the amplitude of the detrusor contraction, the presence of detrusor-sphincter synergy and the presence of a flaccid sphincter. Mayo and Kiviat [51] used multichannel urodynamic studies in patients with incomplete bladder emptying secondary to suprasacral spinal cord lesions. They found that bladder pressure and sphincter EMG measurement during voiding, combined with fluoroscopy, are ideal methods to identify the factors responsible for incomplete emptying in problem cases. Perlow and Diokno [52] and Koyanagi et al. [53] found cystometry-EMG informative in SCI patients.

Blaivas et al. [54] described three types of dyssynergia. Type 1 had a crescendo increase in EMG activity that reached a maximum at the peak of the detrusor contraction, type 2 had clonic sphincter contractions.

Figure 4. Levels of spinal cord injury
interspersed throughout the detrusor contraction and type 3 was characterized by a sustained sphincter contraction that coincided with the detrusor contraction. There was no correlation between the clinical neurologic level and the type of dyssynergia. In DSD, Rudy et al. observed clinically that increases in EMG activity and external urethral sphincter pressure were associated closely with a positive slope of the intravesical pressure trace, whereas decreases in both parameters were associated with a negative slope [55].

Simultaneous recording of intravesical pressure, sphincter electromyography and uroflowmetry was compared by Aoki et al. [56] with cystometry EMG. They found some influence of the catheter in the urethra. Micturition pressure and opening pressure were larger with cystometry EMG, and incidence of DSD was greater. The authors also found that the Credé manoeuvre exaggerated the DSD. Urodynamics with needle electrode EMG permitted Kirby [57] to differentiate between patients with pelvic nerve injury, distal autonomic neuropathy, progressive autonomic failure - multiple system atrophy, and idiopathic Parkinson's disease. This influenced the selection of patients for transurethral surgery. Pavlakis et al. [58] studied cystometry concomitant with perineal floor and rectus abdominis EMG and were able to improve the recognition of intravesical pressure elevation owing to voluntary contraction of the abdominal musculature. EAS motor unit potential (MUP) analysis and EMG cystometry were used to differentiate multiple system atrophy (MSA) from Parkinson's disease in the first five years after disease onset. It showed that involvement of Onuf's nucleus in MSA is time-dependent; before the fifth year of illness, the prevalence of neurogenic change does not seem to be high, so a negative result cannot exclude the diagnosis of MSA [59]. Rapidi et al. used combined urodynamic and electrophysiological study in diabetic cystopathy [60].

**Filling parameters**

The importance of detrusor pressure has been acknowledged for many years. Filling rate is important in NLUTD, and slow filling is recommended by the International Continence Society to minimise artefactually affecting compliance [61].

Bruschini et al. [62] undertook clinical, urodynamic and imaging evaluation of the upper and lower urinary tract in inadequately managed myelomeningocele patients. The urodynamic data correlated with the status of the upper urinary tract (UUT). The cystometry showed detrusor overactivity (DO), poor compliance, increased bladder capacity and normal cystometry in 48, 49, 2 and 1% of the patients, respectively. Detrusor leak point pressure (DLPP) over 40 cm H2O was associated with UUT damage. Patients with decrease of functional bladder capacity (FBC) had more renal scars than their counterparts. Incomplete SCI patients with neurogenic DO should be evaluated with the same caution as complete SCI patients, as there can be little difference in cystometric capacity and leak point pressure between complete and incomplete spinal cord injury patients [63].

The importance of urodynamic tests for diagnosis and follow up was demonstrated in the study by Abrahamsson et al. [64] on urodynamic changes with untethering in myelomeningocele children. After untethering, 35% experienced improved bladder function and 5% deteriorated. All of the patients who deteriorated before untethering improved afterward, and 90% of those who were stable preoperatively continued to be stable postoperatively. Regular evaluation of bladder function in children with myelomeningocele is recommended. Kang et al. [65] used urodynamic tests to determine prognostic factors affecting urological outcome after untethering surgery for lumbosacral lipoma.

Perkash and Friedland [66] found simultaneous transrectal ultrasonography helpful. They recommended not to irritate the bladder when introducing the urodynamic catheter, and to examine the entire curve of the CMG, not simply the initial rise [67].

**Filling technique**

In SCI patients with neurogenic LUT dysfunction, Ko et al. [68] determined whether cystometry performed by filling using diuretics (FMCG) reveals different findings compared with conventional CMG. Significant differences between the two techniques were found in pressures and compliance in neurogenic DO, but not in hyporeflexic or areflexic bladders. Natural filling by the production of urine can change the results of cystometry considerably, and should be considered when performing urodynamic investigations and interpreting the results.

De Gennaro et al. [69] performed continuous urodynamic monitoring over six hours in children and compared this with standard urodynamics. They found continuous monitoring feasible, permitting a better diagnosis than standard cystometry in some cases. Zermann et al. [70] investigated the diagnostic value of natural fill cystometry (NFC) in children with neurologic bladder in comparison to conventional videocystometry. In 45%, NFC detected additional findings. The extra value of ambulatory urodynamics as compared to conventional urodynamics in spinal cord injury patients was investigated by Martens et al. They concluded that ambulatory urodynamics do not seem necessary for diagnosis and risk assessment in SCI patients suspected for DO when conventional urodynamics are done properly [71].

**The outlet during voiding**

Pressure-flow study can demonstrate an obstructive pattern (high pressure voiding) in neurologic patients due to urethral relaxation failure [72,73]. Videourody- namics (VUDS) offers visualisation of bladder neck and urethral sphincter activity during filling and voiding [74,75]. Accordingly, VUDS is a test that can determine the site of obstruction. Zerin et al. [76] found
that the urographic position of the bladder neck in relation to the pubic symphysis was correlated with lower motor neuron (LMN) denervation of the urethral sphincter as detected with electromyography in infants and children with myelodysplasia. They concluded that, although not as precise as urodynamic testing, significant descent of the bladder neck is a reliable urographic finding of complete LMN denervation of the external urethral sphincter in infants and children with myelodysplasia. In men with SCI, some cystometric variables and detrusor overactivity may remain consistent over sequential studies [77].

**Bladder sensation**

In a large cohort study it was shown that impaired perception of bladder filling during CMG is a sign of neuropathy [78]. Nonetheless, despite spinal abnormality, patients can experience bladder filling sensation, signifying the presence of afferent pathways joining the spinal cord at higher levels. In 52 SCI patients, 26% of those with a supposed complete lesion had sensation of bladder filling during cystometry [79]. In 41 patients with myelodysplasia the perception of bladder filling was present in a majority [80]. In a study of 26 SCI patients, bladder sensation was reported by 73% of patients in daily life. However, only 41% of patients had analyzable bladder sensation concomitant with detrusor overactivity during ambulatory Urodynamics [81].

Ersoz and Akyuz [82] investigated bladder filling sensation in 73 SCI patients with complete lesions above T11 and below T10 and with incomplete lesions. Bladder filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and in 38.9% of the patients with complete lesions above T11. Bladder-filling sensation investigations were reproducible in terms of bladder filling sensation category in 36 SCI patients who had a second CMG. The authors concluded that presence of bladder-filling sensation in many SCI patients reveal the potential for sensation-dependent bladder emptying, especially in the ones with complete lesions below T10 and the ones with incomplete lesions. The safe use of sensation-dependent bladder emptying was shown to be dependent on the urodynamic situation [83].

The amplitude of the first overactive contraction and the maximal detrusor contraction were found to be statistically greater in female patients with multiple sclerosis and neurogenic detrusor overactivity compared to women with idiopathic overactivity. The threshold volume for detrusor overactivity was greater, likely secondary to the elevated post void residual urine volume in the MS patients. In this study using a cut off value of 30 cm H2O for amplitude of the first overactive contraction achieved a positive predictive value of 88% for identifying multiple sclerosis [84].

**Complications of urodynamic testing**

Complications of cystometry include hematuria due to the urethral catheter, the development of oedema in the urinary bladder wall and urinary bladder spasm as a result of catheter irritation. One case report of twist and knot formation in the double lumen urethral catheter after cystometry of a patient with a hypocompliant bladder has been published [85]. Another case report describes bladder rupture during filling cystometry many years after bladder augmentation in a girl with meningomyelocoele [86].

Symptomatic urinary tract infections after cystometry are not infrequent and antibiotic prophylaxis has been advocated [87]. Randomised controlled trials (RCTs) comparing effectiveness of prophylactic antibiotics with placebo or nothing in reducing bacteriologically proven UTI after invasive cystometry have been done for all patients, including NLUTD [88]. The use of prophylactic antibiotics in urodynamics reduced the risk of significant bacteriuria but there was not enough evidence to suggest that this effect reduced symptomatic urinary tract infections [89].

**Conclusions**

- Findings of Urodynamic tests can be difficult to anticipate from clinical assessment alone in NLUTD (LOE 2)
- A combination with EMG and/or imaging adds to the diagnostic possibilities (LOE 2)
- Filling rate can influence the outcome of several urodynamic parameters (LOE 2)
- Pressure development in the bladder is one of the important parameters to be studied and high leak point pressure is a risk factor for renal deterioration (LOE 2)
- Sensation of filling may be preserved despite spinal abnormality (LOE 2)
- Complications of urodynamic testing are rare, but antibiotic prophylaxis in NLUTD can be considered (LOE 1)

**Recommendations**

- There is currently inadequate data (LOE3-4) to support recommendations for the use of urodynamics in each specific neurological condition. However, the use of invasive urodynamics is recommended in neurological conditions associated with ‘high-pressure bladders’ which may place renal function at risk (A), as opposed to ‘urodynamically safe’ bladder conditions (C)
- Methods of Urodynamic testing in NLUTD should follow International Continence Society recommendations (A)
2.5. Special tests

Bladder-cooling reflex; the ice water test (IWT)

The ice water test (IWT) is a C-fiber mediated reflex, first described as a way to differentiate upper from lower motor neuron lesions. It is based on the principle that mucosal temperature receptors can elicit a spinal reflex contraction of the detrusor, a reflex that is normally inhibited by supraspinal centers. An upper motor neuron lesion interrupts these inhibitory pathways, resulting in manifestation of the reflex, whereas a lower motor neuron lesion does not. A positive test should therefore theoretically occur in patients with upper motor neuron lesions, whereas those with lower motor neuron lesions and neurologically normal patients should have a negative test. Simultaneous measurement of intravesical pressure with cold fluid instillation enables evaluation of the response. Patients without neurogenic disease have a greater perception of cold during the IWT than neurogenic patients; this must be considered when evaluating test results [90]. The bladder cooling reflex was blocked in 16 out of 17 neurogenic patients when 30 mg intravesical oxybutinin was instilled [91].

There is a significant correlation between a positive IWT with abnormal sensation of bladder filling and inability to inhibit micturition voluntarily. A negative IWT also corresponded with the occurrence of phasic detrusor contractions during cystometry. The IWT may be useful for functional subdivision of overactive bladders. In patients with voiding dysfunction in the absence of LUT inflammation, a positive test is an indicator of a silent or overt neurological disorder. Geirsson [92] reported positive or a false negative IWT in a large cohort study. Geirsson and Fall [93] used the IWT in patients suspected of DSD (cystometry and needle EMG). A positive test with a high detrusor pressure was stated to indicate DSD, whereas the contrary applies to the negative test. All patients who responded to cold stimulation with detrusor contraction but without fluid leakage (called positive non-leakage IWT), manifested DSD on EMG. The authors concluded that the simpler IWT could substitute for a needle EMG study.

Ishigooka et al. [94] evaluated urinary bladder sensation to ice water instillation in patients with diabetes mellitus. There was no apparent relationship between prevalence of peripheral neuropathy and that of negative sensation of IWT. Impairment of ice water perception was less frequent than that of mechanoreceptor sensation in patients with diabetic cystopathy.

Ronzoni et al. [95] studied the IWT in 148 patients with neurologic bladder dysfunction resulting from a traumatic lesion and in 130 patients with neurologic bladder dysfunction and multiple pathogenic disorders. IWT was positive in 95% of patients affected by complete and in 86% of patients with incomplete medullary lesions. The IWT in patients with lower motor neuron medullary lesions was always negative. The test was used diagnostically in patients with lower motor neuron lesions. In those with upper motor lesions it was used as a rehabilitation method during the medullary-shock phase to accelerate the appearance of the micturition reflex. In 9% of patients it was used to induce micturition during cystography. The authors consider IWT as a useful complement to urodynamic examinations in patients with neurological bladder disease. By contrast, Chancellor et al. [96] found lack of sensitivity and specificity of the IWT in SCI patients and concluded it did not contribute to their management. Autonomic dysreflexia can occur during evaluation. Since the IWT is an unphysiological investigation that might significantly bias subsequent urodynamics, Kozomara et al. suggest that the IWT should not precede more physiological standard urodynamic investigation [97].

Repeating the IWT has been shown to increase its positivity [98]. Combining the IWT and electrical perception threshold (EPT) testing will reinforce the results of both tests and can indicate more clearly the possibility of an unsuspected neurologic pathologic finding in patients with idiopathic DO. In multiple sclerosis it may have pathophysiological value, indicating a spinal rather than cerebral mechanism of overactive bladder, and diagnostic value, indicating multifocal demyelination [99].

Conclusions:

- The majority of published studies show value of the IWT in the diagnosis of NLUTD and in the differentiation between reflexic and areflexic neurologic bladder (LOE 2)

Recommendation:

- The ice water test is an optional test which should be interpreted in the context of all data from the diagnostic evaluation, but should not precede regular UDS (B)

Bethanechol supersensitivity test (BST)

Bethanechol is a muscarinic agonist which may improve bladder emptying in some non neurologic patients, and correspondingly increase bladder sensitivity [100]. The BST was developed by Lapides et al. in 1962 [101] to try to distinguish between a neurologic and a myogenic aetiology in an acontractile bladder. It is based on the observation that after an organ is deprived of its nerve supply, it develops hypersensitivity to the normal excitatory neurotransmitters. A neurologically intact bladder should have a pressure increase of less than 15 cm H2O above the control value, whereas a denervated bladder shows a response greater than 15 cm H2O. The clinical utility has not been studied in detail recently.

The test is considered unreliable by some [102]. Penders [103] considered the test reliable when the indications are good (large capacity, hypotonic bladder, clinical suspicion of lower neuron lesion) and when the interpretation is based on a right under-
standing of its mechanism. Pavlakis et al. [104] suggest that the BST is more sensitive and more specific than perineal floor electromyography in corroborating bladder neuropathy. Sidi et al. [105] studied patients with neurologic or non-neurologic detrusor areflexia with the BST, EMG of the urethral rhabdosphincter and bulbocavernous reflex latency and found the sensitivity of these tests in detecting neurologic mechanisms to be 90, 87.5 and 78.1%, and the specificity 96, 76 and 80%, respectively. When all three tests were performed together, the combined accuracy approached 100%. They conclude that these combined tests are useful in the diagnosis of patients with equivocal bladder neurologic conditions and in those with subtle neurological lesions. Denervation supersensitivity to bethanechol was demonstrated in acute idiopathic autonomic neuropathy [106].

Wheeler et al. [107] found the positive BST not diagnostic of neurologic detrusor areflexia because of the many variables that can influence the test. In a later study, the same group [108] suggested that flow rate, surface electromyography, and bethanechol supersensitivity test cannot help differentiate neurologic from non-neurologic detrusor failure. Although no test can accurately differentiate neurologic from non-neurologic female urinary retention, careful neurourologic evaluation will help guide to more appropriate management.

Conclusion:

- The literature on the value of the bethanechol test for the diagnosis of neurologic pathology is contradictory. The test may contribute to overall evaluation of neurologic LUT dysfunction. (LOE 2)

Recommendation:

- The bethanechol supersensitivity test has limitations, and results should be interpreted in conjunction with established diagnostic results. (B)

Electrodiagnostic tests

EMG of the urethral sphincter

EMG of the urethral sphincter has been used for decades in the diagnosis of NLUTD; its value in practice remains uncertain. Use of needle or surface electrodes is debated. Urethral concentric needle electrodes were found to be superior to surface patch electrodes for evaluating relaxation of the muscle during voiding in neurologically intact women [109].

Nordling and Meyhoff [110] used cystometry in combination with urethral and anal sphincter EMG in patients with suspected NLUTD and found anal sphincter EMG to be highly unreliable. Koyanagi et al. [111] also found discordant activities between the anal and the external urethral sphincters in 39% of male patients with SCI. The degree of bladder dysfunction was related more to the degree of dyssynergia of the urethral than the anal sphincter. Nevertheless, Podnar states that anal sphincter EMG is the most useful diagnostic test, particularly for focal sacral lesions, and atypical Parkinsonism [112]. Fowler et al. [113] introduced a technique of recording EMG activity of striated muscle in the urethral sphincter by using a concentric needle electrode and an oscilloscope with a delay line and trigger. Individual motor units were isolated and measured. Vodusek also studied individual motor units [114]. Both conclude that quantitative EMG may be a helpful technique in the investigation of patients with disorders of micition.

Ziemann and Reimers [115] found the sphincter EMG the most sensitive technique in the diagnosis of chronic pudendal lesions. However, pure afferent lesions cannot be detected by the sphincter EMG. In this case, the BCR, using unilateral stimulation of the dorsal nerves of the penis, provides the opportunity to distinguish between afferent and efferent lesions of the sacral innervation. Fowler [116] concluded that sphincter electromyography (EMG) is valuable for identifying patients with Parkinsonism who have multiple system atrophy. Tests which examine aspects of nerve conduction velocity have proved to be of lesser value both because such investigations test conduction of nerve fibres rather than levels of innervation. Furthermore, they examine large myelinated fibre conduction, rather than the unmyelinated fibres which comprise the autonomic innervation. Sphincter EMG is a diagnostic test of Fowler's syndrome in young women with urinary retention [117]. Sphincter EMG can be used in gauging timing of stimulation for suppressing DO [118].

De E J et al. [119] found a significant disagreement between needle EMG and voiding cystourethrogram (VCUG) for diagnosis of DSD. A combination of EMG and VCUG may identify more cases of DSD than either modality alone and underscores the need for more strict criteria when defining this entity from a urodynamic standpoint.

Anal sphincter EMG as well as external urethral sphincter EMG can be used to detect the onset of detrusor contractions in patients with both neurogenic detrusor overactivity (NDO) and detrusor sphincter dyssynergia (DSD) opening a door for the use of triggered devices to inhibit unwanted contractions through continuous electrical stimulation of sensory nerves [120,121]. Light et al. [122] found in patients with detrusor areflexia and a high spinal cord lesion, EMG of the pelvic floor muscles is the neurophysiological test which best predicts detrusor contractility.

EMG of the urethral sphincter has been used to investigate retention in multiple-system atrophy [123], LUT function in Machado-Joseph disease [124], the impact of pregnancy and delivery on vesico-urethral disorders in patients with multiple sclerosis [125] and children with cerebral palsy [126].

ICS Guidelines on urodynamic equipment standardization recommend that EMG during urodynamics should have high input impedance greater than 100 MOhm, a common-mode rejection (CMRR) greater
than 80, and a filtering program to best produce a consistent EMG during testing [127].

**EMG of Detrusor muscle**

Detrusor EMG has not been widely studied in neurologic patients. La Joie et al. [128] recorded simultaneous EMG recordings from the bladder detrusor muscle and the inferior rectus abdominis muscle in 6 normal subjects, in 4 patients with LMN bladder disease and in 2 patients with an UMN type of bladder lesion. The bladder electrodes did not appear to record muscle activity remote from the abdominal muscles so that any increased detrusor electrical activity with abdominal contraction must have some other explanation. Kaplan and Nanninga [129] analysed detrusor EMG in upper motor neuron type NLUTD. Kinder et al. did not advocate detrusor EMG [130]. Recent data are lacking and so the technique cannot be considered a standard diagnostic test.

**Conclusion**

- Sphincter EMG can be valuable in the diagnosis of patients with neurologic bladder dysfunction (LOE 2).
- Detrusor EMG is not established as a diagnostic test

**Recommendation:**

- EMG of the urethral sphincter can be considered as a specialized diagnostic method in patients with neurologic LUT dysfunction and neurologic urinary incontinence (B B)

**Dynamic Bulbocavernous reflex (BCR)**

Walter et al. [131] studied dynamic BCR during micturition induced by using periodic dorsal penile nerve stimulation; the evoked reflex response was recorded with an anal sphincter pressure sensing balloon. Results indicate that an enhanced BCR is a factor contributing to increased urethral resistance during micturition.

Kaiho et al. [132] recorded the evoked potential of the BCR (BCR-EP) with a concentric needle electrode at the periurethral striated muscle. They found BCR-EP was suppressed during voluntary voiding in normal subjects, but it was insufficiently suppressed in the patients with NLUTD. It was suggested that the measurement of BCR-EP could distinguish involuntary voiding caused by pathologic urethral sphincter relaxation from voluntary voiding. The same group [133] investigated the change of sacral reflex activity of the striated urethral sphincter in the urine storage phase with BCR-EP in normal male subjects and male patients with NLUTD due to suprasacral spinal cord injury. Sacral reflex activity was accelerated by bladder filling in both the normal subjects and SCI patients, particularly in the latter. In addition to the conventional evaluation of the integrity of sacral reflex arc by BCR examination, the observation of changes of BCR affected by bladder filling may provide information on the continuity of sacral segment and supraspinal micturition centre. Niu et al. showed that in 8% of patients with SCI and in 70% of patients with peripheral nerve lesions the BCR was abnormal [134].

**Motor evoked potentials**

Motor evoked potentials (MEP) has been used to assess neurogenic lesions affecting the urethral compressive musculature with simultaneous recording of evoked pressure curves [135]. MEP recording is an accurate and easily applicable test for the diagnosis of lumbosacral spinal cord lesions [136].

**Nerve conduction studies**

In patients with diabetes mellitus, conduction velocities are decreased [137]. Vereecken et al. [138] found urethral and anal responses produced by electrical stimulation of penis, bladder neck and anus were delayed and the duration reduced. Carbone et al. [139] assessed the effect of urinary bladder filling on the excitability of somatic spinal motor neurones in patients affected by neurogenic and non-neurogenic DO and proposed that H-reflex modulation may be considered a tool in the differential diagnosis of voiding dysfunctions.

**Somatosensory evoked potentials**

In the committee’s literature search, no recent publications were found on somatosensory evoked potentials (SSEP). Badr et al. [140] described techniques of recording evoked potentials in humans in response to stimulation of the urinary bladder. Galloway et al. [141] described a method of sacral evoked response to measure the integrity and function of the lower sacral segments by stimulation at the urethral and anal sphincters.

Mochida et al. [142] studied evoked spinal cord potentials (ESCP) in surgical patients with cervical myelopathy. The presence of NLUTD was closely correlated with severe limb symptoms and with relatively slow ESCP velocity. However, for 47% of the patients with urinary complaints, findings of urodynamic examinations were negative; these patients may have had pathologic or psychosomatic factors other than neurogenic bladder due to cervical myelopathy.

Curt et al. [143] studied the significance of SSEP recordings in predicting the recovery of bladder function in acute, traumatic spinal cord injury (SCI). They found a good correlation with the recovery of the external urethral sphincter function, but not with the urodynamic impairment. SSEP in response to stimulation of the tibial nerve have been studied in patients with hyperactive urinary bladder to clarify their role in prognosis of tibial neuromodulation efficacy [144].

**Afferent nerve recording on sacral roots**

Afferent nerve activity from the sacral dermatome, bladder and rectum can be recorded using cuff elec-
Electrosensation in the LUT

Measurement of the sensory threshold of the LUT towards electrical stimulation was attempted as early as 1899 [147]. After re-introduction of the technique by Markland et al. [148] several authors have studied its value in neurologic bladder dysfunction. Kieswetter [149], and Powell and Feneley [150] demonstrated abnormal electrosensation in patients with NLUTD. Frimodt-Møller [151] described pathological electrosensation in patients with Parkinson’s disease, multiple sclerosis and meningomyelocoele. He also found abnormal electrosensation in half of patients with diabetes and generalized sensory neuropathy, but only in 10% of the diabetic patients with a neurologic bladder. Electro sensation was present in many meningomyelocoele patients with absent skin sensation and absent reflexes, and in many patients with suspected complete spinal cord injury on clinical evaluation [78,79].

Wyndaele [152] determined the threshold of sensitivity to electrical stimulation in several parts of the LUT in 436 consecutive patients. In the groups with different patterns of disturbed sensation a higher incidence of neuropathy was found than in the group with a normal sensation. Further neurological investigation revealed abnormal innervation in 29% of patients who lacked electrosensitivity in one or more parts of the LUT but who had no previous evidence of neuropathy.

Standardization is necessary to develop the technique and achieve reproducible results [153]. While it is a constructive concept to be able to determine threshold of different fibre types selectively [154], so far no such fibre selectivity has been demonstrated in the bladder [155]. In the committee’s literature search, no recent publications were found.

Conclusion:
- To determine the electrosensation in the LUT might be valuable to evaluate the afferent innervation in cases of neurologic bladder.
- Absent electrosensitivity might guide further neurologic tests in patients with LUT dysfunction (LOE 2)
- Further development and standardisation is needed for the use of electrosensation test to become established as a clinical test.

Functional Magnetic Resonance Imaging (fMRI)

fMRI has been used as a research tool in patients with overactive bladder [156-158], but only a single study has been conducted in SCI patients with neurogenic LUTD [159]

Neuroimaging-positron emission tomography (PET) and single-photon emission computerized tomography (SPECT).

Novel functional brain imaging study (PET) showed evidence for the existence of abnormal interaction between brainstem and cortical centers in women with urinary retention [160]. There are however only limited reports on using these studies in NLUTD, mainly in Parkinson’s disease [161-165]. A report on using SPECT brain imaging with special reference of bladder function, performed in eight multiple system atrophy (MSA) patients suggested that the decrease in tracer activity in the cerebellar vermis during urinary storage and micturition is contributing to the micturitional disturbance in this disorder [161].

Conclusion:
- These tests are still restricted to specialized centres and are considered as a research tool rather than diagnostic test.

Sympathetic skin response

Schurch et al. [166] assessed the descending sympathetic spinal tract and correlated these findings with bladder neck function in SCI patients. Evidence was presented that the integrity of the descending sympathetic spinal tract is necessary for a synergic function of the vesicourethral complex and that sympathetic skin responses (SSR) are of value in the diagnosis of bladder neck dyssynergia. SSR’s are absent in case of bladder neck dyssynergia. For lesions below the T12 level, other investigative methods to exclude bladder neck dyssynergia are necessary. Rodic et al. [167] found that recording the perineal SSR in addition to that of the hand and foot represents a sensitive diagnostic tool for assessing sympathetic nerve function within the thoracolumbar spinal cord, representing a reliable and accurate diagnostic tool for assessing bladder neck competence and incompetence.
Emad et al. showed abnormal suprapubic, palmar, and plantar SSR in urinary incontinence patients due to incomplete SCI. They considered an abnormal SSR from the suprapubic area as another way to show bladder sympathetic system involvement [168].

SSR recordings above a spinal lesion level after urethral electrostimulation might provide a useful and technically simple objective diagnostic tool to assess integrity of autonomic (visceral) afferent nerves from the LUT. Somatosensory deficits are not always paralleled by viscerosensory loss and vice versa. SSR may be superior to visceral sensory evoked potentials, which are more difficult to record. The clinical utility needs to be further studied.

### Conclusion

- Sympathetic skin responses may help evaluate the integrity of LUT-related sympathetic function, including bladder neck competence and synergia (LOE 2)

### 3. CONSERVATIVE TREATMENT

Therapeutic principles in different patterns of NLUTD depend on the underlying processes: dysfunction of the detrusor, dysfunction of the sphincter or a combination of both. Neurogenic detrusor overactivity leads to “reflex-incontinence”, detrusor acontractility with incontinence due to retention (overflow incontinence). An acontractile (incompetent) sphincter causes neurogenic stress-incontinence, an overactive sphincter overflow-incontinence. Quite often detrusor and sphincter are affected simultaneously by the neurogenic lesion. In most patients the storage problem, leading to incontinence, is associated with an emptying problem; therefore both aspects have to be considered at the same time. Therapy of neurogenic incontinence is primarily a conservative one. Timed bladder emptying, by whatever means, controlled fluid-intake and avoidance of urinary tract infections are the prerequisites for successful treatment.

If incontinence persists, and if operative procedures are not indicated or possible, containment products will be needed. The indwelling catheter remains an option for conservative therapy, and can offer acceptable quality of life outcomes [1]. However, most experts regard indwelling catheterisation as being associated with significant problems [3]. While suprapubic catheters are generally preferred over urethral, there is little evidence on which to base practice [4]. Urethral leakage can persist despite continuous drainage with a SPC either due to persisting detrusor overactivity (DO), induced or aggravated by UTI, then pharmacological inhibition of DO as well as UTI treatment/prophylaxis need to be considered. Bladder neck closure is rarely indicated [5].

#### 3.1. Overview according to type of lesion

The aim of neurogenic bladder management is to preserve kidney function and to control incontinence resp. to restore continence.

**Supraspinal lesions (previously included in upper motor neuron lesions)**

In supraspinal lesions, neurogenic DO is mostly combined with normal sphincter function; overactivity incontinence is the main symptom and behavioural treatment together with antimuscarinic therapy is the method of choice, especially in patients with cognitive impairment. Antimuscarinics are able to increase the bladder capacity but are not able to change the underlying pathophysiology.

**Spinal lesions**

They mostly cause simultaneous dysfunction of the detrusor and the sphincter.

**Suprasacral spinal lesions (previously included in upper motor neuron lesions)**

In suprasacral lesions, the spinal reflex bladder manifests the combination of DO with an overactive/ dysnergic sphincter. For these patients, spontaneous reflex voiding may be possible. However, detrusor contractions may be inadequate and detrusor striated sphincter dysynergia present, both potentially leading to inefficient voiding. Triggered reflex voiding is recommended only if it is urodynamically safe and reflex incontinence is manageable; accordingly, careful support is needed to achieve adequate symptom control [6] and long-term renal safety [2]. The method of choice nowadays is – at least in complete lesions – to circumvent the spastic sphincter by intermittent catheterisation. Treatment to lower tone and spasticity of the urethral sphincter can be used to aid emptying, especially in incomplete lesions using sphincterotomy [7], stenting [8] or repeated botulinum toxin injections into the sphincter [9]. Any unit managing patients with SCI should be appropriately set up to manage acute autonomic dysreflexia. Sphincterotomy may help in reducing episodes of autonomic dysreflexia [11].

The mainstream of treatment in current practice is intermittent catheterisation (IC) [12], undertaken by the patient or carer. However, to achieve low pressure LUT urine storage and continence between catheterisations, additional pharmacotherapy may be necessary. If bladder inhibitory agents fail or are not tolerable, electrotherapy is an alternative in incomplete lesions: ano-genital electrostimulation (penile, clitoral, vaginal and anal) can inhibit neurogenic detrusor overactivity by stimulating pudendal nerve afferents (see Electrical neuromodulation section).

**Sacral/subsacral spinal cord lesions (previously called lower motor neuron lesions)**

For complete conus lesions, acontractility of the detrusor with acontractility of the sphincter is character-
istic. Sphincter incompetence causes neurogenic urinary stress incontinence and may be combined with dribbling incontinence if adequate emptying is not achieved. Conservative treatment to achieve continence is often unsuccessful. Bladder expression is potentially dangerous, and pharmacotherapy is not helpful in this situation. Accordingly, appliances and condom catheters are often necessary, and consideration of suitability of surgery may be needed [9].

Acontractility of the detrusor combined with overactivity of the sphincter may occur in epiconal lesions. This pattern may also result from decompensation of a neurogenic overactive bladder after chronic urinary retention. With this combination, overflow incontinence can be controlled by intermittent catheterization—mostly without adjunctive additional pharmacotherapy. If intermittent catheterization is not possible, an indwelling catheter, preferably suprapubic (expert opinion), may be needed. If overactivity of the detrusor is combined with acontractility of the sphincter, reflex incontinence is combined with neurogenic stress incontinence. This pattern is sometimes found in epiconal lesions, especially in myelomeningoceles. Agents inhibiting abnormal bladder pathways may diminish neurogenic detrusor overactivity. In incomplete lesions, electrical stimulation of the pelvic floor musculature may improve sphincter function. However, with this type of neurogenic LUT dysfunction, conservative treatment alone is generally unable to restore continence; therefore either appliances or operative treatment must be considered.

Cauda equina and peripheral nerve lesions are often incomplete. Hypospastic or acontractility of the detrusor may also be combined with a normally functioning external striated sphincter, a combination which can be seen after intrapelvic surgery, when the pudendal nerves remain intact. Conversely, pudendal nerve lesions in which the pelvic plexus remains intact, a combination of a normally functioning detrusor with a hypo- or acontractile external sphincter may be present. If there is DO, pharmacotherapy is the first choice treatment. For some lesions, intravesical electrotherapy has been reported to increase detrusor contractility [13]. Repeated injection of botulinum toxin in the striated sphincter is a potential treatment option, not well accepted as retreatment may be necessary maybe already after three months.

### 3.2. Specific interventions

During the acute period of spinal or cerebral shock, bladder management comprises proper bladder drainage. For the post shock period, or for non-acute neurogenic dysfunctions, several conservative treatments are in use [14, 15]:

a. Behavioral therapy
   a.1 Triggered reflex voiding
   a.2 Bladder expression (Crédé and Valsalva maneuver)
   a.3 Toileting assistance

b. Catheters and appliances
   b.1 Intermittent catheterization
   b.2 Indwelling catheterization
   b.3 Condom catheter and external appliances

c. Pharmacotherapy

### Triggered reflex voiding

“Automatic” or spinal “reflex” bladder behaviour can occur following recovery from spinal shock in suprasacral spinal cord lesions. This can be used as a means to empty the bladder, using voluntary approaches to provoking a bladder contraction by stimulation of the sacral and lumbar dermatomes. The most commonly used manoeuvres are suprapubic “tapping”, thigh scratching and anal/rectal manipulation. A quadriplegic patient who is unable to perform ISC or has nobody who can do it for him may choose this option, however, mostly incontinence aids are necessary and post-void residual urine is present (see below).

If the efferent branches of the pelvic nerve are impaired, reflex emptying is much less complete, and considerable voluntary straining is additionally required to empty the bladder to a satisfactory degree. Integrity of the sacral reflexes predicts the potential to use this approach.

The aims of regular triggered reflex voiding are to achieve “balanced voiding”, decreasing incontinence but ensuring safe (low pressure) urodynamic function. The possibility of collecting the urine in a socially acceptable way and a reasonable time period for bladder emptying are needed. Frequency of emptying has to be specified for each patient. Whether bladder outlet obstruction is present also has to be considered; this is not often considered in published literature. To improve emptying, control autonomic dysreflexia related to bladder filling and contraction, and avoid upper tract damage, the effect of alpha-blockers is still discussed controversially, botulinum toxin sphincteric injections have to be repeated periodically. Sphincterotomy and/or bladder neck incision may sometimes be needed. Regular follow-up is essential, though the frequency of check-up appointments is not validated.

Triggered voiding should not be recommended as first line management; in current practice, IC is the accepted standard for continence, upper urinary tract protection and improvement of quality of life.

### Conclusions

- Reflex voiding is based on an unphysiological sacral reflex. It is potentially dangerous and has a limited role in managing the reflex bladder (LOE3).
- Costs of appliances and of adjuvant therapies (pharmacotherapy, surgery, urethral prosthesis etc) have to be evaluated (LOE 2).
Bladder expression (Crédé and Valsalva)

Bladder expression comprises various techniques aimed at increasing intravesical pressure in order to facilitate bladder emptying. The most commonly used are the Valsalva (abdominal straining) and the Crédé (manual compression of the lower abdomen). It has been recommended for a long time for patients with a combination of an acontractile detrusor with an acontractile sphincter or with an incompetent urethral closure mechanism of other origin (e.g. after sphincterotomy). Difficulties in emptying the bladder by expression may either be due to an inability to open the bladder neck or due to compression of the membranous urethra on its way through the pelvic floor even if it is flaccid during these manoeuvres. Therefore, especially in men, these techniques may induce a functional obstruction at the level of the membranous urethra despite complete paralysis of the musculature of the pelvic floor. Over time, patients may manifest problems such as reflux into the prostate and seminal vesicles, or epididymo-orchitis. Moreover, the high pressures could cause reflux into the upper urinary tract. The stress to the pelvic floor with these techniques several times a day also can make incontinence worse, and causes additional genital-rectal prolapse and haemorrhoids.

Adjunctive therapy to decrease outflow assistance includes alpha-blockers, sphincterotomy or botulinum toxin injections. If effective, they usually cause or increase neurogenic urinary stress incontinence. Expression of the bladder for voiding by Crédé and Valsalva can be effective. To empty the bladder, the pressures measured may be high and potentially dangerous for the upper urinary tract. Bladder expression is often not safe. Sphincter-hyperreflexia and detrusor-sphincter dyssynergia are contra-indications for bladder expression.

Conclusions

- Bladder expression by Valsalva or Crédé is potentially hazardous for the urinary tract due to functional obstruction at the level of the pelvic floor (LOE 3).
- It is contraindicated if it creates a high intravesical pressure, particularly in association with reflux into the ureters or seminal vesicles. Hernias, pelvic organ prolapse, haemorrhoids and urethral pathology (strictures) are relative contraindications (LOE 3).
- Bladder expression may adversely affect a flaccid pelvic floor, potentially exacerbating incontinence (LOE 3).
- Alpha-blockers, sphincterotomy or botulinum toxin may reduce the outflow resistance, but may also induce or increase urinary stress incontinence (LOE 3).

Recommendations

- Before recommending bladder expression by Valsalva or Crédé, it must be proven that the LUT is urodynamically safe. (B)
- Exclude contraindications, such as vesico-ureteric reflux, pelvic organ prolapse, hernias, urethral pathology and symptomatic UTIs before recommending this type of bladder emptying. (B)
- In general, bladder expression should be replaced by CIC in most patients with neurogenic bladder-sphincter dysfunction. (B)
- Adjunctive therapy of outflow obstruction can be considered. (B).

Toileting assistance: timed voiding, habit retraining, prompted voiding

See also the chapters on adult conservative treatment and frail elderly.

Adaptation of the drinking and voiding regimen requires education and can be implemented by the patient and/or caregivers. The aim of the behavioural process in adults is to re-establish the control of urinary incontinence. The goals include correcting faulty habit patterns of frequent urination, improving ability to control bladder urgency, prolonging voiding intervals, increasing bladder capacity, reducing incontinent episodes, and building a patient’s confidence in controlling his/her bladder. In dependent patients all these techniques can be proposed and tried, provided that caregivers (physiotherapist, nurse, family members, etc.) are supportive.

Timed voiding is characterized by a fixed interval between toileting, e.g. every two hours. It is a passive toileting assistance program, initiated and maintained by caregivers. It is considered appropriate for patients who cannot participate in independent toileting. It has
been used where incontinence is associated with cognitive and/or motor deficits. Its aim is more to avoid incontinence than to restore a normal bladder function. For neurologic patients it has also been considered as an adjunct to tapping and/or Crédé manoeuvre and/or intermittent catheterisation. Timed voiding can also be recommended in the management of patients with excessive bladder volumes, exemplified by diabetic patients with impaired bladder filling sensation. With habit retraining the intervals between toileting are based individually on the voiding diary. As with timed voiding also the aim of habit retraining is to help patients to avoid incontinence by decreasing voiding intervals. Prompted voiding is used to teach people to initiate their own toileting through requests for help and positive reinforcement from caregivers. These techniques are more suited to patients with brain diseases than spinal cord diseases, and for patients with cognitive and/or motor deficits. Such a program is very useful for institutionalised patients, there are no specific evaluations on neurologic patients in the literature.

Conclusions

- Behavioural techniques should be used in conjunction with other therapies (pharmacological treatment, catheterisation) (LOE 2).
- When appropriate, toileting assistance should be used to improve continence of neurologic impaired patients (LOE 3).
- Timed voiding, habit retraining and prompted voiding may be able to decrease incontinence episodes. Patients likely to benefit from the technique are those with less cognitive impairment and higher dependency (LOE 2/3).

Recommendations

- Behavioural techniques are a suitable component of the rehabilitation program for each individual. (C)
- There are no guidelines or consensus on suitable intervals for bladder emptying. They should ideally be derived from the voiding diary and other related factors (bladder volume, fluid intake, post-void residual urine volume, urodynamic parameters). (C)
- The mental status of a patient must be taken into consideration, and a rehabilitation program realistically tailored to the patient’s possibilities. (B/C).

Intermittent catheterization

Intermittent catheterization (IC), including intermittent self-catheterization (ISC), aims to resume normal bladder storage and regularly complete urine evacuation. They avoid some of the complications of indwelling catheterization (IDC). IC can improve incontinence, or make patients with neurogenic bladder continent, if; bladder capacity is sufficient, bladder pressure is kept low, urethral resistance is adequate, and fluid intake is balanced with frequency of catheterization. In children with SCI, IC used with anticholinergic drugs appears to minimise upper urinary tract deterioration, improve continence and decrease infections; safe increase in capacity appears to increase with growth [16, 17]. Post-void residual signifying the need to institute IC remains to be clarified. However, Dromerick et al. [18] (LOE 2) demonstrated in a series of stroke patients that a post-void residual greater than 150 ml is an independent risk factor for development of UTI.

Most appropriate technique and catheter depend on individual anatomic, social and economic possibilities [19] (LOE 1). Two main techniques have been adopted, aseptic IC (IC) and clean IC (CIC). The aseptic non-touch technique involves the use of sterile materials each time and insertion of the catheter “out of the sheath” without touching it directly (“non-touch technique”). In an intensive care unit, some advocate wearing a mask and a sterile gown as well [20]. De Ridder et al. [21] compared SpeediCath hydrophilic-coated catheters versus uncoated polyvinyl chloride (PVC) catheters, in SCI patients. This 1-year, prospective, open, parallel, comparative, randomised, multi centre study included 123 male patients injured within the preceding 6 months. Primary endpoints were occurrence of symptomatic UTI and hematuria. Secondary endpoints were development of urethral strictures and convenience of use. The results indicate a beneficial effect regarding UTI when using hydrophilic-coated catheters. Bjerklund-Johansen et al. evaluated patient willingness to change and satisfaction with catheters for IC in neurogenic bladder dysfunction. They also compared patient response to conventional catheters and a packaged hydrophilic catheter: LoFric Primo [22]. 409 neurogenic patients were recruited and 378 (283 males, 95 females; mean age 43.5 years) completed a short-term trial. Patient satisfaction was expressed on a Visual Analogue Scale for seven topics covering use and general satisfaction. Differences regarding satisfaction, handling, time spent, and ability to cope with daily life were reported. Kovindah and Madersbacher investigated whether a silicone catheter reused over years for clean IC was safe for men with SCI [23]. Reused silicone catheter appeared to function as well as disposable. However, to reuse urinary catheters, one should consider the increased risk of infection. The authors suggest that for SCI patients in developing countries, CIC with a reusable silicone catheter may be a suitable and safe choice if one cleans and applies it. In the same way, Getliffe performed a systematic Cochrane review summarizing current evidence on the relationship between sterile single-use catheters or clean reused catheters and the incidence of UTIs [24]. 13 trials met the inclusion criteria. There was considerable variation in length of follow-up, definitions of UTI, and numbers of subjects. Attrition was a problem for several studies, and all were underpowered. Several studies were more than 10 years old,
and outcome measures were imprecise, making it difficult to draw conclusions on the benefit of one catheterization method over another. They concluded that there are no definitive studies illustrating that incidence of UTIs is affected by sterile single-use or coated catheters compared to clean reused catheters. However the current research base is weak and design issues are significant. Based on the current data, it is not possible to state that one catheter method is better than another and further research is needed (LOE1). Research to evaluate clean vs. sterile PVC catheter use, and coated vs. uncoated catheter use (both sterile and reused), is needed. It seems that single or multiple use silicone catheters are becoming more popular especially in Asian countries, studies are available only from the Japanese silicone catheter [25].

Frequency of catheterization depends on many factors, e.g. bladder volume, fluid intake, post void residual, and urodynamic parameters (compliance, detrusor pressure). Usually it is recommended to catheterize 4 – 6 times a day during the early stage after spinal cord lesion. Some will need to keep this frequency if IC is the only way of bladder emptying. Others will catheterize 1 – 3 times a day to check and evacuate residual urine after voiding. To overcome high detrusor pressure, adjunctive therapy with antimuscarinic drugs or other bladder relaxants can be indicated. For those who develop a low compliance bladder, upper tract deterioration or severe incontinence, injection of Botulinum toxin in the bladder wall or surgery, such as bladder augmentation, may be necessary.

If catheterization is begun by patients with recurrent or chronic UTI and urinary retention, the incidence of infection usually decreases. If symptomatic infections occur, improper CIC or misuse should be considered. Chronic infection persists if the cause of the chronicity remains. Treatment of UTI is necessary if the infection becomes symptomatic. Lindehall et al. evaluated the rate of complications associated with catheterization and the risk of urethral lesions in myelomeningocele treated with clean IC for a minimum of 10 years. They found that there were remarkably few problems [26]. The incidence of major urethral lesions did not increase during puberty. Larger catheters seemed to be protective against major lesions [27] (LOE3). In contrast, Chen et al. found that the incidence of urethral strictures increases with a longer follow-up, and bladder stone formation is associated with long-term use of CIC in SCI patients [28] (LOE3).

Oh et al. evaluated health-related quality of life (HRQOL) with IC in neurogenic bladder. They conducted a prospective trial involving 132 patients (81 men and 51 women, mean age 41.8 years, range 18 to 80 years) with SCI and 150 age and sex-matched controls [29]. Patients using IC have a reduced quality of life in all health domains, as assessed by the SF-36 (LOE2). In another prospective, cross-sectional study involving 102 SCI patients and 110 controls, the same group of researchers found that the risk for depression was 4.6-fold higher in patients unable to perform CIC (LOE2) [30].

Conclusions

- IC in the neurogenic bladder is effective and safe in short- and long-term use. (LOE 1)
- Complications such as UTI are regularly seen and seem to be related to both, the catheterization itself (technique and materials) and the pre-existing LUT condition (LOE 2)
- Urethral and bladder complications seem to increase in the long-term (LOE 3)
- In order to reduce and prevent complications, appropriate materials and correct techniques should be taught, performed and controlled (LOE 3)
- Adequate frequency of IC, a non-traumatizing technique and suitable materials are the key factors for a successful outcome (LOE 2)

Recommendations

- IC is the first choice treatment for those with inability to empty the bladder adequately and safely in neurogenic voiding dysfunction. It is a valuable tool for achieving continence. (A)
- Proper education and teaching are necessary to achieve a good outcome. (B)
- To prevent and reduce complications, a non-traumatizing technique (external lubricant or lubricant coated catheters) with adequate frequency of catheterization and complete emptying should be achieved. (B)
- Annual follow-up is needed. (B/C)
- Due to the poor quality of studies it is currently not possible to state whether any IC method or catheter type is advantageous (Grade D) and further research on the topic is strongly recommended.

Indwelling Catheter (IDC)

The Foley catheter was developed in the early 20th century. After the World War I, most SCI and other neurologic patients were treated with indwelling urethral catheterization (IDUC) or suprapubic catheterization (SPC) due to difficulty in voiding or urinary incontinence. While IC is nowadays recommended for neurologic patients, many still choose IDC due to difficulty in performing IC, or persistent leakage between catheterizations. In developing countries, IDC can still be the method of choice for those with urinary retention or incontinence. IDC placement requires meticulous technique. More frequent catheter changes may be needed in patients with recurrent UTIs. IDC can cause various complications, such as; urethral trauma and bleeding,
urethritis, bladder stones, cystitis, acute and chronic UTI, bladder neck incompetence, meatus and urethral sphincter erosion, and bladder carcinoma. Fistulas can result from pressure effects, caused by improper catheter size and inadequate securing technique, particularly with long-term use. Therefore, many experts advocate removal of an IDUC as soon as possible, and usage of other methods such as IC or SPC. Nowadays the complications of IDUC seem less, presumed due to better materials, judicious size selection and a proper technique of securing the catheter. For CIC wet patients, overnight IDUC self-placement seems to decrease risk of febrile episode due to UTI, as compared to CIC alone [31].

In the morning, the catheter was removed, washed with tap water and stored in disinfectant (LOE3).

The study by Pannek (LOE 3) reported an incidence 0.11% for bladder cancer in catheterised SCI individuals (48 out of 43,561 patients), similar to that observed in the general population [32]. However, more than 60% of the patients with SCI initially presented with muscle-infiltrating bladder cancer. Hypothetically, the expression of inducible nitric oxide synthase with IDUC [33] might predispose to formation of potentially carcinogenic nitrosamines in the bladder. Hamid et al. [34] did not find bladder cancer on bladder biopsies in patients with SCI and a mean IDUC use of 12.1 years. Literature remains conflicting as in a recent series of 129 consecutive patients suffering from NLUTD for at least 5 years, investigation with bladder washing cytology and urethrocytoscopcy identified a range of relevant histological findings (bladder melanosis, nephrogenic adenoma, keratinizing squamous metaplasia, intestinal metaplasia, and muscle-invasive adenocarcinoma) in 5% of them [35]. Nevertheless, both general guidelines on bladder cancer (EAU)[36] and more specific spinal cord medicine guidelines [37] recommend urethrocytoscopcy and/or cytology as part of routine follow-up for patients with NLUTD.

Routine antibiotic prophylaxis for patients with IDC is not recommended. Attempts at eliminating bacteriuria associated with indwelling or intermittent catheters are generally unsuccessful [38, 39] (LOE 4). For prevention of UTI, general cleanliness and local hygiene should be encouraged. In symptomatic UTI, it is important to consider catheter blockage and problems such as urinary stones. Symptomatic UTIs have to be treated with the most specific, narrowest spectrum antibiotics available for the shortest possible time. Guidelines for selecting antimicrobial agents in SCI patients are similar to guidelines for the treatment of complicated UTIs in the general population. Characteristics of the quinolones make them well suited for treating UTI in SCI patients [40] (LOE 4). Recommendations of the local microbiology department should be sought.

The benefit and risks of SPC are similar to IDUC, including the risk for UTI, stone formation and maintenance cost of catheter and bag. Advantages include:

- Long-term IDUC use in neurologic patients can predispose to complications. (LOE 2)
- Catheters should have as large a lumen as possible to maximise time to blocking by encrustation (12-14 Fr silicone catheters in men and 14-16 Fr silicone catheters for women), and 5-10 ml self-retaining balloons to minimise the pressure effect on the bladder neck. (LOE 4)
- Closed drainage systems are associated with lower infection risk. (LOE 1)
- Frequency of change largely depends on time to blockage, which is influenced by catheter materials and lumen, patient factors and infection. (LOE 3)
- SPC is a reasonable alternative to IDUC, but IC is the first line intervention (LOE 3).
- SPC is a safe and effective short-term management of urinary retention. (LOE 3)

Recommendations:

- Silicone or hydrogel-coated catheters are preferable. (A/B)
- Use sterile materials and aseptic technique, and routine catheter care in the context of a closed drainage system. (C/D)
- Catheters should be changed regularly, to try to pre-empt obstruction or infection. (C/D)
- Bladder irrigation and antibiotic prophylaxis are not recommended as a routine infection-control measure. Symptomatic UTI should be treated with narrowest spectrum antibiotic possible, according to local microbiology practice. (B)
- Patient education on daily cleanliness (meatus) and hygiene care are mandatory. (C)
- Short-term IDC during the acute phase of neurological injury is a safe management for neurologic patients. (B)
- Long-term IDC should be the last resort and may be safe only if a careful check-up of urodynamic,

Conclusions:
renal function, and upper and lower tract imaging are performed. (B)

- Bladder screening for bladder cancer is strongly recommended, especially those with IDC more than 5-10 years. (C) Annual bladder washing cytology is recommended after the 5th year, which should be combined with urethrocystoscopy after year 10 (B)

- Annual cystoscopy and biopsy may be necessary for those with gross hematuria, or chronic symptomatic UTI refractory to therapy. (C)

- Consider the use of antimuscarinic drugs in individuals with suprasacral lesions using chronic indwelling catheters. (C)

- Patient comfort, convenience, sexuality and quality of life need to be considered. (C)

Condom catheters and external appliances

Male patients with neurogenic bladder and chronic urinary incontinence can be candidates for a condom catheter connected to a collection bag. However, some men have difficulty in applying condom catheters, e.g. due to obesity, penile atrophy or retraction.

Conclusions

- Condom catheters facilitate urinary containment in neurologic male patients (LOE 3)

- Long-term use does not increase the risk of UTI when compared to other methods of bladder management. (LOE 3)

- Complications may be less if technique, hygiene, replacement and maintenance of low bladder pressures are optimised. (LOE 3)

- Due to possible Latex allergy especially in children with congenital NBD silicone condom catheters are to be preferred.

Recommendations

- Size selection should consider control of leakage, and prevention of penile compressive effects. (B)

- Regular bladder emptying with low bladder pressures and low post void residual should be confirmed (B)

4. PHARMACOTHERAPY

This chapter deals primarily with specific issues of continence pharmacotherapy in neurologic patients. For a fuller description of the drugs in use, see chapter 8. The principal causes of urinary incontinence in this subpopulation are neurogenic DO and/or incompetence of urethral closing function. Accordingly, treatment aims to decrease storage-phase detrusor activity, increase bladder capacity and/or increase bladder outlet resistance. This picture is blurred by the occurrence of DSD, which can be present concomitantly with DO. Pharmacologic therapy alone is particularly helpful in relatively mild degrees of neurogenic bladder dysfunction. Patients with more profound neurogenic bladder disturbances may require pharmacologic treatment to improve results of other forms of management, such as IC.

In 2013 Madersbacher et. al published a review on efficacy, tolerability and safety of oral antimuscarinics in patients with neurogenic detrusor overactivity, based on thirty studies, thereof 16 randomized controlled trials, enrolling 1479 patients.

The following conclusions were made: Only oxybutynin, propiverine and trospium were evaluated in large-placebo controlled studies, demonstrating a decrease in the maximum detrusor pressure by 30 - 40% and an increase of maximum cystometric bladder capacity 30 - 40%. Antimuscarinics were able to normalize the intravesical pressure and to increase cystometric bladder capacity. Self selected dosing of AM, exceeding the recommended doses, improve efficacy and tolerability.

However other important parameters were not adequately investigated so far as e.g. achievement of continence inbetween catheterizations in patients on IC, also long-term data were not assessed, despite the fact that most patients with NDO are on antimuscarinic medication life-long.

Therefore the authors proposed that any further study should aim at incorporating not only urodynamic, but also crucial clinical parameters as achievement of continence and long-term results.

In 2016, three years later, an integrative review of standardized clinical evaluation tool utilization in anticholinergic drug trials for neurogenic lower urinary tract dysfunction published by Stothers et al. identified infrequent use of standardized clinical evaluation tools and reporting measures state, that data from future trials evaluating therapies for neurogenic bladder would likely be more applicable to specific patient groups, if current standardized classification and descriptors are used consistently.[1] Still the “ideal” studies are not yet available.

Also between 2013 and 2016 only a comparatively small number of relevant papers were published: 6 with Oxybutynin (Oxy.), 4 of them dealing with children, 3 with Solifenacin, 1 with each Fesoterodine, Propiverine, Imidafenacin and 1 with the “newcomer” Mirabegron. There was no study published during these years with Trospium (only in a study in combination with Oxybutynin [2] and no study with Tolterodine, only in one study with Solifenacin as active control [3].
4.1. Drugs for neurogenic storage dysfunction

Oral bladder relaxants

Antimuscarinics

General indications of pharmacological treatment in neurogenic DO are to improve reflex incontinence, decrease high intravesical storage and voiding pressures and support other interventions e.g. IC and IDC. Antimuscarinic therapy is a symptomatic treatment. In neurogenic DO, antimuscarinics may increase post void residual urine.

The evidence base for the use of antimuscarinics in patients with a neurogenic bladder is limited. In fact, in a recent Cochrane review performed on all current literature regarding anticholinergic therapy for MS-related incontinence, only five usable studies were found, and no conclusion supporting benefit could be drawn from the analysis [4].

Oxybutynin

Oxybutynin hydrochloride is a moderately potent antimuscarinic agent with a pronounced muscle relaxant activity and local anesthetic activity as well- the clinical relevance of the latter is debatable. In a prospective, 12-week dose titration trial of controlled release oxybutynin (OXY-XL), Bennett et al. [5] evaluated the efficacy and tolerability of higher dose oxybutynin chloride in patients with neurogenic bladder and multiple sclerosis, spinal cord injury or Parkinson's disease. A 7-day washout period was used before initiation of the starting dose of 10 mg OXY-XL. Doses of OXY-XL were increased by 5 mg at weekly intervals to a maximum dose of 30 mg per day guided by patient perception of efficacy versus side effect. At the end of the study statistically significant decreases in the number of voids in 24 hours, episodes of nocturia and incontinence episodes were observed. Residual urine remained unchanged. No patient experienced serious adverse events (LOE2). In a prospective, open label trial of 3 formulations of oxybutynin (tablets, syrup and extended release tablets), Franco et al. [6] evaluated the efficacy and safety of oxybutynin in children with neurogenic DO. The effect of treatment on average urine volume per catheterization and on secondary urodynamic outcomes was evaluated. Maximal cystometric capacities increased, and mean detrusor and intravesical pressures were significantly decreased at week 24. Improvements in bladder function were consistent across all oxybutynin formulations (LOE 2). Gajewski et al. demonstrated in a prospective randomized study that oxybutynin was more effective than propantheline in the treatment of DO in patients with multiple sclerosis (LOE 1) [7].

More recently two Oxybutynin papers deal with intravesical application (0.1%), one in adults, one in children (see topic Antimuscarinics Intravesical Bladder Relaxants).

Lee et al. (2014) published a retrospective, multi-centre, observational study with Oxybutynin in paediatric neurogenic bladder due to spinal dysraphism: of 121 patients 41 (34 %) received OXY at less than 5 years of age. During a mean observation time of 19 months (range 0.3 to 111 months) there was a significant improvement of both primary efficacy outcomes, MCC increased about 8 %, mean EFP was reduced from 33 to 21 cm H2O. No serious AEs were reported; constipation and fascial flushing consisted of the major AEs. (LOE3) [8].

Propiverine

In a randomized, double-blind, prospective multicenter clinical study, Stöhrer et al. [9] compared the efficacy and tolerability of propiverine and oxybutynin in patients with neurogenic detrusor overactivity. Propiverine and oxybutynin were equally effective in increasing bladder capacity and lowering bladder pressure. The trend for better tolerability of propiverine compared to oxybutynin achieved significance for dryness of the mouth (LOE1). Propiverine hydrochloride has also been shown to be effective in neurogenic detrusor overactivity in children and adolescents, even in some of those cases unresponsive to other anticholinergics [10, 11]. The low incidence rate of adverse events evidenced a favourable risk-benefit profile of propiverine hydrochloride (LOE3).

In 2013 a review on Propiverine, of its use in the treatment of adults and children with overactive bladder associated with idiopathic or neurogenic detrusor overactivity, as well as in men with lower urinary tract symptoms was published by McKeage [12].

Propiverine is now also produced in an extended release (ER) formulation. Comparing patients with neurogenic detrusor overactivity in a double-blind randomized multi-centre study, comprising 66 patients with proven NDO Stöhrer et. al (2013) demonstrated, that both galenic formulations are equi-effective. However following propiverine ER 45 mg s.i.d higher continence rates compared with propiverine ER 15 mg t.i.d were achieved, indicating most probably more balanced plasma-levels with the ER formulation [13]. A slight tendency for superior tolerability outcome with ER compared with IR was demonstrated; however it did not reach statistical significance. (LOE2)

Trospium

Trospium is a quaternary ammonium derivative with mainly antimuscarinic actions. Trospium has been shown to significantly reduce the number of urinations, increase cystometric capacity and mean effective volume of the bladder, and reduce the incidence of urgent voids in neurogenic patients [14, 15] (LOE1). It is the only antimuscarinic which does not pass the healthy blood-brain-barrier as proved by Staskin et al. (2010) comparing the trospium levels in the blood and the CNF after trospium treatment in a group of healthy elderly people [16]. Since 2013 no further study with trospium in NDO was published.
**Tolterodine**

Tolterodine is a competitive muscarinic receptor antagonist. Tolterodine has a high selectivity in vitro and exhibits selectivity for the urinary bladder over the salivary glands in vivo. Several phase II studies have demonstrated the efficacy and safety of tolterodine in patients with overactive bladder [17]. Ethans conducted a prospective, randomized, double-blind, crossover trial plus open-label comparative stage, aiming at comparing tolterodine with oxybutynin and placebo in people with neurogenic DO. Tolterodine, when used at self-selected doses (SSDs) was comparable with oxybutynin at SSDs in enhancing bladder volume and improving continence, but with less dry mouth. It seems that larger doses of tolterodine are needed to achieve best effect on neurogenic bladder [18, 19] (LOE3). Since 2013 no study with tolterodine in NDO was published.

**Solifenacin succinate**

Solifenacin has been extensively studied in OAB [20, 21] (LOE1). In a prospective, open-label study of solifenacin for the treatment of OAB in MS patients, van Rey et al. demonstrated a significant improvement in number of micturitions, number of pads used per day and severity of urgency compared to baseline following eight weeks of treatment [22] (LOE 2).

Three studies were published between 2013 and 2016 using Solifenacin. Krebs and Pannek (2013) report on the effects of solifenacin in patients with neurogenic detrusor overactivity as a result of spinal cord lesion. In this retrospective analysis of case histories and urodynamic data (35 SCI patients) solifenacin (dosage unknown) resulted in significant improvements in bladder capacity, decrease in maximum detrusor pressure (median -7 cm H2O), reflex volume (median + 62, 5 ml) and detrusor compliance (median +25.0 ml/cmH20). The findings indicate that solifenacin significantly improves bladder capacity, detrusor compliance, reflex volume and maximum detrusor pressure. Res. two patients discontinued Solifenacin treatment due to insufficient efficacy or intolerable adverse event. [23] (LOE3)

The second study is a double-blind, randomized, active- and placebo-controlled urodynamic study (SONIC), in which 189 patients with neurogenic detrusor overactivity-NDO due to multiple sclerosis (MS) or spinal cord injury (SCI) were randomized to placebo or active treatment (solifenacin 5 mg, 10 mg and oxybutynin 15 mg) for four weeks [3]. In the primary analysis solifenacin significantly improved mean change from baseline MCC vs. placebo and was associated with improvements in bladder volume at first contraction and at first leak as well as detrusor pressure at first leak. Similar results were obtained for oxybutynin versus placebo. However the study was not powered for the comparison of Solifenacin with oxybutynin. Solifenacin 10 mg was more effective than solifenacin 5 mg in most of the parameters. (LOE1)

The third trial with solifenacin is a double-blind, randomized, placebo-controlled, 3-site study with an open label extension phase to determine the efficacy of Solifenacin in idiopathic PD patients with OAB (Zeiewicz et al., 2015). The primary outcome measure was the change in the mean number of micturitions per 24 h period, secondary outcome measures included the change in the mean number of urinary incontinence episodes. In this pilot trial Solifenacin treatment led to an improvement in urinary incontinence, despite persistence in other OAB symptoms. Adverse events included constipations and xerostomia, central nervous system side effects are not mentioned, however in a study on patients with cerebral diseases the tolerability and safety of antimuscarinics should include systemic evaluation of central nervous system side effects. [24] A good example how to do it, is the paper of Sakakibara et al. (2013), with Imidafenacin (see below) [25]. (LOE2)

**Darifenacin**

Dariferacin has a higher relative selectivity for the M3 receptor compared with other anticholinergics. Dariferacin has been extensively studied in OAB, but not in neurogenic bladder dysfunction.

**Fesoterodine**

Fesoterodine acts functionally as a prodrug, hydrolysed by nonspecific esterases to 5-hydroxymethyl tolterodine (5-HMT). This active metabolite, responsible for the antimuscarinic activity of fesoterodine is also an active metabolite of tolterodine. Phase 3 trials have evaluated fesoterodine in OAB. There is one dose-escalating study on the pharmacokinetics and tolerability of Fesoterodine in children with overactive bladder. Of 21 children enrolled, 11 had neurogenic detrusor overactivity. Treatment-related adverse events (all mild or moderate) including 1 event each of dry mouth, constipation, dry eyes and blurred vision, and 2 events each of nausea and increased post-void residual volume. Moreover, oral administration of Fesoterodine in children produced steady-state plasma 5-hydroxy-methyltolerodine exposures similar to those in adults. [26] (LOE3)

**Imidafenacin**

A study by Sakakibara et. al with 62 patients, mean age 70 years (25-86) with OAB due to neurologic diseases investigated the urinary symptoms survey, moreover cognitive tests (MMSE, FAB, ADAS-cog) were performed in all patients. Urodynamics were conducted in 35 patients and real-time near-infrared spectroscopy (NIRS)-urodynamics in eight patients before and after Imidafenacin for 3 months at 0,2 mg/day. [25]

Imidafenacin significantly ameliorated urinary urgency, night-time urinary frequency, and quality of life and - most important - the three cognitive measures did not change significantly. Urodynamics showed increased bladder capacity, but detrusor overactivity did not change significantly. NIRS showed changes
in the bilateral prefrontal area but without statistical significance. It is concluded, that imidafenacin effects on bladder and brain function, ameliorated bladder sensation without cognitive worsening, with a trend of prefrontal activation. Imidafenacin seems safe in treating OAB patients with or due to neurological diseases.

The long term results of double anticholinergic therapy for refractory neurogenic and non-neurogenic detrusor overactivity were reported in a paper by Nadeau et.al. (2014) in a prospective open-label study. Results showed that with DO or NDO refractory to anticholinergic monotherapy double anticholinergic therapy is feasible and efficient approach. Side effects were reported by half of the patients (28/56) light by 20, moderate by 8 and severe in 2 with withdrawal from the study. [27]

**Dual therapy with antimuscarinics**

Dual therapy (between combinations of oxybutynin, tolterodine and trospium) has been shown to be effective and well tolerated in a few patients with neurogenic bladder dysfunction [28] (LOE 2).

Hadjii et.al (2014) evaluated efficacy of anticholinergic agents in the treatment of neurogenic overactive bladder and neurogenic detrusor overactivity in spinal cord injury patients on clean intermittent catheterization. Neither the monotherapy nor a combination of Oxybutynin with Trospium was not always satisfactory in terms of control of NDO and rarely allowed full continence. [2]

**Antimuscarinics in neurological patients with cognitive impairment**

In the cognitively impaired, antimuscarinics should be prescribed with a warning about possible deterioration in memory or the onset of confusion. It would appear sensible to recommend the use of antimuscarinics that are likely to have less impact on cognition, either by lower propensity to cross the blood–brain barrier (e.g. trospium chloride) or by relative selectivity for the M3 receptor (e.g. darifenacin) which is not known to be involved in cognition; evidence affirming these considerations is limited. Only one study by Sakakibara et al. (2009) with results on the management of overactive bladder in elderly individuals with dementia, the combined use of donepezil (a central acetylcholinesterase inhibitor) and propiverine (a peripheral muscarinic receptor antagonist) showed by evaluated MMSE and mean ADHS-coc that there was no significant change in these parameters when propiverine was added to cholinesterase inhibitor therapy. The authors conclude that this combination of therapy - acetylcholinesterase inhibitor plus propiverine could become an option in patients who suffer from dementia and OAB together.[29] In a randomised, double-blind, parallel group, multicentre study of 3 weeks treatment with darifenacin in the healthy elderly, no significant effects on memory compared to placebo was observed, in comparison to oxybutynin ER which caused significant memory deterioration [30] (LOE 1). In a single-centre, non-comparative, pre-post dose intervention phase IV study of healthy elderly that was primarily designed to evaluate CSF trospium levels after orally dosed trospium, no decline in performance on tests of learning and memory was observed following ten days [31] (LOE 2).

**Recommendations**

- The evidence demonstrating the efficacy of oral pharmacotherapy in the management of storage NLUTD symptoms concerns mainly the older antimuscarinics. More large-scale randomised controlled studies are needed to evaluate this further.

**Beta-3-Andrenoceptor agonists – Mirabegron**

Only one study is so far published reporting the initial experience with the treatment of neurogenic detrusor overactivity with the β-3 agonist Mirabegron as monotherapy in patients with spinal cord injury in a retrospective chart analysis comprising 15 patients with NDO during a period of at least 6 weeks. There was a significant reduction of the frequency of bladder evacuation per 24h (8,1 vs 6,4, P = 0,003) and incontinence episodes per 24h (2,9 vs. 1,3, P=0,027). Furthermore there was a improvement in bladder capacity (from 365 to 419, of compliance and of detrusor pressure during storage phase (45,8 vs. 30 cm H2O). However, due to the limited number of patients and the retrospective nature of the study, prospective, placebo-controlled studies are needed. In regards to tolerability it is mentioned, that NDO treatment with Mirabegron in patients with NLUTD due to SCI is feasible and well tolerated, without giving any further details on tolerability and safety. [32]

The different working mechanisms of antimuscarinics and the beta-3-adrenoceptor agonist Mirabegron let us assume that a combination of both could have synergistic effect. In a study by Wada et. al (2015, phase IV study, article in Japanese) efficacy and safety of Mirabegron in patients with neurogenic bladder, who had detrusor overactivity or a low compliance bladder despite taking anticholinergic medications are reported. Mirabegron was added to the anticholinergic medication (Solifenacin 5 mg, 10 mg and Tolterodine 4 mg). After 7 months of the combination with Mirabegron (50 mg, once daily) together with the anticholinergics, incontinence improved in all patients, bladder deformity improved as well, VUR disappeared in all 3 patients. The authors conclude that combination therapy of Mirabegron with anticholinergics is effective and beneficial for neurogenic bladder resistant to anticholinergic monotherapy. [33]

Based on these however limited results Mirabegron is an alternative in NDO if antimuscarinics are contra-indicated, not effective or cause intolerable side effects. Cognitive impairment should not occur. Beta-3-
receptors are also in the brain, however, their functions is unknown.

**Oral cannabinoid agonists**

The cannabinoid system comprises exocannabinoids and endocannabinoids. Both anecdotal reports of MS patients [34] and clinical trials [35-37] suggest that cannabis and cannabis-based medicinal extracts (CBME) improve skeletal muscle spasticity as well as bladder and bowel dysfunction. An open-label (LOE3) study using sublingual spray of extracts containing delta-9-tetrahydrocannabinol (THC) and/or canabinol (CBD) in patients with advanced MS and NLUTD concluded that both extracts significantly reduced urinary urgency, the number of incontinence episodes, daytime frequency, nocturia, daily total voided and catheterized urine volumes as well as incontinence pad weights [35]. Freeman et al. (2006) investigated the effect of a CBME (Δ9-THC) on urgency incontinence in a large multi-center, randomized, placebo controlled trial (the CAMS-LUTS study) involving 647 patients with MS. The study demonstrated a significant effect of CBME on incontinence episodes compared to placebo (LOE1)[36]. Another multicentre double-blind, placebo-controlled trial specifically studying LUTS in 135 patients with advanced MS used an endocannabinoid modulator comprising THC and CBD in a 1:1 ratio (Sativex). The active treatment improved daytime frequency, nocturia, and Patient’s Global Impression of Change significantly more than placebo (LOE1)[37]. Improvements in urgency and urgency incontinence episodes did not reach statistical significance over placebo.

With regards to endocannabinoids, Strittmatter et al. (2012) investigated the distribution of fatty acid amide hydrolase (FAAH; cannabinoid degrading enzyme) immunoreactivity in the human urothelium [38]. Aizawa et al. (2014) demonstrated in a rat experiment that inhibition of peripheral FAAH suppresses the A-delta and C-fiber activity of primary bladder afferents via CB1 and CB2 receptors, a promising finding for further research [39].

**Intravesical bladder relaxants**

**Antimuscarinics**

Since the first use of the intravesical application by Brendler et al. in 1989 [40], there have been several articles reporting successes of intravesical oxybutynin to treat OAB and neurogenic DO. The main findings were, at least at short term follow up; improved LUTS, fewer incontinence episodes, an increase of maximum bladder capacity and decreased DO. George et al. 2007 compared the therapeutic response of intravesical oxybutynin, propantheline, and capsaicin in the treatment of neurogenic DO [41]. Oxybutynin 5 mg in solution or propantheline 15 mg in solution and capsaicin were instilled intravesically in each patient. Urodynamic studies were done before and after the intravesical instillation of each drug. There was a significant difference in therapeutic response between intravesical oxybutynin, propantheline, and capsaicin in the treatment of detrusor overactivity for leak volume (LV) and leak frequency at 2nd week. When comparing responses of oxybutynin and propantheline, more subjects demonstrated improvement with intravesical propantheline than oxybutynin for reflex volume, detrusor leak point pressure, clean intermittent catheterization volume, and LV (LOE3). However, there is no standard instillation protocol concerning the use of intravesical oxybutynin; doses used range between 5-30 mg, diluted in 30-40 ml saline [41, 42]. Also the instillation frequency is not standardized and varies between 1 to 3 times /d. Small case series report on long-term success of intravesical oxybutynin (up to 3 years in adults, up to one year in children with NDO (LOE4) [43, 44]. Despite favourable results on urodynamic parameters, there is also a low level of evidence for the use of intravesical oxybutynin in low-compliance neurogenic bladders [45]. Modulation of the ice-water test and suppression of the electrical perception threshold by oxybutynin has been studied [46]. An animal experiment suggested that early administration of oxybutynin might have a protective effect on structural bladder alterations, at least in obstructed animals [47].

Fader et al. 2007 [48] tested the efficacy and side effect profiles of intravesical atropine compared to oxybutynin immediate release (IR) in MS. They performed a study to determine the most effective dose of atropine. Eight participants used increasing doses of intravesical atropine (2 to 6 mg in 20 ml saline) during a 12-day period. Bladder diary data showed that the instillation of 6 mg atropine 4 times daily was most effective for increasing bladder capacity (voided/catheter volumes). Afterwards they performed a randomized, double-blind crossover trial. Participants received 14 days of treatment with oral oxybutynin IR 5 mg twice daily (range 2.5 twice to 5 mg 4 times daily) or with intravesical atropine, followed by 14 days of alternative treatment. Participants recorded a bladder diary and rated side effects and quality of life. The primary outcome variable was bladder capacity. 57 participants with MS completed the study. Average change in bladder capacity was higher in the atropine arm. Changes in incontinence events and voiding frequency were not statistically different between the arms. Changes in total side effect and dry mouth scores were significantly better in the atropine treatment arm. These findings suggest that intravesical atropine is as effective as oxybutynin IR for increasing bladder capacity and has less antimuscarinic side effects (LOE2). However, no further results of clinical trials with intravesical atropine have been published since. Since 2013 two papers deal with intravesical application of oxybutynin (0,1 %), one in children and one in adults:

In the paediatric long-term study with evaluation 15 ± 1 years after the switch from oral to intravesical, bladder compliance shows a statistically significant increase; pyélonéphritic episodes decreased, from 10
during the 2 years on oral to 3 over 15 years with intravesical oxybutynin indicating that intravesical oxybutynin provided more than adequate suppression of detrusor activity without side effects for a period of 15 years [49] (LOE3).

The adult study is a randomized, prospective, controlled multi-centre trial comparing intravesical 0.1 %, oxybutynin 3 times per day with a group on oral oxybutynin 5 mg, 3 times a day, each for a period of 28 days: There was a statistically significant increase in maximum bladder capacity with intravesical application compared to oral oxybutynin ADR were reported by 55.6 % with intravesical and 82.5 % with oral administration. Significant differences in favour of intravesical application were observed in ADR affecting vision, gastrointestinal tract, nervous system, skin and subcutis [50]. ADR from the nervous systems are reported 2/10 with intravesical vs 8/14 with oral OXY. But also in this study as in others (exception a study of Sakakibara on Imidafenacin [25]) no systematic evaluation of CNS effects using relevant cognitive tests was undertaken. (LOE 2)

**Nociceptin/orphanin FQ (N/OFQ)**

Nociceptin is a peptide that exerts several physiologic actions at both the central and the peripheral level by activating a specific G-protein-coupled receptor named nociceptin orphan peptide (NOP) receptor. Animal studies have demonstrated that N/OFQ inhibits the micturition reflex in the rat [51]. Lazzeri et al. recently studied the feasibility, safety and efficacy of daily intravesical instillation of 1 mg of the endogenous peptide N/OFQ in a selected group of patients who performed CIC for neurogenic DO [52]. A total of 18 patients were randomized to receive 1 mg nociceptin/orphanin FQ in 10 ml saline or placebo (saline) at the first catheterization for 10 days. Mean daily urinary leakage episodes significantly decreased from 2.18 at baseline to 0.94 during nociceptin/orphanin FQ treatment, while no significant changes were reported in the placebo group. The bladder capacity significantly increased in patients receiving nociceptin/orphanin FQ. The urodynamic parameters showed an increase in cystometric capacity and a decrease in maximum bladder pressure. Although these findings supported the use of nociceptin/orphanin FQ peptide receptor agonist as an alternative approach for controlling NDO incontinence (LOE2), no further study results have been published since 2006.

**Compounds acting via the transient receptor potential (TRP) channels**

The vanilloids, capsaicin (CAP) and resiniferatoxin (RTX), desensitize afferent nerves by binding TRPV1 receptors. CAP has been the subject of small, short-lasting placebo-controlled trials in patients with SCI or MS [53] (LOE1-2). Thus, the use of CAP is still largely experimental and limited by the fact of prolonged and painful excitation of the sensory c-fibers. The alcoholic solvent may be a major factor in the poor tolerability of alcoholic CAP instillation, as suggested by the result of one placebo controlled study showing that side effects appeared to be the same after intravesical instillation of CAP diluted in 30% ethanol as after instillation of ethanol alone (LOE2).

RTX acts without the potent neuronal excitatory effect of capsaicin, and therefore elicits less discomfort. The difference in tolerability of the 2 vanilloids (CAP vs. RTX) was usually attributed to the differential propensity of the 2 agents. Nevertheless, because we know the role of the solvent in the irritative effect on bladder mucosa, it is reasonable to assume that differential effects could be related to the use of different vectors. From a technical point of view the choice of the solvent is limited because of the poor hydrosolubility of CAP, imposing the use of an alcoholic, lipidic or glucidic vector. The safety of the lipidic solution could be imperfect because of difficulty of achieving complete elimination of lipidic solution from the bladder. On the contrary, a glucidic solution may represent a safe and valuable alternative to the alcoholic vector. De Seze et al. [54] compared the efficacy and tolerance of intravesical instillations of CAP and RTX using a glucidic solvent for CAP and the 10% ethanol solvent for RTX in a controlled randomized, double blind study in patients with severe urinary incontinence due to spinal cord injury. On day 30, improvement was found clinically and urodynamically in 78% and 83% respectively of patients treated with CAP vs. 80% and 60% treated with RTX. No significant difference between the 2 groups was observed. The benefit remained in two-thirds of the 2 groups on day 90. There were no differences in regard to incidence, nature or duration of side effects in CAP vs. RTX treated patients. These results once more strongly argue for the importance of accounting for the role of vanilloid solute when interpreting efficacy and tolerance of vesical vanilloid instillation in neurogenic DO cases. They suggest that a glucidic solution is a valuable solvent for CAP instillation (LOE2).

RTX seems to have a beneficial effect on neurogenic DO (LOE 2). However, good randomized controlled studies are needed to determine its place in the treatment of NDO. Also the optimum doses (concentration) as well as the inter treatment intervals need to be determined. Moreover, the long-term safety of vanilloid agents, particularly concerning mutagenic and carcinogenic effects on the bladder wall is not perfectly known. RTX belongs to the family of tumor promoting phorbol esters, strengthening the need to ensure the safety of RTX before extending its therapeutic applications.

Initial interest in RTX has declined following the introduction of intradetrusor Botulinum toxin injections in the treatment of intractable neurogenic DO. In a randomized trial comparing onabotulinumtoxinA injection to resiniferatoxin intravesical instillation in 25 patients with spinal neurogenic DO [55] there was a significant decrease in catheterization and incontinence episodes for both treatments at 6, 12, and 18-months of follow-up. However, onabotulinumA injections provided superior clinical and urodynamic benefits as compared to intravesical resiniferatoxin, although...
RTX did not necessitate subsequent intermittent catheterisation (LOE 1-2).

Transient receptor potential channels are being increasingly investigated as targets for the treatment of detrusor overactivity. Piperine, a novel vanilloid compound, was found to have both acute and prolonged in vitro effects [56]. In an animal model of chronic spinal NDO, systemic administration of GRC-6211, a novel TRPV1 antagonist, could abolish DO [57]. An antagonist of another TRP channel, the ankyrin-repeat transient receptor potential 1 channel (TRPA1), could decrease the number and amplitude of non-voiding bladder contractions in SCI rats [58]. Finally, nitro-oleic acid, an electrophilic fatty acid nitroalkene derivative which modulates gene transcription and protein function via post-translational protein modification demonstrated TRP-agonist actions affecting both the TRPV1 and the TRPA1 receptors in rat bladders [59].

For both vanilloids no clinical studies were published between 2013 and 2016.

Potential intravesical treatments with Cannabinoid modulators

While orally administered cannabinoid modulators appear to improve neurogenic OAB symptoms, particularly in MS patients [60], the identification of functional cannabinoid receptors (CBs) in the human bladder urothelium [61, 62] has intensified research in intravesical cannabinoid agonists for bladder dysfunctions. To date, only preclinical studies exist, and in non-neurogenic bladder models. Cannabinor, a selective CB2 receptor agonist, was found to affect bladder function in both normal rats as well as rats with bladder outlet obstruction, by increasing intervals between bladder contractions as well as flow pressures [63, 64]. In rats, but not humans, a Cannabis sativa extract enriched in cannabidiol drug substance reduced cholinergic-mediated bladder contractility in vitro [65]. Intravesical application of a non-selective cannabinoid agonist suppressed afferent activity via activation of CB1 receptors [66]. Finally, intravesical administration of the fatty acid amide hydrolase, the enzyme responsible for the degradation of the endocannabinoid anandamide, altered afferent-related urodynamic parameters in normal rats [67]. In a single study using a spinal cord injury model, systemic administration of a CB2-selective agonist could improve spontaneous voiding, possibly via a positive effect on inflammatory responses in the spinal cord [68].

4.2. Drugs for sphincter deficiency

Several drugs, including alpha-adrenergic agonists, estrogens, beta-adrenergic agonists and tricyclic antidepressants, and duloxetine have been used in an effort to increase outlet resistance. No adequately designed controlled studies of any of these drugs for treating neurogenic sphincter deficiency have been published.

4.3. Drugs for treating voiding dysfunction

Alpha-adrenergic antagonists (alpha-blockers)

Alpha-adrenoceptors are present in the bladder base, posterior urethra and prostate. Alpha-blockers have been already reported to be useful in neurogenic bladder by decreasing urethral resistance during voiding. Tamsulosin has been shown to improve bladder storage and emptying in MS and SCI [69]. Abrams et al. [70] evaluated the efficacy and safety of tamsulosin in patients with neurogenic lower urinary tract dysfunction secondary to suprasacral spinal cord lesions in a 4-week randomized controlled trial (RCT) followed by a 1-year, open label, long-term study. A total of 263 patients were randomized to 4-week double-blind therapy with placebo, or 0.4 or 0.8 mg tamsulosin once daily. The primary efficacy parameter was maximum urethral pressure (MUP). In the long-term study, but not in the RCT trial, there was a statistically significant mean decrease in MUP from baseline to end point. In the long-term study tamsulosin also improved several cystometry parameters related to bladder storage and emptying, e.g. decreased maximum urethral closure pressure. It also increased mean voided volume based on the micturition diary. There was statistically significant improvement for the International Prostate Symptom Score Quality of Life. Both doses were effective and well tolerated. (LOE 1).

The value of alpha blockers with neurogenic LUT dysfunction is still discussed controversially. The efficacy of selected alpha-blockers in the treatment of children with neurogenic bladder dysfunction is investigated by Kroll et.al. (2016). The aim was to assess the usefulness of selective alpha-1-blockers in children with neurogenic urinary tract dysfunctions and increased leak point pressure (LPP). 14 children from age 6 to 16 years with LPP higher than 40 cm H2O were enrolled in the study. All patients received the selective a1-blocker doxazosin for 6-8 weeks (initial dosage 0.03 mg/kg). The differences both in LPP and LPV before and after treatment were not statistically significant. This observation is consistent with the conclusions from other studies and showed no evident efficacy of doxazosin in children with neurogenic bladder. [71]

Conclusions

- Antimuscarinic drugs improve storage function (LOE 1).
- Antimuscarinic drugs have a high incidence of side effects (dry mouth, constipation, urinary retention, etc.). Tolerodine, propiverine, trosospium and controlled-release oxybutynin have significantly less side effects compared to immediate-release oxybutynin (LOE 1).
- High doses of oxybutynin have been used to treat patients with neurogenic bladder dysfunction (LOE 3)
• Intravesical instillation of oxybutynin may be an alternative route of administration (LOE 4).
• An alternative to antimuscarinics is the beta-3-agonist Mirabegron, however, only one study was published so far. The advantages in regards to side effects compared to antimuscarinics are evident.
• There is LOE1 data to support a beneficial effect of oral cannabinoid agonists on neurogenic lower urinary tract dysfunction in patients with MS.
• Intravesical instillation of capsaicin/resiniferatoxin has been reported to improve spinal reflex incontinence. Resiniferatoxin is preferable (LOE 3). Recent results supporting their use are lacking.
• Long-term alpha adrenergic antagonists are effective and well tolerated in patients with MS and suprasacral spinal cord lesion with neurogenic lower urinary tract dysfunction (LOE1).
• There is no adequately designed controlled study of any drug for neurogenic sphincter deficiency.

Recommendations
• Antimuscarinic drugs should be recommended for the treatment of neurogenic detrusor overactivity (A). Titration of the dosage of these drugs individually should be done to optimal balance of therapeutic and adverse effects. If one drug is not tolerated, another drug should be tried (C/D).
• The use of oral cannabis-based medicinal extracts can be recommended for MS patients with NLUTD, currently in specialized research centres (C). Further research is needed on oral and intravesical cannabinoids in patients with NLUTD.
• Vanilloid intravesical therapy still remains experimental and therefore is not recommended except within clinical trials (C/D).
• For decreasing outlet resistance in neurogenic bladder α-adrenergic antagonists may be used (B/C).
• For neurogenic sphincter deficiency, no effective drugs are available up to now; further research is needed (D).
• For detrusor acontractility no effective drugs are available up to now; further research is needed.

5. MINIMALLY INVASIVE TREATMENTS

5.1. Botulinum neurotoxin type A injections

Botulinum neurotoxin type A for neurogenic incontinence

Efficacy. Botulinum neurotoxin type A (BoNT/A) intradetrusor injections has become the newest approved treatment for urinary incontinence in adult neurological patients with inadequate response to (or reduced tolerance of) an anticholinergic medication (U.S. Food and Drug Administration approval) in the OnabotulinumtoxinA (BOTOX®) format. Similar approval has been granted in European countries. Several systematic reviews [1-4] [5, 6], meta-analyses [7] and randomized, controlled trials (LOE1) [8-14], an active comparator-controlled trial (LOE1-2) [15], four LOE2 studies [16-19], as well as numerous LOE3 studies have confirmed the efficacy of BoNT/A in the treatment of refractory neurogenic DO incontinence. Clinical improvement is accompanied by significant ameliorations in bladder function, as urodynamic parameters that matter in the management of NDO, namely maximum cystometric capacity, maximum detrusor pressure and reflex volume, appear to gain substantial benefits [1-3, 20]. Almost all studies have published on two BoNT/A preparations, onabotulinumtoxinA (Botox®) and abobotulinumtoxinA (Dysport®) [3, 5]. The two formats are not interchangeable and there are no direct comparisons for dose, efficacy and safety, at least in urological indications. Although both products appear to be efficacious in NDO, onabotulinumtoxinA has been more comprehensively studied than abobotulinumtoxinA [3]. Two LOE1 studies have been published reporting abobotulinumtoxinA [14, 17]. An LOE3 study suggests that onabotulinumtoxinA may be more efficacious than a novel BoNT/A preparation, Prosine, in the treatment of refractory NDO [21].

The mean duration of efficacy of a single injection is 6-16 months for onabotulinumtoxinA and 5-12 months for abobotulinumtoxinA [3]. The FDA regulatory trials (275 and 416 patients, respectively) demonstrated a mean duration of effect of 37-42 weeks for onabotulinumtoxinA compared to 13 weeks for placebo [10, 12]. Complete continence was achieved in 36-38% and 40-41% respectively with the 200U and 300U doses of onabotulinumtoxinA as opposed to 7.6-10% with placebo. Interestingly, significantly higher post-treatment continence rates have been reported in single-centre studies with both preparations (a mean 71% with onabotulinumtoxinA and 65% with abobotulinumtoxinA) [3]. Similarly, reduction in the number of daily leaks was significantly superior in LOE3 compared to LOE1&2 studies (80% vs 63%, p=0.01) [5], but the majority of LOE3 studies had used 300U onabotulinumtoxinA. The concomitant use of anticholinergics does not appear to provide additional benefit [22], although this needs to be
confirmed in specifically-designed studies. In those taking anticholinergics, onabotulinumtoxinA initially reduces the dose of anticholinergics needed, but this tends to increase again at longer follow-ups [23] [24]. A single real-life study has investigated the effect of switching from the earlier used 300U to the newly approved 200U onabotulinumtoxinA [25]. Although 94% of patients continued to experience symptomatic improvement, 25% reverted back to the original 300U dose. Somewhat greater reductions in daytime frequency and nocturia were recorded with 200U vs. 300U (87.5% and 81.3% respectively vs. 75% and 75%) but lesser urgency improvements (75% vs 81). At three year follow-up, 82% of patients who had switched to the lower dose were happy and keen to continue receiving 200IU OnabotulinumtoxinA. Several retrospective studies [19, 26-36] and a single prospective trial [37] now attest to the sustained efficacy of repeat treatment sessions with either of the two formulations. In prospectively followed-up patients opting for repeat injections, the median duration of effect was ≥9 months, with one in four patients enjoying an even more lasting effect of at least one year [37].

Reported failure rates are 5-25% for onabotulinumtoxinA and 10-32% for abobotulinumtoxinA [3] [39]. Clinical predictors of success/failure in NDO have little been studied. A study of spinal cord injured patients proposed that the level of injury may be important as patients with thoracic and lumbar injury had better clinical and urodynamic outcomes compared to cervical injury patients [38]. A longer duration of MS has been proposed as a predicting factor for treatment failure [9] (LOE3). To date there is no robust evidence to link treatment failure with the formation of neutralizing BoNT/A antibodies, but a wide range of antibody formation rates following treatment has been reported (0-35%) [40-43] and its clinical significance needs further investigation. A small, mid-term, controlled study in children (LOE1-2) found no association between antibody formation and treatment failure, but reported an increased rate of antibody formation in those receiving repeat versus single injections (71% vs. 38%) [44] up to 4 months post treatment. In the long-term, antibody titers returned to control levels. Patient-related factors also affect adherence to treatment; in a long-term study with a mean 12-year follow-up, 21% of patients discontinued treatment due to inadequate efficacy, but another 19% opted for other treatments (antimuscarinics, sacral neuromodulation) despite the toxin’s efficacy [36]. In another study, only 59.3% of spinal cord injured patients were satisfied with repeat treatments and only 20% continued after a fourth injection, with 33.9% reporting inadequate efficacy and 6.8% discontinuing due to adverse events [35]. Nevertheless, in treatment failures toxin switch could be more effective than re-injection with the same toxin (51.7% vs. 24.1%). Patients treated with a switch from abobotulinumtoxinA to onabotulinumtoxinA and those treated with a switch from onabotulinumtoxinA to abobotulinumtoxinA had similar success rates (52.9% vs. 50%) [45].

**Patient populations.** The majority of the studies involved participants with neurogenic bladder due to SCI or MS, often mixed, while only small case series investigated efficacy in patients with Parkinson’s disease, multiple system atrophy or cerebrovascular accident (CVA) [46-49]. Comparisons of efficacy between neurological subpopulations are generally lacking, although a small LOE3 study suggested better continence outcomes and more significant improvements in maximum detrusor pressures in SCI patients compared to those with CVA [49]. The largest RCTs which involved MS and SCI patients conclude that the toxin is highly efficacious in both subpopulations [10, 12]. A lower placebo effect in the SCI subpopulation could be noted, although the studies were not designed for head-to-head comparisons.

**Doses.** The FDA registration studies demonstrated a similar efficacy and adverse event profile for the 200U and 300U onabotulinumtoxinA (BOTOX) doses, suggesting a plateau in the efficacy of the toxin. Similar conclusions were drawn by a smaller randomized study [19]. Providing the best benefit/risk ratio, the 200U onabotulinumtoxinA dose was recommended for the treatment of refractory NDO incontinence [10] [12]. A LOE2 study suggested a trend towards better clinical and urodynamic improvements with 750U as opposed to 500U abobotulinumtoxinA [46]. Other, non-randomized and inadequately powered studies (LOE3)[16, 17, 50] could not identify a clear dose-response for higher doses of abobotulinumtoxinA, although 1000U abobotulinumtoxinA might produce a beneficial effect of greater duration than that with 500U[17].

Little data exists on lower doses. A pilot LOE3-4 study suggests that 100U onabotulinumtoxinA could be effective in MS patients and minimize unfavourable side-effects, particularly the need for IC [51], while a LOE1 dose-response study confirms a more significant clinical benefit of the 200U dose as opposed to the 50U and 100U doses of onabotulinumtoxinA in patients with SCI [13].

**Effect on quality of life (QOL).** Both preparations have been shown to improve patients’ QOL in RCTs. The I-QOL questionnaire has been used in the majority of LOE1 studies. Patients with NDO-associated incontinence receiving a single injection of 500 units abobotulinumtoxinA, diluted in 25 ml saline and injected into 25 injection sites, had a more significant change in clinical, QOL and urodynamic parameters when compared to placebo at 26 weeks, in addition to reduced use of anticholinergics [9]. Similarly, 200U and 300U onabotulinumtoxinA administered into 30 injection sites improved QOL scores significantly more than placebo in all LOE1 studies [10-12, 52][53, 54]. Moreover, OnabotulinumtoxinA-treated patients achieve their treatment goals at significantly higher proportion than placebo-treated patients (LOE1) [55]. Fully published data on QOL following repeat treatments is sparse; in a 3-year extension study of the registration trials, QOL improvement was sustained.
with repeat injections (up to six) in parallel with clinical benefits [56].

**Administration technique.** A large variance in the number and volume of injections has been described. However, in the majority of studies onabotulinumtoxinA was given at 30 injection sites (range 10–40) at a dilution of 10U/1ml per injection site (total volume of 30 ml, range 3–30 ml), as described in the original publication by Schurch et al. [57]. The same dilution and number of injection sites was used when administering either 300U or 200U onabotulinumA in the regulatory trials. Administration of abobotulinumtoxinA is less standardized (10–30 injection sites, total volume of 5–30 ml), but a total 30 ml given at 30 injection sites appears to be the most common again [3]. The effect of these variables on outcomes has little been studied. A recent LOE1 study compared 15 to 30 injection sites (Dysport 750 U or the equivalent placebo) and concluded that a reduction of injection sites does not affect efficacy [14]. Urodynamic results were more robust than the clinical ones, the small sample size possibly affecting the statistics. A randomised, non-controlled study on OnabotulinumtoxinA only exists in short report format [58]. Comparing 10 to 30 injection sites (300 U Botox), Karsenty et al. found no significant difference in number of incontinence episodes or cystometric capacity, but a significant reduction in post-procedure pain was noted in the 10 injection-sites group.

The vast majority of studies reported injections into the detrusor muscle sparing the trigone, as in the original technique [57]. There is, however, LOE2 evidence to suggest that trigonal injections may produce better continence rates than detrusor injections alone; urodynamic parameters were affected to a lesser extent, as only reflux volume was improved more significantly in patients who received trigonal injections [18]. There is also LOE1-2 evidence suggesting that submucosal injections are comparable in efficacy to intradetrusor injections, with the exception of voided volume [59] and detrusor compliance [60]. An impressive difference was found, however, in patient satisfaction favouring the suburothelial injections (88.8% vs. 64.3% of patients satisfied) [60].

Alternative delivery techniques are being investigated including intravesical instillation of BoNT/A encapsulated in liposomes [61] or via electromotive drug administration (EMDA) [62]. The former has only been tested in non-neurogenic patients in small, short-term, placebo-controlled trials [63, 64] (LOE1-2) with inconclusive results. In the largest trial (n=62 patients), intravesical instillation of liposomal onabotulinumtoxinA (200U) improved micturition frequency and urgency severity scores over placebo at 4 weeks, but not urgency episodes or urgency incontinence [64]. No urinary retention episodes were reported though. The EMDA method has been tested in a pilot LOE3-4 study in children with myelomeningocele. Significant improvements were reported in maximum cystometric capacity, detrusor pressure, urinary incontinence, vesicoureteral reflux and even fecal incontinence [65], but results need to be confirmed in controlled trials.

**Safety.** The treatment appears to be overall safe in currently used doses and techniques. The most common adverse event is the significant increase in post-void residual in patients not using CIC prior to treatment. In onabotulinumtoxinA placebo-controlled trials, 12-22%, 30-47%, and 42-49% of patients in the placebo, 200U, and 300U groups, respectively, initiated CIC post-treatment [10] [12]. Rates of de novo CIC appear to be reduced after repeat treatments: in a 4-year study with up to six onabotulinumtoxinA injections, de novo CIC rates were 29.5, 3.4, and 6.0% (200U), and 43.0, 15.0, and 4.8% (300U) for treatments 1-3, respectively; de novo CIC rates were 0% for treatments 4-6 [56].

Although earlier studies had reported a reduced incidence of UTIs in NDO patients treated with BoNT/A [31, 66, 67], recent large RCTs [10][12] as well as systematic reviews [6] and meta-analyses [7] suggest a higher incidence of UTIs in those treated with onabotulinumtoxinA as opposed to placebo-treated patients. This might be associated with the increased rate of de novo CIC in the Botox®-treated population. In prospective, long-term, follow-up trials UTIs remained the most common adverse event, but with no increased incidence over time [37, 56]. Long-term controlled trials could clarify these apparent discrepancies.

Haematuria, constipation and flu-like symptoms have also been described [3, 10, 12], while inclusion of trigonal injections does not appear to produce vesicoureteral reflux (LOE2-3) [18][68][69]. A study in SCI male patients found a post-treatment decrease in the volume of ejaculate accompanied by improvements in semen quality, sperm mobility and vitality, as well as semen culture [70]. Further research is needed to confirm these results and explore whether they are due to local re-organization of autonomic function which also affects the reproductive system.

The most serious adverse event is generalized paraparesis/ fatique, which has been described in 0.005% of patients receiving onabotulinumtoxinA and in 0.026% of patients receiving abobotulinumtoxinA [3]. The effect resolves spontaneously after 4-6 weeks and appears to be dose-related, with most cases reported in those patients injected with 750-1000U abobotulinumtoxinA or 300U onabotulinumtoxinA [12, 29, 71].

As BoNT/A studies in skeletal muscles have identified autonomic, histological and other secondary effects [72, 73], further investigation is needed on safety issues, especially after repeat injections [2]. Preclinical studies provided evidence for transport of the toxin from the bladder to the CNS and vice versa [74, 75]. A single study to-date prospectively examined distant effects post-BoNT/A bladder injection using single-fibre EMG; one-third of the patients had findings of neuromuscular jitter post-treatment, but there was no
placebo arm or pre-treatment data for comparison [76] (LOE3). Frequency and severity of autonomic dysreflexia episodes were reported to be reduced following onabotulinumtoxinA bladder injections (LOE3)[77]. Other studies produced histological evidence of reduced or no additional fibrosis after one or multiple injections, including in children [78-80].

Future research should highlight the gaps in our knowledge of long-term treatment with focus on patient-reported outcomes and satisfaction, safety and tolerability issues as well as technical aspects such as alternative techniques of application, ways to minimize post-treatment voiding dysfunction in patients who void freely and larger studies in select patient populations.

**Botulinum neurotoxin type A for neurogenic voiding dysfunction**

Sphincter injections were historically the first application of BoNT/A in the lower urinary tract [81], but there is still inadequate evidence to support its use. The most commonly injected volume is 4ml of either the onabotulinumtoxinA or the abobotulinumtoxinA preparations. Usually 100U onabotulinumtoxinA or 150U abobotulinumtoxinA have been delivered transperineally or transurethrally [82, 83]. No direct comparison of injection techniques exists; there is low evidence (LOE4) to suggest the two delivery approaches are equally effective [82].

In a LOE1 study, the effects on DSD of botulinum toxin versus placebo was studied in 86 multiple sclerosis (MS) patients [84]. The study employed a single transperineal injection of onabotulinumtoxinA, 100 U in 4 ml normal saline, or placebo, into the striated sphincter with EMG guidance. The primary endpoint was post void residual volume at 30 days. The secondary endpoints included voiding and urodynamic variables. OnabotulinumtoxinA failed to decrease post-void residual volume in this group of MS patients, although it increased voided volume and reduced pre-voiding and maximum detrusor pressures. These findings differ from those in patients with spinal cord injury and may be due to lower detrusor pressures in MS patients. A small LOE1-2 study (n=13 patients) showed a superior effect of onabotulinumtoxinA over lidocaine 0.5% injected in the urethral sphincter in MS patients [83]. Another small (n=21 patients), controlled study (LOE1-2) in CVA patients with urethral sphincter pseudodysynergia reported superior clinical efficacy in the active treatment group (91% response rate and higher improvements in QOL and symptom scores with 100U OnabotulinumtoxinA) despite highly significant urodynamic benefits noted in the control group (reduction in voiding pressures and increase in maximum flow rates) [85]. In MS patients there is also LOE3 to suggest that a combination of detrusor and sphincter injections may facilitate bladder emptying [86]. In children with NDO and DSD due to myelomeningocele there is LOE1-2 from a single study to suggest that sphincter injections additional to the detrusor injections accomplish significant improvements in post-void residuals, as well as more significant benefits in urinary incontinence, constipation, vesicoureteral reflux and creatinine levels [87].

Since the last ICI update (2012) there has been a single LOE3 study in SCI patients with NDO and DSD comparing urethral injections of 100U onabotulinumtoxinA to detrusor injections of 200U onabotulinumtoxinA depending on the main symptoms (voiding dysfunction vs. NDO-associated incontinence) and found less patient satisfaction in the urethral injection group (60.6% vs. 77.3% in the detrusor injections group) as well as greater improvements in the UDI-6 and IIQ-7 scores in the detrusor injection group, despite significant urodynamic benefits in both groups [88]. Not unexpectedly, patients in the urethral injection group were dissatisfied due to increased degree of post-Botox incontinence whereas the detrusor injection group suffered higher rates of post-treatment voiding difficulty.

Overall, randomized controlled trials (RCTs) or quasi-RCTs investigating the use of BoNT/A in patients with neurogenic DSD in comparison to placebo or active comparators were reviewed by the Cochrane database. Published data were found to be of limited quality due to the small sample sizes, the heterogeneity in the protocols, and with a high risk of bias. Nevertheless, the authors conclude that intraurethral BoNT/A injections improve some urodynamic parameters at 30 days post-injection and propose future high-quality research to address the optimal dose and mode of injection for neurogenic DSD [89].

**Conclusions**

- Botulinum neurotoxin A (BoNT/A) injection into the detrusor muscle improves clinical and urodynamic parameters (LOE1) as well as the quality of life (LOE1), and has been approved as second-line treatment for urinary incontinence associated with neurogenic detrusor overactivity in patients with inadequate response to or intolerance of an anticholinergic.
- Both the OnabotulinumtoxinA and the AbobotulinumtoxinA formats are effective (LOE1), but the vast majority of currently published data concerns OnabotulinumtoxinA
- Repeat intradetrusor injections of BoNT/A provide sustained clinical benefits (LOE3)
- Published LOE1 data almost exclusively concern intra-detrusor injection administration, but there is limited LOE2 data to favour trigonal and submucosal over detrusor injections
- Treatment with intradetrusor BoNT/A is considered overall safe, with increased post-void residual and need for post-treatment CIC being the most common adverse event (LOE1). A higher incidence of UTIs in those treated with the toxin has become apparent in LOE1 studies.
Antibody formation is not associated with treatment failure, but may be increased after repeat injections (children)(LOE1-2)

BoNT/A is probably safe and effective for the treatment of DSD in spinal cord injury patients (LOE2). However, on the basis of one LOE1 study,

BoNT/A does not provide significant benefit for the treatment of DSD in MS patients.

Recommendations

BoNT/A should be offered as a treatment option for incontinence associated with neurogenic detrusor overactivity (A).

Further research is needed on long-term outcomes and safety, administration techniques, the bio-equivalence of the various preparations, the concomitant use of anticholinergic drugs or β3-agonists, mechanisms of action, and wider effects (A)

BoNT/A may be considered for DSD in spinal cord injury patients (B)

5.2. Electrical Neuromodulation

In the last decade, sacral nerve neuromodulation (SNM) has been established as a treatment option for patients with OAB. The success with SNM has increased the interest in other neuromodulation techniques. Additional methods include: (a) anogenital stimulation (b) pudendal nerve stimulation, (c) dorsal genital nerve stimulation (d) percutaneous tibial nerve stimulation, (e) magnetic stimulation and (f) deep brain stimulation. It is not really known how neuromodulation works, but there is evidence that sites of action are spinal and supraspinal [90]. Firstly the non-surgical ways of neuromodulation will be presented, followed by the surgical techniques.

Anogenital Stimulation

This has been applied in children with OAB complaints. Gladh et al. found a response for anogenital stimulation in 53% of the children [91]. Trsinar and Kralj used an endoanal electrode and reported a complete or partial response to the treatment in 75% of the patients [92]. In a control group of patients who had the endoanal electrode introduced but not activated, no patient had the symptoms resolved completely. No recent publications could be found.

Pudendal Nerve Stimulation

Pudendal nerve stimulation and electrode positioning can be carried out under neurophysiological monitoring (using a St. Mark’s electrode) in order to guide the electrode in Alcock’s Canal as close as possible to the pudendal nerve [93]. Electrode implantation can also be carried out by a rear approach under local anesthesia according to the method described by the same team [94, 95]. On the other hand, an anatomical study demonstrated that the technique for implanting electrodes at the pudendal level may carry some risk [96].

Direct pudendal nerve stimulation has beneficial effects on numerous pelvic floor function impairments such as urinary and/or fecal incontinence, retention, and constipation. In preceding literature the implant technique required a fairly complex and invasive procedure, although recent advances with percutaneous placement of the lead through an introducer have made the procedure much less invasive. Electrical stimulation of pudendal nerve afferents can inhibit bladder contractions in patients with SCI, and bladder capacity can be increased [97] (LOE3). Implants such as the InterStim system have made this treatment modality commercially available (see sacral nerve stimulation). Common to these implantable systems is that they use continuous stimulation. Detrusor inhibition is in principal only necessary during an involuntary contraction and, thus, stimulation could be turned off between contractions (i.e. conditional stimulation) [98]. Such a stimulation scheme could have a number of advantages. Power consumption may be decreased and, thus, extend battery lifetime. Furthermore, continuous stimulation of a reflex may lead to habituation, which would be minimized or prevented by conditional stimulation. Hansen et al. [99] examined the effect of the automatic, event driven electrical stimulation of pudendal nerve afferents on bladder capacity in patients with SCI. The study included two women and 14 men older than 18 years with NDO, bladder capacity below 500 ml and complete or incomplete suprasacral SCI. Detrusor pressure (P$_{\text{det}}$) was recorded during natural bladder filling. In a similar subsequent recording P$_{\text{det}}$ was used to trigger electrical stimulation when pressure exceeded 10 cm H2O. Of the 16 patients enrolled in this study, 13 had increased bladder capacity and reduced storage pressure decrease achieved by event-driven electrical stimulation. During stimulated filling, P$_{\text{det}}$ never exceeded 55 cm H2O. An average bladder capacity increase of 53% was achieved (LOE 3). Ohlson et al. treated eight patients with NDO in whom vaginal/rectal stimulation failed, with acute pudendal nerve stimulation. Five achieved a decrease in urinary frequency and four had an increase in cystometric capacity [100].

Spinelli et al. [94] performed a staged procedure similar to that of sacral neuromodulation (SNM) to place a tined lead near the pudendal nerve, using neurophysiological guidance. They named this approach chronic pudendal nerve stimulation (CPNS). Fifteen neurogenic patients (eight male, seven female) with urgency incontinence underwent CPNS. All patients had complete neurophysiological and urodynamic evaluation at baseline and follow-up and were asked to complete a voiding and bowel diary for 7 days. During screening, the average number of incontinent episodes per day decreased from 7+/−3.3 to 2.6+/−3.3
patients with failed previous SNM [103].

et al. (2006) reported success with pudendal nerve stimulation by a minimally invasive procedure in 15 patients without improvement did not continue to second stage. In implanted patients with 6 months follow-up, urodynamic evaluation showed an objective improvement in the maximum cystometric capacity which increased from 153.3+/−49.9 to 331.4+/−110.7 ml (P<0.01, paired t-test). The maximum pressure decreased from 66+/−24.3 to 36.8+/−35.9 cmH2O (P=0.059, paired t-test). Eight patients reported significant improvement in bowel function (LOE3).

Another elegant way to approach the pudendal nerve is the laparoscopic one as described by Posover et al. [101].

Only recently in 2016 an experimental study with electrical stimulation of dog pudendal nerve is showing that stimulation of the pudendal nerve trunk is a promising method to modulate bladder function. It can well be that in medium term sacral neuromodulation could be replaced by pudendal nerve stimulation, a method which was described already in 1986 by Vadusek et al. [102] and more recently, also Spinelli et al. (2006) reported success with pudendal nerve stimulation by a minimally invasive procedure in 15 patients with failed previous SNM [103].

**Dorsal Genital Nerve (DGN) stimulation**

DGN stimulation can be continuous or conditional. Goldman et al. used continuous stimulation for one week [104]. They found a 55% increase in cystometric capacity. In 47% there was >50% reduction in incontinence episodes, and in 81% there was >50% reduction in number of urgency events. Increases in cystometric capacity vary significantly between studies using continuous stimulation (range 11-177%) and also conditional stimulation (range 37-144%). Horvath et al. and Oppisso et al. showed that DO was suppressed conditionally, with a subsequent increase in bladder volume and postponement of incontinence [105, 106]. Martens et al. found with conditional stimulation that an increase in stimulation current results in a more pronounced detrusor inhibition [107]. Besides DO suppression, increases of the pressure at the bladder neck and the urethral sphincter contribute to continence [108]. In general, patients tolerate conditional stimulation well and they adapt to the sensation in long-term use [109]. Stimulation effectively suppresses urgency and decreases urgency episodes. Suppression of urgency during stimulation might contribute to tolerance of stimulation. This might enable stimulation at higher current to increase effectiveness when stimulation is applied conditionally.

**Posterior tibial nerve stimulation**

Percutaneous posterior tibial nerve stimulation (PTNS) was described 20 years ago as a minimally invasive treatment for urge incontinence due to neurogenic detrusor overactivity (NDO) in spinal cord injury (SCI) patients. Interestingly, the location where the tibial nerve is stimulated is in the same area as the Sanyinjiao (SP6) point used in Chinese acupuncture to treat pelvic floor organ dysfunctions. The PTN is derived from the L4-S3 nerve roots and therefore shares common roots with those serving bladder functions. SCI and Parkinson patients with neurogenic DO have been treated with PTNS. PTN seems to increase cystometric bladder capacity and bladder volume at which DO and associated leakage occurs [110, 111] (LOE3). Gobbit et al. looked at the effect in 21 MS patients. Eighty-nine percent of patients reported a treatment satisfaction of 70%. Significant improvement in QoL was seen in most domains of the King's Health QoL questionnaire [112]. Kabay et al. looked at the clinical and urodynamic effects in MS and Parkinson's disease [113, 114]. They found significant clinical and urodynamic improvements, although it was impossible to completely suppress DO. De Seze et al. looked at transcutaneous PTNS in 70 MS patients [115]. With daily stimulation sessions, they showed clinical improvement in urgency and frequency in more than 80% of patients at three months. They also observed an initial acute cystometric response in > 50% of the patients without correlation with clinical efficiency. There is still debate about the possibilities to really influence voiding behavior via the posterior tibial nerve [116]. PTNS is a stimulation technique that allows for sham comparison. It should therefore be tested in this fashion.

As in SNM, the literature reports of PTNS in the neurogenic bladder population is complicated by limited number of studies, small sample sizes, non-standard treatment plans, poor descriptions of the extent and severity of neurologic disease, and heterogeneous patient populations. A recent meta-analysis by Gayev et al. (2013) including MS and Parkinson's disease showed mixed findings on success rate ranging from approximately 40 % to 100 % for neurogenic overactive bladder or urinary retention [117] (LOE3). In 2015 Kabay et al. published the results of a retrospective case-controlled study with 34 patients enrolled to PTNS treatment. 21 patients completed the one year PTNS treatment with controls at 6, 9 and 12 months of therapy. After 12 weeks of therapy, PTNS was applied at 14-day intervals for 3 months, then 21-day intervals for 3 months, and in the end for another 3 months with 28-day intervals. The improvements for all voiding diary parameters were significant at each control when compared to the baseline. Daytime frequency decreased by 5.4 voids daily, urgency incontinence decreased by 3.4 episodes daily, urgency episodes decreased by 7.4 episodes daily, nocturia decreased by 2.6 voids, and voided volume improved by a mean of 72.1 cc. The reported results demonstrate an excellent durability of PTNS over 12 months [118] (LOE3).
Repetitive transcranial magnetic stimulation (rTMS) of the motor cortex induces a long-lasting modulation of spinal cord excitability [119]. Thus, it represents a potentially useful tool for the treatment of neurogenic urinary disturbances. Centonze et al. [120] investigated the effects of low frequency (5 Hz) excitatory rTMS over the motor cortex on LUT dysfunction in 10 MS patients complaining of urinary symptoms. All but one of the patients reported an improvement of voiding phase LUT symptoms and a significant reduction of post void residual volume. In patients with pure detrusor underactivity, there was increase of PdetQmax and Qmax. In patients with DSD, on the other hand, rTMS produced negligible effects, although the observation of a reduction of PdetQmax in this context seems to suggest a better relaxation of the urethral sphincter (LOE3). Brusa et al. also observed positive effects lasting 2 weeks after rTMS in 8 patients [121].

Deep brain stimulation

Subthalamic nucleus deep brain stimulation (STMN-DBS)

A large proportion of patients suffering from Parkinson’s disease present with urinary dysfunction including urgency, increased frequency or incontinence [122]. Deep brain stimulation (DBS) of the subthalamic nucleus (STN) has been established as a surgical treatment of motor symptoms in Parkinson’s disease patients [123]. However, data from experimental urodynamic measures in men [124] and animal models [125] have also demonstrated a significant influence of STN-DBS on urinary bladder function. In these studies, the main effect of STN-DBS appeared to be a normalization of urodynamic parameters in the storage phase with a delayed first desire to void and an increased bladder capacity. Herzog et al. investigated the effect of STN-DBS on the neural mechanisms underlying cerebral bladder control. Using PET to measure changes in regional cerebral blood flow (rCBF), 11 patients with bilateral STN-DBS were studied during urodynamic bladder filling in STN-DBS ON and OFF condition. A filled bladder led to a significant increase of rCBF in the anterior cingulate cortex, which was further enhanced during STN-DBS OFF. A significant interaction between bladder state and STN-DBS was observed in lateral frontal cortex with increased rCBF when the bladder was filled during STN-DBS OFF [126, 127] (LOE3).

Thalamic deep brain stimulation

The precise mechanisms underlying cerebral regulation of lower urinary tract function are still poorly understood. Essential tremor (ET) is not known to induce lower urinary tract symptoms (LUTS) or neuropathological changes in the thalamus. Consequently, DBS in patients with ET offers the unique opportunity to investigate the role of the thalamic ventral intermediate nucleus (VIM) nucleus in lower urinary tract function. Kessler et al. [128] evaluated the effect of thalamic DBS on urodynamic parameters in patients with ET. Seven patients were examined (two females, five males) with ET 15–85 months after implantation of DBS leads into the VIM. They compared urodynamic parameters during thalamic DBS (ON state) and 30 min after turning the stimulator off (OFF state). In the ON compared with the OFF state, there was a significant decrease in bladder volume at first desire to void (median, 218 ml vs. 365 ml, p = 0.031), at strong desire to void (median, 305 ml vs. 435 ml, p = 0.031), and at maximum cystometric capacity (median, 345 ml vs. 460 ml, p = 0.016). No significant differences between the ON and OFF state were detected for changes in detrusor pressure during filling cystometry, bladder compliance, maximum detrusor pressure, detrusor pressure at maximum flow rate, maximum flow rate, voided volume, and postvoid residual (LOE3).

Conclusions

- Electrical neuromodulation is not first line treatment for neurogenic DO. There are some limited reports showing that it may be beneficial (LOE 3).
- Automatic, event-driven electrical stimulation in the treatment of neurogenic DO is feasible (LOE 3).
- Chronic pudendal nerve stimulation is feasible. Neurophysiological guidance seems to be mandatory to place the lead near the pudendal nerve (LOE3).
- Percutaneous Tibial Nerve Stimulation gives improved clinical and urodynamic parameters. (LOE3), but its role is not established.
- Enhancing corticospinal tract excitability by rTMS might be useful to ameliorate detrusor contraction and/or urethral sphincter relaxation in MS patients with bladder dysfunction (LOE3).
- Thalamic deep brain stimulation resulted in an earlier desire to void and decreased bladder capacity, suggesting a regulatory role of the thalamus in lower urinary tract function (LOE3).
- STN-DBS appeared to tend to normalization of urodynamic parameters in the storage phase, with a delayed first desire to void and an increased bladder capacity (LOE3).

Recommendations

- If pharmacotherapy fails to relax the overactive detrusor, electrical neuromodulation may be optional in patients with neurogenic DO (C/D)
- Although the setup for conditional, event-driven electrical stimulation is not suitable in a clinical setting, the treatment modality is promising and it warrants further investigation (D).
- Further studies on chronic pudendal nerve stimulation must be carried out to identify the best
stimulation parameters and to verify the long term results (D)

- The thalamus may be a promising target for the development of new therapies for lower urinary tract dysfunction. Further investigation on this matter is needed before its potential role can be elaborated.

5.3. Electrical stimulation of the pelvic floor musculature

The aim of electrical stimulation in patients with neurogenic urinary stress incontinence is to improve key functions, namely the strength and/or timing of the pelvic floor muscle contraction. Electrical stimulation is provided nowadays mostly by portable battery powered stimulation, offering a wide combination of wave forms, frequencies, intensities, electrode placements etc.

In patients with incomplete denervation of the pelvic floor muscle and of the striated sphincter, electrical stimulation via anal or vaginal plugs performed over months, may improve pelvic floor function, and may thus improve incontinence. The incompleteness of the lesion should be as such that the patient is able to contract voluntarily the pelvic floor to some extent, even if such contraction is weak.

Conclusions

- There is no study published which deals with electrical stimulation via anal or vaginal plugs could be able to improve the strength of pelvic floor musculature (LOE 4)

Recommendations

- In patients with incomplete denervation and some voluntary contraction of the pelvic floor muscle and the striated sphincter, electrical stimulation may be an option to improve pelvic floor function, thus improve incontinence (C/D)

5.4. Intravesical electrical stimulation (IVES)

The technique involves a catheter with a stimulation electrode, introduced into the bladder and connected to the stimulator. Saline (0.9 %) is used as the current leading medium within the bladder. The neutral electrode is attached to the skin in an area with preserved sensation, usually in the lower upper abdomen. The afferent stimuli induced by IVES travel along afferent pathways from the LUT to the corresponding CNS structures. This “vegetative afferent” results in sensation of bladder filling/urge to void, with subsequent enhancement of active contractions, and possibly also in voluntary control over the detrusor. Feedback training is mediated by enabling the patient to observe the change of the detrusor pressure on a water manometer, which enables the patient to notice when a detrusor contraction takes place. This also facilitates voluntary control.

Intravesical electrical stimulation of the bladder (IVES) is still not established as a therapy for patients with neurogenic detrusor dysfunction. IVES may help to verify function of afferent pathways, proper indication is crucial and this type of therapy should only be applied in those with afferent fibers between the bladder and the cortex, proved by the evaluation of visceral sensory cortical evoked potentials. Intravesical electrotherapy may be able to improve neurogenic bladder dysfunction. Studies about IVES were reviewed in previous consultations [129].

Conclusions

- Basic research during the last decade supports the underlying working concept of IVES (LOE 3)

- The results reported in the literature are controversial, mainly because of varied inclusion and exclusion criteria (LOE 3).

- In the only sham-controlled study the treatment period was short and the inclusion and exclusion criteria were not fully defined (LOE 3).

Recommendations

- Intravesical electrotherapy may improve neurogenic bladder dysfunction, inducing bladder sensation and the urge to void (B/C)

- IVES is the only available option to induce/improve bladder sensation and to enhance the micturition reflex in patients with incomplete central or peripheral nerve damage, but corroborating controlled evidence is needed (B)

- Selection of patients is crucial and IVES should be applied only if afferent fibers between the bladder and the cortex are still intact and if the detrusor muscle is still able to contract (B)

- The ideal indication is the neurogenic hypocontractile and hypocontractile detrusor (C)

5.5. Sacral neuromodulation

Two indications for neuromodulation are clearly valid in urology: overactivity/ urgency urinary incontinence and chronic urinary retention (aside from vesicoureteric dyssynergia) [130], as discussed elsewhere in the consultation. This section focuses on the possible application of sacral neuromodulation in patients with neurological bladder dysfunction. The literature survey was undertaken with the key words: neurogenic bladder; spinal cord injury; spina bifida; meningomyelocele; multiple sclerosis, sacral neuromodulation

Hypotheses on the modes of action of neurostimulation

The first effects of electricity on the bladder were reported during electro stimulation treatment of pelvic floor muscles (with the aid of electrodes situated in the anus, the vagina, on the penis...) during urinary
incontinence reeducation [131-134]. Inhibition of bladder contractions by electrostimulation was seen. Tanagho and Schmidt, the pioneers of neuromodulation, attributed the benefits of neuromodulation in urinary incontinence to a hypertrophy of the pelvic muscles, allowing better control [135]. Voluntary contractions of the pelvic floor muscles can cause reflex relaxation of the bladder. However, the most widely held hypothesis currently is that neuromodulation allows a restoration of normal vesical reflexes [136-138] (LOE4). This hypothesis explains that the stimulation can inhibit the guarding reflex pathway and restore normal urination or turn off supraspinally mediated overactivity by blocking ascending sensory pathways. The role of cortico-subcortical structures was recently emphasized in studies of patients with incontinence [139, 140] (LOE4) or retention [141] (LOE4). Somatic afferents as the vectors for neuromodulation mechanism of action is supported by the observation that visceral nerve fibers are not activated by the parameters normally used [142] (LOE4). Despite data obtained in animals [143] (LOE4), it seems that neuromodulation cannot be effective in patients with a non functional peripheral nerve circuit.

**Treatment of neurogenic detrusor overactivity incontinence**

Prior to 2010 the literature examining the use of sacral neuromodulation (SNM) in the neurogenic population was scarce and limited by heterogeneous patient populations including multiple neurologic diagnoses, lack of randomized controlled trials, small sample sizes, and short-term follow-up. Many studies even recorded results for incontinence and for retention at the same time, without always separating the results. Since the technique’s first stages, Vodusek [134, 135] (LOE4) reported that non-muscular electrical stimulation of the sacral somatic afferents can induce bladder inhibition in patients who present with DO secondary to a medullary lesion, be it due to trauma or to multiple sclerosis (MS). The data on SNM in the neurogenic population is more or less limited to patients with stroke, Parkinson’s disease, MS and incomplete spinal cord injury. In recent years, however, the literature has shifted somewhat to separate studies based on individual neurologic diagnoses, moreover, one randomized trial to this effect is underway (Knüpfer et al. 2014, [144]) (LOE3). With these limitations in mind, the current literature is generally positive and indicates that SNM demonstrates similar efficacy among the neurogenic and the non-neurogenic populations in terms of successful test phase, device implantation, clinical outcomes and urodynamic outcomes.

Two points must be kept in mind when treating patients with neurological bladder:

- The disappearance of wettings between catheterizations can be considered a success by itself in patients using IC. In contrast, in able-bodied patients, treating retention with IC is most often considered a failure.
- On the other hand (contrasting, for example with botulinum toxin injections), neuromodulation does not systematically require the use of IC. Furthermore, reversibility of neuromodulation is a strong point that must be considered when devising a therapeutic plan.

The main published series are summarized in **Table 4.** Author definitions for neurological pathology differed widely; some authors considered a history of pelvic surgery as a possible etiology while others included only patients with medullary neurological lesions. Despite this, several points considering the neurological etiology of the bladder dysfunction can be discussed;

- MS is not a contra-indication for neuromodulation [139, 145, 146] (LOE3-4). However, it seems important to propose this treatment only in patients who present with a stabilized form of multiple sclerosis. In addition, patients must be clearly informed that the results of neuromodulation may be altered by the evolution of their underlying illness.
- Patients with incomplete medullary lesions, whether of traumatic or other origins, may benefit from neuromodulation [139, 147-152] (LOE3-4). On the other hand, all authors agree on excluding patients with complete medullary lesions. Clinical data, especially from the Hohenfellner series [149] (LOE3), support among others those reported by Schurch et al. in 2003 [153] (LOE4). These authors published a study in which they recorded external anal sphincter (EAS) electromyographic activity caused by stimulation of the S3 sacral root during a percutaneous needle evaluation (PNE) test in three patients who presented with neurogenic DO and DSD secondary to a complete traumatic medullary lesion. They describe a reflex response with early and late latency in the three patients. They also demonstrated that the EAS contraction observed during the PNE represented an indirect motor response mediated by the afferent nerves towards the spinal cord. Despite the recording of an EAS motor response in the three patients, they did not obtain any urodynamic or clinical benefit. This suggests the participation of supraspinal neuronal centers—presumptively a spino-bulbar spinal pathway—in the SNM mode of action. However, these data are contradicted by an experimental study using bilateral neuromodulation in the cat [154] (LOE4).
- Guys et al. [155] demonstrated significant but limited urodynamic differences in children (LOE3). However, the clinical translation of these modifications has not been reported. It must be emphasized that, in the absence of electrodes adapted to paediatric sizes, the study was carried out without the usual percutaneous evaluation phase.
• Encouraging short term results in neurogenic bladder dysfunction do not necessarily translate into long-term efficacy [149] (LOE2). Despite a positive test in about half of the patients tested, long term (54 months) results were poor in almost all patients (1/12 had neuromodulation efficacy).

• Sievert et al. [156] performed acute bilateral sacral S3 nerve stimulation in 10 patients with complete spinal cord lesions (SCLs) during the spinal shock phase, with six patients as controls. After a mean follow-up of 26 months, the cystometric capacity increased and IDC were abolished in the stimulation group. Further studies should look into this technique and question the ideas about the working mechanism in sacral nerve stimulation since afferent stimulation effects are unlikely in complete SCI.

• One of the largest and latest series is from Chaabane et al. [157]. They looked at the results of PNE testing and SNM implants with a mean follow-up of 4.3 years in 62 patients (34 with DO, 28 with chronic urinary retention). DSD was present in nine cases. 41 patients (66.1%) had more than 50% improvement on urodynamic evaluation and bladder diary with PNE, and 37 were implanted. At follow-up results remained similar to the evaluation phase in 28 cases (75.7%). In six cases (16.2%), clinical response had been lost; in these six cases, neuromodulation failed on average 12.0 months after implantation.

Particular attention has been given to the outcomes of SNM in the MS population. These patients present unique challenges given the heterogeneity of neurologic lesions and the ability of the disease to progress over time. Engeler et al. (2015) performed a single center prospective series for the treatment of neurogenic lower urinary tract dysfunction (NLUTD) caused by Multiple Sclerosis. Out of seventeen patients (13 women, 4 men) treated with SNM for refractory NLUTD, enrolled 2007–2011, 94 % had a positive test phase and received the implantable pulse generator. This group of patients was compared with the group of patients with non-neurogenic bladders. Most patients (> 50 %) in both groups reported moderate and marked improvement in overall bladder symptoms of two years, and the patients with neurogenic bladder dysfunction experienced benefits after neuromodulation similar to the benefits experienced by those without coexisting neurologic condition. These results are encouraging, however, there are still some issues which need to be solved, e.g. unilateral vs. bilateral implantation especially in patients with a neurogenic underactive detrusor. Life time of the implanted generator (battery) of course depends very much on how much electricity is necessary. Moreover, also the issue of performing MRI needs to be discussed with the patient and his neurologist as MRI might damage the implant (according to the producing company). (LOE3)

Scheepens et al. [150] reported two prognostic factors for poor response (the study population was six incomplete medullary injuries, five patients with cauda equina syndrome, six with multiple sclerosis, and one with myelomeningocele) (LOE3): duration of the symptoms (more than seven months in this study) and the existence of a neurological cause for bladder dysfunction. Neurological patients with a very localized and incomplete nervous condition were the most successful. Patients with herniated disc surgery had a greater chance of good response. Patients with complete medullary or large sacral lesions were poor neuromodulation candidates.

Clinical results of neuromodulation do not necessarily correlate to urodynamic results. Bosch indicated in his series [147] that almost half of the patients considered to have had a good outcome in reality retained some overactivity. One publication reported correspondence between urodynamic test data and clinical data [139] (LOE4). In 2001 Chartier-Kastler [161] et al. published the results of a prospective study concerning the evolution of urodynamic parameters during the acute phase of the PNE test in 14 patients with neurogenic DO. The authors concluded that the acute phase of PNE was accompanied by a significant change in urodynamic parameters in more than 2/3 of the patients, and that this should be a possible means for selecting patients.

Sacral neuromodulation for urinary retention in neurological bladder dysfunction

Only two studies reported specific results for neurogenic urinary retention. The first is by Hohenfellner et al. [149] (LOE3), reporting on 11 patients. Of these
patients, three were implanted with temporarily satisfactory results in only two.

Lombardi et al. in 2014 evaluated 95 incomplete SCI patients suffering from chronic, neurogenic non-obstructive urinary retention. Only 41% were suitable for implant after the test phase. The implant was done unilaterally. After three years 25 of all patients (29%) were considered to be successful, 11 (19%) were failures. The majority of them with the unilateral implant had success when the contralateral L3 sacral root was stimulated. The authors conclude that SCI patients with neurogenic, non-obstructive urinary retention are good candidates for SNM in the medium follow-up. [162] (LOE2)

Due to the limited available data and the rather low success rate, SNM currently holds a marginal place in neurogenic retention patients. Patients need to be clearly informed of the high risk of failure. In this respect the bladder contractility test could be helpful in order to predict a successful outcome of sacral nerve stimulation in acontractile neurogenic bladders [163]. It is also necessary to be especially prudent in patients with cauda equina problems, who may have the illusion of recovering urination, but actually may be enhancing abdominal straining to evacuate their bladder. In reflex incontinence, patients with complete spinal cord or cauda equina lesions are poor candidates (LOE4). While a few studies have reported on SNM in specific contexts [164-167], patients should be informed that IC is the first-line therapeutic option for neurogenic urinary retention.

Recommendations

- Sacral neuromodulation can have an inhibitory effect on neurogenic DO (C)
- While sacral neuromodulation has a place in the care of neurological urinary incontinence or neurological urinary retention, the proportion of patients whose condition is improved is much less than in non-neurological pathologies (B).
- Indications for sacral neuromodulation in the care of DSD in neurological urinary dysfunction are still not established (D).

6. SURGICAL TREATMENT OF URINARY INCONTINENCE

6.1. Denervation procedures for treating reflex urinary incontinence due to detrusor overactivity

Peripheral bladder denervation

The best known bladder denervation technique was developed by Ingelman-Sundberg [1,2]. The technique comprises resection of the inferior hypogastric plexus in contact with the bladder through an inverted U-shaped vaginal incision, dissecting the bladder laterally and posteriorly, as widely as possible. In the most recent paper [2], the authors report up to 54% recovery over a mean follow-up of about three years. Each published series is from the same group, is retrospective and reports only a small sample size (LOE4). It has only occasionally been used in neurogenic DO.

Isolated rhizotomy of ventral and/or dorsal sacral roots

Historically, attempts at sacral root surgery first focused on cutting the motor (ventral) sacral roots in order to abolish detrusor reflex contractions. It was soon clear that this method failed within six months. With a different objective, Brindley [3] developed a technique involving stimulation of ventral sacral roots to obtain controlled and complete bladder voiding in cases of SCI. He realised that patients only acquired continence if the stimuli causing reflex bladder contraction could be blocked [4]. Early techniques consisted in selective destruction of the dorsal sacral roots that evoke detrusor contractions. These selective rhizotomies did not, however, give the best results. Only after complete de-afferentation of the sacral micturition centre by intradural rhizotomy were better results obtained [5-8] (LOE2-3).

The technique of "selective" dorsal sacral rhizotomy has been studied more extensively but since 1988 no publications can be found anymore. It involves making an extra-dural approach to the sacral roots (S2-5), isolating and stimulating the dorsal (sensory) contingent whilst monitoring changes in urodynamic pressure within the bladder in order to cut only those fibres responsible that do not show evoked overactivity. This implies that only the senory nerves are cut and the motor nerves are preserved. To retain reflex erection, S2 must be preserved, at least on one side. This treatment may be proposed for patients with neurogenic DO, and also those with urgency incontinence. The most recent article from 1988 by Lucas et al. [9] is about 22 patients (LOE3). At the mean follow-up of 4 years, 39% of patients retained a urodynamically stable bladder with satisfactory clinical response. The authors ascribe these improved results to a more extensive rhizotomy. However, it should be noted that there was a marked heterogeneity of patients in this series, three out of the eight, considered to be "successes", were IDC patients with leakage due to DO.

Mertens et al. [10] applied a technique previously used for limb spasticity, namely microsurgical DREZotomy, the aim of which is to destroy the dorsal root entry zone (DREZ). This zone, first defined in 1972 by Sindou [11], is a functional anatomical entity that groups together the proximal portion of the dorsal root, the medial portion of the dorso-lateral tract and the superficial layers of the dorsal horn. The technique involves making a micro-surgical lesion (by micro-coagulation) on the ventro-lateral portion of the entry zone, near the apex of the dorsal zone. The effect of DREZotomy is to selectively block nociceptive afferents, and their relays, and myotatic afferents. The benefit of the limited lesion is to avoid complete abolition of tactile and proprioceptive sensitivity and to prevent the development of deafferentation phenomena. To treat neurogenic DO, the lesion must be made on both sides from S2 to S3, or even S4. The results from the first series concerned 38 patients treated for incapacitating lower limb spasticity, treated by extended DREZotomy from L2 to S1. 58% of these patients were permanently catheterized. At six months, DO had disappeared in 82%, with 63% having significantly improved bladder capacity. At 18 months post-surgery, leakage had disappeared in 89% of cases. Since 2003, no publications on DREZotomy for neurogenic LUT disorders were found, although the technique is still applied to alleviate pain.

Percutaneous sacral root block

Sacral root block is an old technique, since Dogliotti [12] proposed it as early as 1931 to relieve vertebral cancer pain by chemically sectioning several dorsal roots. An injection of alcohol causes denervation due to the fragmentation of myelin in the endoneurium. In the 1950s, Bors [13] applied the technique to the bladder, standardized the procedure and described preliminary results. Later authors reported on a few series (LOE3) [14, 15], but always with the same result; the benefit disappeared after a few months. Phenol, considered to be "selective" for C fibers was then tried but the results were no better [16-18]. Chemical destruction of the sacral nerve roots has proved ineffective and is accompanied by a high rate of minor complications (pain), resulting in significant discomfort and prolonged hospitalization (LOE3) [14, 15]. Mulcahy et al. [19] proposed sacral rhizotomy by percutaneous radiofrequency for neurogenic bladder (LOE4). A recent study was published by Ferreire et al. [20]. In 8 SCI patients they performed a bilateral block of S3 with bupivacaine. These 8 responders had an increased bladder capacity and for 3 out of 4 patients autonomic dysreflexia (AD) improved.

Rhizotomy of posterior sacral roots and stimulation of the anterior sacral roots

Electrostimulation to improve micturition in patients with spinal cord injury has been extensively re-
Micturition is not continuous: the detrusor cannot be preserved. Para- or tetraplegic patients. Sacral reflex arc must be only be performed in those with spinal damage who is difficult to perform, especially extradurally [21] (LOE4). This technique can overactivity, though this is difficult to perform, especially extradurally, so as to stimulate the sacral roots from S2 to S4. At the same time, it is essential to perform posterior rhizotomy from S2 to S4 to remove any detrusor spasm of the lower part of the body, but it should be remembered that the principal object of sacral nerve stimulation combined with posterior rhizotomy is to achieve urine continence and bladder voiding. Induced erection is a secondary benefit but not an indication for the procedure, and men should be warned that they would lose reflex erection after posterior rhizotomy.

The results of the intervention are summarized in Table 5. Briefly, the outcome with regard to continence and bladder voiding are good (LOE 2-3). Failures result from incomplete rhizotomy, where bladder hyperactivity persists, or from sphincter insufficiency which may be treated by additional placement of an artificial sphincter [7, 8] (LOE3). Incomplete rhizotomy can be surgically completed [7, 8, 24] (LOE 2-3). In all reported series, mean bladder capacity increased significantly (LOE 2-3). Micturition was obtained by electrostimulation with a post-voiding residue (PVR) of ≤ 50 ml in 69 to 100% of patients. All series reported decreased incidence of urinary infection, but the defining criteria were too varied to allow conclusions to be drawn. Posterior sacral rhizotomy probably protects the upper urinary tract from detrusor overactivity. It can resolve the problem of pre-operative reflux [24, 25] (LOE4). However, posterior sacral rhizotomy should be complete. Indeed, in a series of 500 patients, Brindley [24] (LOE3) reported twelve cases of upper urinary tract impairment, ranging from grade I reflux to upper urinary tract dilation.

Micturition is not continuous: the detrusor cannot be stimulated without also stimulating the sphincter. The parasympathetic fibers and the fibers destined for striated muscles are stimulated together. The response of detrusor smooth muscle fibers causes a gradual increase in pressure, which continues after stimulation has ceased. The "on-off" response to stimulation of striated muscle fibers is different. When stimulation stops, the striated sphincter immediately relaxes, whilst the detrusor continues to contract. A new wave of stimulation increases and maintains sufficient detrusor pressure to cause micturition after stimulation stops. The careful selection of stimulation and stopping times results in a discontinuous, but satisfactory, micturition. Sphincter fatigue due to electrical stimulations, blocking of pudendal nerve motor fibers [22] (LOE 4) or use of specific detrusor stimulation by performing an anodal block [23] (LOE 4) have been reported, together with poor efficacy.

Stimulation can also help defecation and erection and it resolves to some extent autonomic dysreflexia and also spasm of the lower part of the body, but it should be remembered that the principal object of sacral nerve stimulation combined with posterior rhizotomy is to achieve urine continence and bladder voiding. Induced erection is a secondary benefit but not an indication for the procedure, and men should be warned that they would lose reflex erection after posterior rhizotomy.

The results of the intervention are summarized in Table 5. Briefly, the outcome with regard to continence and bladder voiding are good (LOE 2-3). Failures result from incomplete rhizotomy, where bladder hyperactivity persists, or from sphincter insufficiency which may be treated by additional placement of an artificial sphincter [7, 8] (LOE3). Incomplete rhizotomy can be surgically completed [7, 8, 24] (LOE 2-3). In all reported series, mean bladder capacity increased significantly (LOE 2-3). Micturition was obtained by electrostimulation with a post-voiding residue (PVR) of ≤ 50 ml in 69 to 100% of patients. All series reported decreased incidence of urinary infection, but the defining criteria were too varied to allow conclusions to be drawn. Posterior sacral rhizotomy probably protects the upper urinary tract from detrusor overactivity. It can resolve the problem of pre-operative reflux [24, 25] (LOE4). However, posterior sacral rhizotomy should be complete. Indeed, in a series of 500 patients, Brindley [24] (LOE3) reported twelve cases of upper urinary tract impairment, ranging from grade I reflux to upper urinary tract dilation.

Martens et al. looked at patients in the Netherlands who underwent a Finetech-Brindley procedure [26]. They investigated the effects on quality of life in a group of 46 patients that still used the implant. They also looked at the presumed beneficial effects of the rhizotomy only, comparing with a group of 70 matched controlled patients that had optimised standard care. The patients had a significant better Specific Impact of Urinary Problems score, general QoL index (Qualiveen), and continence rate, and less urinary tract infections compared to the Control Group. If the stimulator was not used anymore, patients still benefited from the rhizotomy with regard to QoL and continence rate. The subscales of the SF-36 had better scores for the patients who used their stimulator as compared to those who did not use the stimulator and compared to the Control Group. The conclusion was that the active group had a better QoL than the rhizotomy group, and both groups had advantages over optimized standard care. Schurch [27] focused on the specific problem of dysreflexia and recorded its persistence during stimulation in all patients who had suffered prior to surgery, but with marked improvement in symptoms.

Krasnik reported on the outcome of 137 retrospective analysed patients. After a mean follow-up time of 14.8 years elevated detrusor pressure was reduced from 65/137 to 2/137 patients, whereas low detrusor compliance changed from 62/137 to 13/137 patients. Mean bladder capacity significantly (P<0.001) improved from 272.4 ± 143.0 to 475.0 ± 82.7ml. The mean number of symptomatic UTI also decreased significantly (P<0.001) from 6.2±4.5 to 2.5±2.6 per year. The number of patients suffering from incontinence had significantly (P<0.001) decreased from 70/137 to 44/137. At the last follow-up visit, 107 (78.1%) patients were still using the stimulator. A total of 84 complications requiring surgical revision were observed. Defects of the stimulator cables or the receiver plate were the most common events (n=38) [28].

Castano-Botero et al reported on a retrospective analysis of 104 SCI patients who underwent an extradural implant procedure. Incontinence resolved in

NEUROLOGICAL URINARY INCONTINENCE | 1143
86% of cases whereas UTI's went down from 91% to 16% [29].

Moreover the effect on bowel emptying can also be very rewarding as was published by Rasmussen et al. They reported that 73% of the 586 responding patients used the device for defecation and were very happy with it [30].

Conclusion

- Bladder denervation is mainly reserved for those suffering complete spinal cord injuries.

Recommendations

- No peripheral bladder denervation technique has passed the test of time (D)
- Injections of neurolytic products to treat detrusor overactivity should be abandoned, since they are ineffective in the medium and long term and expose patients to morbidity (A)
- Sacral dorsal rhizotomies need to be quite extensive to treat successfully neurogenic DO. So they may be performed only in patients with lower limb neurological impairment (B)
- In certain situations, dorsal rhizotomies can be undertaken in association with ventral root stimulators (Brindley’s technique) or even with continent cystostomy (B)
- Electrostimulation of the anterior sacral roots is a valid option for managing neurogenic bladder in patients with spinal lesion, with long-term follow-up (B)
- It must be combined with destruction of all or part of the posterior sacral nerves, and cannot therefore be performed in patients with conserved lower limb motility (B)
- The reflex arc must be intact (B)
- Posterior rhizotomy exposes men to loss of reflex erection and women to a loss in reflex vaginal lubrication (B)
- It is vital to assess the patient carefully before implantation so as to determine whether he/she will be able to mount a toilet or grasp a urinal handrail (B)

6.2. Surgery for Incontinence associated with poor bladder emptying

Incontinence in neurological patients can be aggravated by deficient bladder emptying and retention. Two mechanisms can be involved: detrusor sphincter dyssynergia (DSD) or detrusor underactivity.

6.3. Surgical treatment of detrusor external sphincter dyssynergia (DSD)

DSD is a characteristic feature of suprasacral and infrapontine lesions and can be treated with sphincterotomy. The aim of sphincterotomy is to produce reflex micturition into a condom catheter which acts as a pressure relieve valve, thus protecting the upper urinary tract. For the last thirty years, endoscopic sphincterotomy has been the technique of choice for patients who cannot or do not want to do IC. It is invasive, irreversible and the patient has no adaptation period [35, 36] (LOE3). Prosthetic sphincterotomy using a urethral endoprosthesis (or stent) is an alternative.

Sphincterotomy recommendation supposes a diagnosis of a neurological cause of DSD that is complicated by hydronephrosis, vesicoureteral reflux, autonomic dysreflexia or repeated urinary infections secondary to poor bladder voiding. Patients should have failed or refused IC. Main contra-indications are [37, 38]:

- Impossibility to retain a condom catheter. All sphincterotomy techniques, including stenting, are contra-indicated for men who cannot retain a condom catheter (hence also for women). A semi-rigid penile prosthesis can be placed to help retain the condom catheter [39] (LOE3). However, patients must be informed that there is a 20% to 30% risk of erosion and infection of the penile prosthesis for those with SCI, as opposed to only 2.7% in the general population [40, 41] (LOE3).
- Detrusor acontractility or hypocontractility. Patients with spinal cord injury and no reflex detrusor contraction during urodynamic tests are poor candidates for the various techniques of sphincterotomy.
- Patients who wish to father children and are candidates for vibro/electro-ejaculation and an artificial insemination program.

Endoscopic sphincterotomy

Emmett [42] first described endoscopic sphincterotomy in 1948. He performed cervico-prostatic incisions in patients with SCI, but later realized that the problem lay in the striated sphincter. External sphincterotomy was performed in 1958 by Ross et al. [43]. They carried out cold-blade surgery and placed a catheter (Ch 22-26) for tamponade, since nearly all patients required transfusion (one of the ten patients in the series died after surgery). A few attempts at surgical sphincterotomy via the perineal and subpubic myotomy routes were tried later. Complexity and frequent serious complications explains why these approaches were abandoned [44, 45]. Endoscopic sphincterotomy with electrocoagulation was finally found to be the best technique.

Endoscopic sphincterotomy morbidity includes hematuria, which can be abundant and sometimes difficult to control, requiring transfusion in 2-13% of patients (LOE2-3). Incision at the twelve o’clock position seems to offer the lowest risk of hemorrhage, with three and nine o’clock sphincterotomies entailing the highest risk [46] (LOE4). Post-operative impotence is also a common complication. Rates of up to 56% were reported in early series [47-50] (LOE3). More recent series (Table 6, LOE 2-3), most using a median, or slightly deviated incision, have not affected sexual function. However, it should be noted that the population concerned may
have many other reasons (neurological, psychological, etc.) for suffering from erectile dysfunction. When sphincterotomy is accompanied by complete incontinence there are obvious reasons for psychological difficulties during intercourse. This issue must be discussed with the patient before surgery. The fear of this sequel sometimes causes the patient to decide against surgery; use of an incontinent prosthesis as first-line therapy can enable the patient to gain insight into this potential consequence of endoscopic sphincterotomy.

If striated sphincter section fails, the possibility of bladder neck stenosis should be investigated. This is seen in from 2 to 21% of patients (LOE 2-3). Section of the bladder neck may then improve voiding, but will result in permanent incontinence. Before surgery, the surgeon must make sure that the patient accepts this situation and can use a condom catheter.

Results of endoscopic sphincterotomy are summarized in 6 (LOE2-3). Any analysis is made difficult by the absence of unequivocal criteria of success. Some patients are improved by sphincterotomy, even with a 200 ml residue. Most authors use indirect urodynamic criteria to evaluate success (decrease in bladder pressure during micturition, decrease in PVR). The most obvious result is the improvement in autonomic dysreflexia observed in tetraplegic patients. It also appears that the intervention reduces the rate of symptomatic UTIs. However, chronic bacteriuria is not improved [51]. The reported results concerning resolution of hydronephrosis and vesicoureteral reflux differ, and in each series, there are very few patients. Another essential point, well known in practice but rarely reported, is the recurrence of neurogenic DSD in many patients [36, 52, 53] (LOE3). Riccotone et al. (LOE3) [53] reported 82% recurrence of symptoms after ten years of follow-up. Juma et al. [36] (LOE3) report similar results after eleven years, with patients undergoing an average of 1.7 sphincterotomies. Pan et al. reported a mean duration of benefit of almost seven years, which could be sustained with a repeat procedure [54]. A single study has tried to address predictive factors for a successful sphincterotomy. In this retrospective study, although detrusor leak point pressure and retrograde perfusion pressure were found to be superior to residual urine volume in predicting sphincterotomy success, results were not statistically significant [55]. 30-68% of patients eventually develop some impairment of the upper urinary tract [36, 54]. Patients who have undergone this surgery must therefore be regularly monitored to detect any distension of their upper urinary tract.

The group from Ginsberg published their long term data on 97 patients who underwent bladder neck incision with external sphincterotomy (BNI/ES) over a period of 40 years. During the period reviewed, a solitary redo BNI/ES was done in 46 patients, a second redo BNI/ES was done in 23 patients, and a third redo BNI/ES was done in 7 patients with success rates of 50%, 68.2%, and 85.7%, respectively. All patients had a normal serum creatinine level at the end of the follow-up. Mean elapsed follow-up after the last redo BNI/ES was 119 months (range, 6-408 months) for all patients evaluated. Mean durability of successful redo BNI/ES was 109.1 months. [56]

Prosthetic sphincterotomy

In 1990, Shaw et al. proposed using a wire mesh stent (Urolume) to treat patients with spinal injury presenting with DSD [58] (LOE3). Since then, various stents have been used.

Temporary prosthetic sphincterotomy

Temporary stents make it possible to carry out a therapeutic test to check the feasibility of condom catheter use, check that placing a foreign body in the urethra does not induce autonomic dysreflexia and ensure the patient accepts the mode of micturition. Moreover, during this trial period, it is possible to study how the bladder empties in the seated position, and assess the necessity of additional treatment for smooth muscle sphincter dyssynergia at the level of the bladder neck. As this treatment is simple and reversible, it is possible to propose it very early to the patients, rendering the patient autonomous with regard to carer-assisted catheterization, if this were the prior mode of micturition; i.e. return to his former state, change to another temporary stent, replace it by a permanent stent, or choose surgical sphincterotomy.

By definition, temporary stents should be self-retaining, easy to remove and must not epithelialize. Only the temporary stent Diabolo [61] is specific for the external urethral sphincter. The results of two types of temporary stenting (test) for incontinence have been published in the same series [62] (LOE3). In a retrospective study of 147 patients, the authors demonstrated a significant effect on incontinence throughout the mean ten month test period, with very low morbidity (15%). The temporary stents were removed easily from all patients without sequelae. After this period, 62.6% of patients chose permanent sphincterotomy, usually by means of a permanent stent. Memokath is another device that has been studied in neurological patients [63-68] (LOE3-4). Several authors report complications (32-100%) using this stent, which seems to induce a lot of bladder stones and to be quite difficult to remove, especially if it is left longer than 18 months. When used as second-line treatment following failed sphincterotomy, Memokath success-
fully reduced post-void residuals, but failed to improve urodynamic parameters including bladder capacity, detrusor leak point pressure, bladder compliance, and maximum detrusor pressure [63].

**Permanent prosthetic sphincterotomy**

Permanent stents are designed to integrate with the urethral wall [69]. They resist the striated sphincter and prevent its closing during reflex contraction. They can be removed if necessary, or at the patient’s request, with recovery of striated sphincter contraction [70, 71]. Permanent stents are made of biocompatible materials such as nitinol (a nickel and titanium alloy) and titanium. They usually consist of a mesh comprising a single thread (e.g. Urolume) or several threads (e.g. Ultraflex). None of the stents are specifically adapted for the urethral striated sphincter. Three have been reported for treating neurological patients with DSD: Urolume, Memotherm and Ultraflex. All can be placed under local anesthesia. Table 8 summarizes the principal series published on these devices. Only Urolume was studied according to strict prospective criteria [51] (LOE1-2). Using stringent clinical and statistical methods, they classified the stent as LOE 1 for effectiveness and morbidity in DSD with a 5-year follow-up. 160 patients with SCI (mean age 36.3 years) in 15 North American centres, were treated prospectively with Urolume for DSD. Urodynamic parameters for micturition pressure, PVR and functional bladder capacity were measured before treatment and then annually up to 5 years afterwards. Mean micturition pressure, the primary criterion, was significantly lower 5 years after stenting. PVR decreased significantly and was maintained after 5 years. Mean bladder capacity remained constant. Hydronephrosis, suffered by 28 patients before surgery, disappeared in 22 (78.6%) and was improved in the others. Autonomic dysreflexia resolved in 70% of cases. The indwelling catheters of 63 of the 86 (84.9%) patients catheterized before surgery could be removed. The percentage of positive urine cultures remained unchanged after stenting. No cases of peri- or post-operative bleeding, soft tissue erosion or bladder lithiasis were observed during the study. One case of prosthetic encrustation occurred during the first year; three during the second year; three during the third year; two during the fourth year and five in the fifth year. Urothelial reaction was reported in 44.4% of cases, but 93.3% of these were mild and none required treatment. No erectile dysfunction was reported. Stents had to be removed from 24 patients (15%), four of whom received new implants. 80% of the patients considered their situation improved by stenting, and 84% of physicians considered the treatment effective. 47 patients required supplementary treatment on the bladder neck (endoscopic section in 20 cases). In the mid-term, prosthetic sphincterotomy using a Urolume stent appears to be satisfactory. However, the situation is not so clear over the longer-term. It is not always easy to remove the stent, especially from patients who have not been monitored regularly. Some teams report highly complex surgery for stent removal, especially in the event of associated urethral stenosis [72-75] (LOE3). A small study (n=12) following patients up to twenty years after insertion, suggests a high rate of complications, as 5/6 patients who completed the 20-year follow-up developed bladder neck dyssynergia requiring incision, 2 patients developed obstructive encrustations within the first year of insertion and another patient developed bladder cancer [76]. However, in those patients who completed the 20-year follow-up, sustained significant improvements in maximum detrusor pressure and duration of detrusor contraction were recorded.

Whether patients should be offered prosthetic or endoscopic sphincterotomy is not yet agreed. Endoscopic sphincterotomy is the preferred standard treatment for DSD, where IC cannot be performed. Two prospective studies carried out in the US in 1994 indicated that prosthetic sphincterotomy was at least as effective as standard sphincterotomy in patients with SCI, and offered advantages in terms of morbidity, duration of hospitalization and cost [77, 78]. The two studies were not randomized. Follow-up was short (mean 15 months), with a potential risk of bias, since the conclusion that external sphincter balloon dilatation is as effective as endoscopic and prosthetic sphincterotomy is not borne out by long-term outcomes [79].

A prospective, multicenter, randomized study comparing endoscopic sphincterotomy with prosthetic sphincterotomy was published in 1999 by Chancellor and Rivas, using the Uroleum stent [80]. Fifty-seven patients in three specialist spinal cord injury centers were included. The study concluded that prosthetic sphincterotomy was as effective as endoscopic sphincterotomy and required shorter hospitalization. Polguer et al published their experience with the Uralflex (n=11) and Memotherm (n=11) during 56 months in patients with DSD. Complementary procedures after stenting included: five stent prolongation or displacement (mean interval 7.6 months), six bladder neck incisions (12.2 months), three urethrotomy (42 months), ten obstruction treated by laser (47.3 months). Eight patients had a change of their urinary pattern: four underwent ileal conduit diversion, one had a continent urinary diversion, one chose self intermittent catheterization waiting for another treatment. Stent retrieval was either harmful or impossible for four of them. Three patients were free of complementary procedures. They conclude that nitinol urethral stent was an effective treatment initially. However after years urethral stenosis and hypertrophic growth of the urethral mucosa usually require extra endoscopic procedures (0.31 per patient per year). They recommend yearly endoscopic follow-up. [81]

### Recommendations

- Where clean intermittent catheterization is not possible, the use of a urethral stent is possible (B).
- Whatever type of sphincterotomy is chosen (surgical or prosthetic):
  - Patients must think carefully about the different modes of micturition possible for them (A).
- The few studies reporting long-term results of sphincterotomy demonstrate the vital importance of regular patient monitoring for the recurrence of DSD or blockage (B).
- This mode of micturition is contraindicated in women, and in men with difficulty in maintaining a condom catheter (B).
- For patients who have chosen surgical sphincterotomy:
  - The reference technique involves an elective 11, 12 or 1 o’clock incision of the urethral sphincter (B).
- Although surgical sphincterotomy is the accepted reference treatment for neurogenic DSD, analysis of the literature highlights the lack of reliable efficacy and reproducibility criteria for the technique (B).
- For patients who have chosen prosthetic sphincterotomy:
  - Different types of stent are used, depending on whether sphincterotomy is temporary or permanent. Stents are complementary, and different designs can be used for different situations (B).
  - Surgical complications depend as much on the surgeon’s competence as on the material and may be reduced by experience (C).
  - Clinical studies have demonstrated that neurogenic patients prefer prosthetic sphincterotomy because it is reversible, even when permanent stents are placed (C).
  - Careful follow-up, using yearly cystourethroscopy is mandatory when leaving a permanent urethral stent (B).
- Published data is inadequate to support a recommendation on the use of bladder neck incision in patients with inadequate bladder emptying due to detrusor-bladder neck dyssynergia (DBND)

The rationale to use BNI was that sympathetic overactivity might inhibit detrusor contraction and transurethral incision of bladder neck might interrupt the inhibitory reflex arc and result in restoration of detrusor contractility. In a single retrospective study BNI was performed in 22 patients with high-level SCI and DBND demonstrated upon video-urodynamics, who were previously managed by either IC or indwelling catheter [82]. Voiding symptoms were complicated by autonomic dysreflexia in 17/22 patients. Deep incisions were carried out at the 5 and 7 o’clock positions, sparing the external urethral sphincter. A satisfactory surgical outcome was recorded in 86.4% of the patients 3 months post-op (LOE3). While all patients additionally suffered from DSD preoperatively, an open urethral sphincter during voiding was reported in 86.4% of them following BNI, and autonomic dysreflexia became less severe or resolved in 88.2% of sufferers. The authors hypothesized the presence of a urethra-to-bladder neck reflex pathway to explain additional improvements in DSD.
6.5. Surgery to increase detrusor strength

For some patients, the cause of detrusor underactivity lies in the bladder wall. In this case, the control circuit functions but the bladder muscle is too weak. At present there is no medical treatment for this situation. The general objective is to reduce peripheral resistances as much as possible and where this fails, to propose IC. However, some teams have suggested placing rolled strips of muscle around the bladder. Some authors have also suggested a strip of rectus abdominis muscle. This is easier to perform and may be used essentially for reconstructive surgery, such as in bladder exstrophy [83-85] (LOE4). The only team to have published results on detrusor underactivity in man is that of Ninkovic et al. [86] (LOE2). They reported interesting results from 20 patients suffering from neurogenic detrusor underactivity and requiring self-catheterization. They reported a technique that they had designed in animal experiments [87,88] (LOE4) and which consisted of transferring a free strip of latissimus dorsi muscle, which was anastomosed to the epigastric vessels and the lowest branch of the intercostal nerve. Out of 20 patients, with a mean follow-up of 44 months, 60% no longer required IC, with PVR below 100 ml. After complementary surgery on the bladder neck, there was a 90% success rate that was stable over time. The authors reported no heavy morbidity, particularly with regard to the donor site. These promising results were largely confirmed in a multicentre trial involving 24 patients with a median follow-up time of 46 months [89]. Complete spontaneous voiding (mean PVR 25ml) was restored in 71% of the patients, while frequency of CIC was reduced in another 13%. Recurrent UTIs ceased in 91% of patients. A critical increase in bladder contractility index may be required to achieve complete bladder emptying, but the number of patients was too small for safe conclusions. Future development could use tissue-engineering techniques to construct vascularized and contractile strips implanted around the bladder with the same procedure.

Recommendations:
- Latissimus dorsi myoplasty on the bladder is a promising technique that needs to be validated further (C).

6.6. Stress urinary incontinence (SUI) due to sphincteric incompetence

Some patients with neurogenic lower urinary tract dysfunction will suffer from incontinence due to sphincter weakness. In general, patients with lesions affecting the brain or suprasacral spinal cord will not suffer from this problem, as the sacral sphincter guarding reflexes will be intact. However, patients with lesions of the conus medullaris, the cauda equina or peripheral sacral nerves are at risk of developing neurogenic stress incontinence. Patients with neurological disease may also suffer from stress incontinence due to direct sphincter injury from urethral catheter trauma or as a result of previous interventions such as sphincterotomy or dorsal rhizotomy. In women, SUI may be present for non-neurogenic reasons such as urethral hypermobility due to previous pregnancy and childbirth.

People with neurogenic lower urinary tract dysfunction and SUI may also have impaired bladder storage function. If this is the case, a surgical procedure that treats the stress incontinence in isolation might put the patient at risk of upper urinary tract deterioration (as the upper tracts become exposed to the full force of the bladder dysfunction, having lost the “safety valve” effect of a weak sphincter) or of persisting incontinence. Pre-operative urodynamic evaluation of bladder function is therefore mandatory before undertaking surgery for neurogenic SUI.

The question as to when it is safe to treat neurogenic SUI while leaving bladder dysfunction uncorrected has been studied most intensively in the paediatric age group. Most series relate to children with spinal dysraphism/myelomeningocele and, typically, authors report the necessity to proceed to bladder augmentation in at least a third of patients. Even with a thorough urodynamic and radiologic preoperative evaluation, some patients will have late bladder compliance deterioration [106-123]. However, the issue continues to generate debate and studies have not reached total consensus; for example, Snodgrass et al. [124] (LOE3) published a retrospective analysis of 30 children (mean age: 8.6 years) who had a bladder neck sling procedure and appendico-vesicostomy without augmentation. At 22 month of mean follow-up, only one patient had had to undergo a bladder augmentation. In a subset of 16 patients who had urodynamics at 24 months, 13/16 had an increase of their maximum bladder capacity. However, 67% of the patients required anticholinergic therapy. In contrast, Dave et al. [125] (LOE3) strongly advocate the case for simultaneous bladder augmentation. The authors report a series of 15 children followed for at least five years after an isolated bladder outlet procedure (5 Pippi-Salle, 5 slings and 5 artificial urinary sphincter). At a mean follow-up of 11.25 years, all the patients underwent surgery to increase bladder capacity, either for recurrent incontinence or for upper urinary tract deterioration. At present, no definitive conclusions can be drawn as to advisability of routine prophylactic bladder augmentation, but many authors recommend a concomitant bladder augmentation when performing a bladder outlet procedure [126] (LOE4). The option of using detrusor injections of botulinum toxin in children offers a further therapeutic approach in circumstances where there is uncertainty.
A further important consideration when contemplating neurogenic SUI surgery is the means of bladder emptying following treatment of the sphincter weakness. In particular, patients who are emptying their bladders using an element of straining will not be able to empty in this way post-operatively. Patients will therefore need to consider how they will empty their bladder once continence is achieved. The options available to patients will include: IC (either via the urethra or a continent catheterisable abdominal conduit) or the use of a suprapubic catheter (either on free drainage or with a catheter valve). There will be some patients, who have only limited neurological damage, who will continue to be able to empty their bladder using voluntary voiding post-operatively but, even in this group, it is necessary to warn patients of the possible need for post-operative IC and to make sure that they are capable of using the technique before embarking on treatment.

Farag et al performed a systematic review on the treatment of stress urinary incontinence in neurogenic patients published from 1992 to 2013. Thirty studies were identified with Level 3 evidence. The quality of reporting was 43-81%, with significantly higher quality noted in studies published after 2002. None of the studies followed a randomized controlled trial (RCT) design. Three primary surgical procedures were used in 29 of 30 studies: artificial urinary sphincter (AUS), urethral slings, and urethral bulking agents. One study used a ProACT device. AUS was considered more successful than urethral bulking agents (77 ± 15% vs. 27 ± 20%, P = 0.002). Urethral bulking agents reported higher failures than urethral slings procedures (49 ± 16% vs. 21 ± 19%, P = 0.016) and AUS (21 ± 19% vs. 10 ± 11%, P < 0.002). They concluded that the quality of evidence obtained from non-RCTs is modest. Surgeries for NSUI have relatively high success rates but also high complication rates. [127]

6.7. Bulking agents

There have been some studies reporting on the use of bulking agents in neuropathic patients (Table 9). Most of the published series relate to the use of periurethral injections in children. Various agents have been used. Polytetrafluoroethylene (TEFLON) was one of the first [128, 129]. It was once popular for treating vesico-ureteric reflux, but it has been abandoned after several authors reported possible particle migration and granulomatous reaction to this product [130, 131] (LOE2). Collagen has also been used, but is no longer available. Collagen lysis was found to lead to the loss of the bulking effect over time [129, 132-139]. Other synthetic products that have been used include polymethylsiloxane (MACROPLASTIQUE) and dextranomer hyaluronic acid copolymer (ZUIDEX) [128, 140-146]. Henly et al. [188] demonstrated that distant migration of particulate silicone was observed in animals after periurethral injection with polymethylsiloxane (LOE4). One of the main advantages of periurethral injections of bulking agents is that they are minimally invasive and can even be carried out as an outpatient procedure. The product is usually injected in the region of the bladder neck using a retrograde endoscopic approach. The bulking agent is injected at up to four sites with the aim of achieving urethral coaptation. Dean et al. [146] have suggested using an antegrade approach whereby the bladder neck is accessed using a percutaneous puncture into the bladder.

The results of periurethral injection surgery are summarized in Table 9. There are difficulties in comparing results from different series, because patient population and definitions of treatment success differ. In particular, the criteria for defining “improvement” and “social continence” vary. Therefore, it seems appropriate to consider the proportion of “dry patients” as defining clear-cut success (even if some authors add to this result a notion of “dryness for some hours” between voiding or catheterization). Using this definition, 0 to 36% of the patients are considered to be cured using bulking agents (LOE2-3).

Most results are observed after a mean follow up that rarely exceeds 2 years (LOE2-3), although one series has reported long-term improvement up to 7 years after the last injection [148].

There are other important considerations to be made when interpreting the results of periurethral bulking agents. The first is that the studies in children generally contain patients with two types of problems: congenital urinary tract malformations (epispadias, bladder extrophy) and neurogenic lower urinary tract dysfunction (mainly myelomeningocele). This is of importance because there is some indication that, in children, bulking agents work slightly better in patients with malformations than in those with neurological problems [128, 135, 143, 148]. The global results of the series are therefore probably more optimistic than the results that might be observed in a population of only neurological patients. A second point is that these children have frequently already undergone various surgical procedures, which could modify the results of the injection procedure. Although a high proportion of the patients in these studies use IC, some have satisfactory outcomes while continuing to void spontaneously.

Although the use of bulking agents does not appear to cause any severe complications, there is the suggestion that the presence of deposits of inert material might lead to greater difficulty in performing future bladder neck surgery [143, 148]. It is also important to acknowledge that the failure to correct incontinence is in itself a complication of the operation [126]. Gender and previous bladder/sphincter surgery do not seem to be reliable prognostic factors regarding the success of the injections.

6.8. **Autologous Sling Procedures**

In women with neurogenic lower urinary tract dysfunction, the use of an autologous fascial sling to support the urethra (usually close to the bladder neck) has been widely used to treat stress incontinence. A sling can either be used in isolation or in conjunction with other procedures such as bladder augmentation. **Table 10** summarises the results of published case series. Complete continence is observed in 83 to 89% of the patients (LOE3). Once again it should be emphasised that many patients will be dependent on bladder emptying using IC or an SPC, because the patient's neurological dysfunction may preclude voluntary voiding and because the sling may have to be inserted under tension in order to provide sufficient outflow resistance in the face of neurogenic intrinsic sphincter deficiency. All of the series report a low morbidity rate from the procedure. In particular, the risk of urethral erosion is very low when fascial slings are used. Synthetic sling materials have generally not been advocated when significant sling tension is required because of the risk of secondary urethral erosion [129] (LOE3). However, there is a lack of studies that compare the use of autologous tissue and synthetic material. Bladder neck slings appear to be capable of providing good results in children. Some series suggest that girls have better outcomes [124,149-151].

The group from McGuire published retrospectively about 33 women with neurogenic SUI treated with an autologous fascial sling. The mean follow-up time was 52 months, while the mean age of the patients was 37 years. Causes of neuropathic bladder were myelomeningocele in 21 and spinal cord injury in 12 patients. A total of 30 patients were successfully treated and satisfied with the outcome of the operation (91%). Twenty-five patients (76%) were totally dry, while 5 patients (15%) had markedly improved but still required one pad per day. The complication rate was 15%. [152]

(LOE: level of evidence, NS not stated)
6.9. Suburethral tapes

Midurethral tape operations, such as the tension-free vaginal tape procedure, have taken a major role in the management of stress incontinence in the non-neuropathic population but have not been adopted for the treatment of neurogenic stress incontinence; concerns about the risk of urethral erosion have been discussed already. Furthermore, intrinsic sphincter deficiency represents the usual pathophysiology in neurogenic SUI, contrasting with urethral hypermobility in non-neuropathic women.

There is very little published data available on the efficacy of midurethral tension-free tape operations in adult women with neurogenic LUTD. In a retrospective series of 12 women treated by TVT [153] with a mean follow up of 10 years, 9 patients were available for assessment of which 7 were dry and 2 were improved. The authors did not report any urethral erosions on follow up.

For male patients with post-prostatectomy incontinence, the use of synthetic tapes is increasing but, there is very little data for patients with a neurological cause to their incontinence, other than case reports. The use of this type of device in patients with underlying neurological illness should clearly be very cautious until further data emerges from clinical trials (LOE4).

6.10. Artificial urinary sphincter (AUS)

The AUS is recognized as one of the most effective treatments for urinary incontinence. It has the inherent advantage that it provides an adequate urethral closure pressure during the urine storage phase of the micturition cycle but then allows voiding to take place in the face of a low bladder outlet resistance. In patients with SUI, it is able to deliver either complete or “social” continence in 75 to 87% with satisfaction rates ranging between 85 and 95%. These rates are provided by published case series that contain a majority of patients with post-prostatectomy stress incontinence (PPI), along with some neuropathic patients. However, outcomes are probably similar for patients with neuropathic stress incontinence and a low-pressure bladder reservoir (LOE4) [154]. It should be noted that most of the published data on the use of the AUS in neurogenic SUI relates to men, although the device is also used in female patients with neurological disease as was published by Phe et al [155].

Before using the AUS in neurogenic SUI, several factors must be considered:

- Firstly, the risk of implant infection and erosion is probably higher than in the PPI population. It is generally recommended that patients undergo pre-operative urine culture and sterilisation of the urine before surgery [156] (LOE4).
- Manual dexterity must be sufficient to allow the patient to use the AUS pump—either to open the cuff to urinate, or to allow IC [154]. They must also accept the need for IC should the bladder have reduced contractility. However, some studies seem to indicate that the cycling activation of the pump could be avoided in patients performing IC (LOE3) [157, 158]. Bersch et al. [157] have described a modified technique.
- The cuff implantation site in adult patients with a neurologic bladder dysfunction is debated. The cuff can be implanted via a retropubic approach at the level of the bladder neck or around the prostatic apex. Alternatively the cuff can be implanted around the bulbar urethra using a perineal incision. Proponents of the retropubic approach argue that perineal incisions may cause cicatrisation problems for patients in wheelchairs. Moreover, traumatic catheterization is a well-known risk factor of urethral erosion in the non-neurological population undergoing an AUS [118] (1 to 5.5% in contemporary series) and, although it is recognized that IC is possible in AUS implanted patients [159], the risk of traumatic catheterization and subsequent cuff erosion might be higher when the bulbular urethral site is used. On the other hand, inserting an AUS cuff around the bladder neck is technically more difficult in adults in comparison with peri-bulbar implantation (LOE4). Some investigators are now exploring the possibility of using a laparoscopic technique for sphincter implantation [160].
- It is necessary to know the ejaculatory status of males in order to discuss the possible impact of the device on ejaculatory function. Cuff implantation around the bladder neck may allow patients to achieve antegrade ejaculation [161] (LOE4). As previously stated, a thorough urodynamic evaluation of the bladder is mandatory in order to evaluate the potential impact of bladder compliance following AUS implantation. This has been reported in several retrospective series (LOE3) [108-123]. The reasons for this change in bladder behaviour are not known, and it has been observed particularly in populations of patients with myelomeningocele [115, 117, 119, 120, 122]. In the event of any doubt about the quality of the bladder reservoir, bladder augmentation should be performed. The main results of published series are summarized in table 11. The continence rate is high, especially when a bladder augmentation has been performed (59 to 100% of the patients). The older series include some patients with the previous version of the AMS 800 (AMS 792). Therefore, it is possible that the long-term outcomes for patients being implanted today may be better than those seen in the past as a result of technical modifications of the device. Device infection, cuff erosion into the urethra and loss of fluid from the implant are the main causes of loss of an AUS. Infection and erosion typically occur in the early months after implant but late erosions are seen [114] (LOE3). The majority of the authors consider AUS to be the “gold standard” procedure to treat neurogenic sphincter deficiency in men.

6.11. Surgery of the bladder neck

Three main procedures have been described. Historically, the technique of Young [162], later modified by Dees [163] and Leadbetter [164] came into use, essentially for reconstruction in cases of exstrophy and epispadias. The principle was to mobilise the trigone (after ureteric reimplantation) in order to resect bladder neck tissue, so as to reconstruct the trigone around a small catheter. Although some authors [165, 166] described its use in neurogenic patients, the procedure has rarely been used in this patient group. The Kropp procedure [167] involves the use of a tubularised flap of the anterior bladder wall, which is used to extend the bladder neck and create an intravesical conduit. The tube is secured to the posterior bladder wall between the ureteric orifices. In the initial technique, the tube was tunnelled submucosally, but this manoeuvre was thought to increase the risk of tube stenosis [168, 169] (LOE3).

A third technique is that described by Pippi-Salle [170]. It is considered to be a variant of the Kropp procedure (also called a Kropp-onlay), with an anterior bladder wall flap that is not tubularised. Initial descriptions involved routine ureteric reimplantation but this was abandoned in later patients as long as there was an absence of reflux [171, 172] (LOE3). In a systematic review, Kryger et al. [126] (LOE4) stated that only data on 83 patients for the Kropp technique and 25 with the Pippi-Salle procedure have been published. Since that review there has been a lack of further significant data concerning the outcomes of these procedures. The continence results are good (50-69% for the Pippi-Salle procedure, 78-81% for the Kropp procedure) [168, 169]. However, several problems exist with the two techniques. Firstly, the techniques do not allow easy endoscopic access to the bladder. This is a major problem because it prevents or limits future endoscopic procedures (especially ureteroscopy, botulinum toxin injections and litholapaxy). Secondly, 28-45% of patients (especially male) report catheterisation difficulties following a Kropp procedure. For the Pippi-Salle procedure, continence rates are lower than for the Kropp procedure, but fewer cases of catheterisation difficulty have been reported [126]. However, a revision procedure is necessary in significant numbers, and it has rarely been used in male patients.

6.12. Complete bladder neck or urethral closure

Closure of the bladder outlet may be required if alternative approaches to managing stress incontinence are inappropriate or have failed. In women, closure can be achieved either via a vaginal or an abdominal approach while in men, either the bladder neck or the bulbular urethra can be the site of closure. Bladder drainage is maintained using a continent catheterisable abdominal conduit (e.g. using the Mitrofanoff principle), an SPC or (rarely) an ileo-vesicostomy.

Colli published a single surgeon experience in 35 patients with 4-13 years follow-up. BNC was paired with suprapubic catheter diversion. Indications for BNC included severe urethral erosion in 80%, decubitus ulcer exacerbated by urinary incontinence in 34%, urethrocutaneous fistula in 11%, and other indications in 9%. The overall complication rate was 17%. All but two patients were continent at follow-up. [173]

Bladder neck or urethral closure can be technically difficult and a secondary operation to close a persistent fistula may be needed in some cases [174]. Interposing vascularised tissue between the bladder neck suture line and the urethral or vaginal closure is a well-described aid to the avoidance of closure failure; a flap of rectus abdominis can be used for this purpose. Bladder neck closure has also been used in children where other means of correcting SUI have failed or are felt to have a limited chance of success. The published series of cases provided some reassurance that children with closed bladder necks do not suffer from excessive complications in the form of renal deterioration, bladder rupture or stone formation.

As a general principle, urethral closure should not be undertaken in cases where it is possible to maintain urethral patency using alternative approaches to treat SUI. For example, patients with neurogenic lower urinary tract dysfunction are at high risk of stone formation in the bladder or upper tracts and it is desirable to maintain easy endoscopic access to the bladder in order to allow potential endoscopic treatment. Finally, preserving the natural urethra may constitute a safety measure if high bladder storage pressures are present or in the event of any complication with bladder access via a continent catheterisable abdominal conduit or suprapubic catheter [175].

**Recommendations:**

- Patients with stress incontinence in association with neurogenic lower urinary tract dysfunction require careful assessment in order to plan appropriate management. Video-urodynamic study must be used to evaluate both bladder and sphincter function (C).
- The clinical assessment must also evaluate the degree of patient handicap in order to determine whether they can perform self-catheterization, or whether an alternative means of emptying the bladder will be required. (D).
- Patients require careful preoperative counselling with respect to the benefits and risks of different operative approaches
- Autologous slings can be used to treat neurogenic stress incontinence. (B).
- Due to the limited evidence base, possible sphincter deficiency, perceived risk of complications and potential consequences on future management options, the Committee is unable to recommend routine use of synthetic slings and...
tapes to treat stress urinary incontinence in neurogenic patients (D). Synthetic tapes could be recommended in older women with stable neurological conditions and SUI due to urethral hypermobility (C) as opposed to younger patients (e.g. myelomeningocele) with neurogenic ISD (negative recommendation).

- Artificial urinary sphincter can be used to treat neurogenic stress incontinence (A).
- Bladder neck reconstruction can be used to treat neurogenic stress incontinence (D).
- Bulking agents can be used to treat neurogenic stress incontinence when there is a demand for a minimally invasive treatment (D). The patient should be aware that the technique has a low success rate.
- Bladder neck closure should be offered to patients who have persistent neurogenic stress incontinence where alternative treatments have either failed or are likely to fail (B).

6.13. Surgical alternatives excluding denervation procedures to treat reflex incontinence due to neurogenic detrusor overactivity

Keywords; neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis; bladder augmentation; enterocystoplasty; gastrocystoplasty; sigmoidocystoplasty; colocystoplasty; ureterocystoplasty; autoaugmentation; detrusorectomy

The aim of bladder augmentation is to provide long-term protection to the upper urinary tract by reducing the risk of impairment due to high bladder pressure, as well as to improve storage function [181]. First performed in man by Von Mickulicz [182] who used a segment of small intestine, the technique has regained popularity since the 1970s after the introduction of IC [183]. Unlike complete bladder replacement, enterocystoplasty preserves the integrity of the trigone of the bladder with the urethra and ureters, and reimplantation is not necessary. A segment of the gastrointestinal tract is taken out of continuity from the rest of the gut, and sutured onto the bladder. Various augmentation techniques using different segments of the gastrointestinal tract (caecum, colon, and ileum) have been described. Bladder augmentation is indicated wherever bladder capacity and compliance is reduced, or in the event of detrusor overactivity, when all conservative treatments (medical treatments, detrusor injections of botulinum toxin and/or neuromodulation of the posterior sacral roots) have failed [181, 184].

Before performing bladder augmentation, it is essential to ensure that:
- There is no malignant disease or lithiasis in the bladder.
- Renal function is normal and the upper urinary tract is unimpaired (screen particularly for lithiasis).
- There is no gastrointestinal tract disease (Crohn’s disease, hemorrhagic rectocolitis, short gut syndrome, etc.).
- The patient is willing and capable of self-catheterization. This can be combined with continent cystostomy.

Technical principles:

There are two stages to the surgical procedure: first bladder preparation and then augmentation. Usually open surgery is performed, but recently laparoscopy has been reported [185, 186] (LOE3). At present, except for technical articles on laparoscopy, there are no publications comparing this technique with open surgery.

The bladder can be prepared either by clam cystoplasty or by supratrigonal cystectomy. The preferred preparation depends on the quality of the detrusor, and more particularly on whether the bladder has retained its visco-elastic properties. Where the detrusor is very fibrous and thick, supratrigonal cystectomy should be envisaged, since otherwise exclusion of the ileal patch may occur.

Clam cystoplasty

Clam cystoplasty involves freeing the anterior/ posterior surfaces and dome of the bladder. The bladder can be opened either in the transverse plane or sagittal plane, the incision starting and ending about 2 cm above the bladder neck. If the lateral surfaces are not mobilised, the vesical arteries can be preserved to maintain vascularization of the bladder dome. Robot-assisted laparoscopic augmentation cystoplasty has been recently introduced. Preliminary results have been reported in children with spina bifida [187].

Supratrigonal cystectomy

Supratrigonal cystectomy involves resection of the body of the bladder, but retaining the trigone. The bladder is freed under the peritoneum and the superior vesical arteries ligated and sectioned. The bladder pedicles are ligated and sectioned laterally up to the trigone, which is preserved. The body of the bladder is excised 1-2 above the trigone. During the bladder dissection, care must be taken to spare the ureteric vascularization.

Ureteric reimplantation

Ureteric reimplantation must be carefully discussed in the event of vesicoureteric reflux (VUR). Several authors have reported that improved bladder compliance precludes the need for reimplantation (LOE 3)
muscular enterocystoplasty necessitates removing it with a demucosalized sigmoid patch [195]. Sero-lined with urothelium involves removing the detrusor, mucosa that leads to metabolic acidosis. A number of and reduce the reabsorption of urine by the intestinal neo-bladder [184].

The removed intestinal segment must always be de-mucosalized and seromuscular ileocystoplasty was supported by a small non-randomised study (LOE 3), where Wang et al. demonstrated that lack of ureteric reimplantation during cystoplasty in children with neurogenic bladder was a risk factor for residual high-grade reflux, which, in turn, was a risk factor for febrile UTIs [193]. A larger non-comparative non-randomised study (LOE3-4) reported equal success rates for the two methods, but ureteric reimplantation had been mostly reserved for the higher grade reflux cases [194]. These results were presented as part of a literature review which was inconclusive as to the superiority of the results of either method [194]. Accordingly, the need for ureteral reimplantation during bladder augmentation should still be considered, especially for cases of grade V reflux. However, improved bladder compliance will reduce some VUR.

Intestinal segments

The choice of intestinal segment depends on patient’s history and the local conditions. All segments of the gastrointestinal tract may be used, except the jejunum because of the risk of water-electrolyte disorders. The most frequently used segment in adults is the ileum, because it is easy to remove, is close to the bladder and may be shaped easily into a reservoir. Colon segments are used more often in children. The removed intestinal segment must always be detubularized to reduce peristalsis to a minimum and to obtain a reservoir with low pressure. The segment is then placed and sutured onto the bladder in the form of a patch. For supratrigonal cystectomy, the intestinal segment needs to be longer and fashioned into a neo-bladder [184].

Technical variations aim to reduce mucus secretion and reduce the reabsorption of urine by the intestinal mucosa that leads to metabolic acidosis. A number of variant techniques have been proposed but not developed extensively. Seromuscular colocystoplasty lined with urothelium involves removing the detrusor, leaving the bladder mucosa intact, and then covering it with a demucosalized sigmoid patch [195]. Seromuscular enterocystoplasty necessitates removing the mucosal membrane of the intestinal segment surgically, or destroying it by argon beam [196], before placing it onto the prepared bladder [197].

A third technique uses an appendicular-based cecal flap, aiming for a less invasive form of augmentation cystoplasty [198]. The technique involves isolation of a 10-12 x 3 to 5-cm cecal flap on the base of the appendicular pedicle, by which the bladder was augmented and the appendix was brought out through the abdominal wall for catherization. Without any bowel anastomosis, the cecal anterior wall was re-paired.

An experimental technique tested only pre-clinically is the reversed seromuscular ileocystoplasty, where the seromuscular layer of the ileal loop from its antimesenteric aspect was sutured to the bladder mucosa of the previously bivalved bladder. Complete epithelialization of the ileum’s serosal surface with transitional epithelium was confirmed 4 weeks post-operatively [199].

Results of enterocystoplasty

The main published series for patients undergoing surgery for neurogenic bladder are summarized in Table 12. Peri-operative mortality is estimated between 0 and 3.2% (LOE 2-3). The most frequently reported early morbidity (LOE 2-3) is prolonged post-operative ileus in up to 11.7% [200-203]. A nasogastric catheter is no more justified in neurological patients than in the general population (LOE3) [204]. Other common complications include episodes of febrile UTI (4.8-9%), urinary fistula (0.4-4%), that usually resolve, and thrombo-embolic complications (1-3%). When the pelvis has been irradiated, the patient must be warned of the increased risk of enteroc- or colovesical fistula. Stoma revisions (up to 50% in a small series) and wound infections have also been reported [203].

Chronic bacteriuria always occurs with IC and should not be considered a complication [203] (LOE4). Cases of late urosepsis have, however, been reported [255]. The risk of calculus in the enlarged reservoir ranges from 10-50% [205-209] (LOE 2-3). There may be a higher risk of developing upper urinary tract lithiasis than in the general population [210-212] (LOE3).

After bladder augmentation, intestinal transit disorders are frequent and probably underestimated (0-30% [213-215]). Several explanations have been proposed (ileocecal valve not preserved, biliary salt mal-absorption, etc.). Somani et al. conducted a cohort study (LOE2) focusing on this particular problem [266]. They report a high rate of intestinal transit disorders, affecting almost 50% of patients treated for neurogenic bladder. These complications distressed patients and nearly 10% regretted having undergone surgery. Although transit disorders cannot be attributed to surgery alone (patients with neurogenic

NEUROLOGICAL URINARY INCONTINENCE | 1163
bladder may have intestinal transit disorders unrelated to surgery), patients should be informed of this risk.

Since the gastrointestinal tract mucosa resorbs urine, water-electrolyte disorders may occur. Hyperchloremic acidosis is reported in up to 15% of cases (LOE 2-3). These water-electrolyte disorders may be accompanied by anomalies of calcium metabolism that do not appear to have any significant long-term effect, for example on growth in childhood, but the subject is still under debate (LOE 3) [217-220]. However, care must be taken when treating patients with a marked decrease in creatinine clearance, since metabolic acidosis is no longer compensated [184] (LOE4).

In theory, diversions performed using the ileocaecal junction and the end segment of the ileum would expose patients to a risk of vitamin B12 deficiency (with possible onset of megaloblastic anemia). The fact that the intestinal segments measure less than 50 cm would explain why few patients suffer clinically overt vitamin B12 deficiency.

The risk of cancer development of the newly formed reservoir is particularly important, since neuro-urological surgery is often indicated in patients with long life expectancy, many being children. The general consensus today is that patients with a bladder reservoir are at higher risk of developing a tumor than are the general population, but this risk has not as yet been clearly defined. The rates for the risk of tumor development range from 1 to 4.6% [221-224] (LOE 3-4). Most of the published cases concern adenocarcinoma at the junction of the intestinal mucosa with the urothelium. These usually developed long after the initial surgery (over 10 years in most cases). Some patients developed urothelial tumours with the typical risk factors. Two facts should be emphasised with regard to neurogenic bladder (augmented or not):

- The sensitivity and specificity of the routine bladder tumour diagnostic and monitoring tools (urinary cytology, BTA test, simple cystoscopy, etc.) may be reduced. Patient monitoring can only be envisaged by regular cystoscopy with biopsy of suspect areas.
- Monitoring is essential, since many patients develop tumours without symptoms and may not be diagnosed until late.

Monitoring frequency needs further investigation. A review of a series of cystoplasties performed in patients with congenital abnormalities including neurogenic bladder found comparable risk of bladder cancer, compared to control patients managed only by IC (4.6% vs 2.6%, p=0.54) [224]. In addition, a projected cost-analysis based on post-augmentation malignancy and cost estimates from published reports or US government sources concludes that annual screening with cytology and cystoscopy of children with spina bifida subjected to augmentation cystoplasty is unlikely to be cost effective at commonly accepted willingness-to-pay thresholds, but would be justified if the annual rate of cancer development were more than 0.26% (12.8% lifetime risk) or there were a greater than 50% increase in screening effectiveness and cancer risk after augmentation [225].

The most serious and possibly life-threatening complication is cystoplasty perforation (LOE3). This can happen whichever gastrointestinal segment is used, but occurs more often after ileocystoplasty [226] (LOE3). It is estimated to occur in 5-13% of cases [230] (LOE3). Perforation usually occurs on the graft or at the junction of the bladder with the enterocystoplasty, and often results from high pressure within the enterocystoplasty, or more rarely from traumatic catheterization or urodynamic investigations [227] (LOE4).

**Functional outcome**

The functional outcome of bladder augmentation by enterocystoplasty is given in Table 12. Only series of patients undergoing bladder augmentation for neurogenic bladder were retained in our analysis. Given the wide range of indications, surgical techniques and enteric segments used, and retrospective nature of studies, it is difficult to draw any clear conclusions. Nonetheless, all authors reported an improvement in bladder capacity and compliance (LOE2-3). More than 90% of patients achieved nocturnal continence, and 91-100% achieved diurnal continence (LOE2-3).

Two quality-of-life studies (LOE2) reported improvement rates exceeding 90% [202, 231]. A 92% satisfaction rate was reported by a long-term follow-up study (mean 14.7 years) and patients would recommend the treatment to a friend [205]. However, a potential bias might arise due to the heterogeneous population analysed in some of these studies, including a mixture of patients with neurogenic and idiopathic DO.

If the bladder compliance defect persists, exclusion or ischemia of the intestinal patch must be investigated [222, 230]. Sometimes urinary leakage is related to sphincter deficiency and may be treated by an AUS [233] or other means of urethral pressure reinforcement [222, 232]. However, most authors consider that this type of adjunctive treatment should not be performed routinely since most patients have a good functional outcome after bladder augmentation, and only those with marked sphincter deficiency prior to surgery require these measures.

**Possible alternatives to enterocystoplasty**

**Gastrocystoplasty and ureterocystoplasty**

The use of a pedicled segment of stomach (gastrocystoplasty) or ureter (ureterocystoplasty) as an alternative to enterocystoplasty has been reported mainly for children with a neurogenic bladder. In theory, its advantage lies in the absence of metabolic acidosis, but in adults this is very theoretical. Moreover, both these intestinal segments secrete less mucus than the small and large intestines [234-238]. Abdel-Azim et al. [236] reported gastrocystoplasty in adults.
In the light of their experience with children, they decided to use this technique in a set of young adults (mean age: 23 years, range: 4-32 years). Their paper records that the short-term results (3 years mean follow-up) of gastrocystoplasty were satisfactory, with increased functional bladder capacity and no impairment of the upper urinary tract (LOE3). However, two disadvantages are reported. First, a hematuria-dysuria syndrome requiring occasional use of antacids sometimes accompanied gastrocystoplasty. Second, the maximum bladder capacity was lower than that observed with enterocystoplasty. This may have a benefit for easier bladder voiding, but if the bladder were to lose some capacity, further surgery would potentially be required. The outcome in the very long-term for patients who have undergone this procedure remains unknown.

(Max BC: Maximal Bladder capacity, DP: Detrusor pressure at the maximal bladder capacity)
Kidney transplantation and augmentation cystoplasty

The general notion is that augmentation cystoplasty should be beneficial in patients with chronic renal failure and performed prior to transplantation, as a low-pressure reservoir might delay the native kidney’s death and optimize graft survival rates. However, published studies suggest otherwise. In a small series (n=11) of neurogenic bladder patients, augmentation cystoplasty did not affect progression to end-stage renal disease (LOE2-3) [239]. More strikingly, prior cystoplasty was found to be associated with higher risk of graft rejection compared to non-cystoplasty transplants, up to 7 years post-operatively (LOE2-3). Although the authors suggest this may be due to higher rates of febrile UTIs and chronic rejection, it might also be due to a more severe underlying pathophysiology which resulted in the necessity of a cystoplasty in those children [240]. The same group of authors conclude that the timing of augmentation cystoplasty in relation to the transplant surgery (before or after) has no significant effect on the outcome of the transplantation, with respect to graft acute rejection, graft survival (up to 7 years) and incidence of febrile UTIs (LOE2-3) [241]. In terms of serious complications, patients with augmented bladders and a history of renal transplant on chronic immunosuppression were found to have a significantly higher incidence of stage renal disease (LOE2-3) [239]. More strikingly, prior cystoplasty was found to be associated with increased bladder capacity and reduce incontinence. However, the authors did not report mean follow-up and described a mixed population with 39 patients with neurogenic bladder and 11 patients without. The two other published series concerning adults [252, 253] did not confirm these findings but did confirm the marked superiority of enterocystoplasty with respect to both urinary symptoms and upper urinary tract impairment (LOE3). Detrusor myectomy achieves better results for idiopathic DO; nearly all patients (5 of 6) with neurogenic DO were not improved, with a mean follow-up of 79 months [252] (LOE3). There is little information on specific complications, but detrusorectomy is simpler and seems to present less risk than enterocystoplasty. A comparative retrospective study (LOE4) reported 20% complications for enterocystoplasty (infectious, digestive and parietal complications) against only 3% for detrusorectomy [253]. The rate of secondary rupture and/or perforation is poorly documented. An experimental animal study concluded that the bladder rupture pressure was slightly lower after detrusorectomy than after enterocystoplasty, thus potentially exposing the patient to an increased risk of rupture [259] (LOE4).

Autoaugmentation by detrusor myotomy

Bladder autoaugmentation without any associated gastrointestinal tract surgery as an alternative to enterocystoplasty was proposed as early as 1972 by Mahony and Laferte [242] who performed detrusorotomies (detrusor incision without resection) to increase bladder capacity and reduce incontinence. With Cartwright and Snow [243], the technique then evolved to detrusorectomy (myectomy). This involves excising a thick segment of muscle from the dome of the bladder, leaving only the mucosal membrane in place. Bladder pressure gradually dilates the “demuscularized” area resulting in bladder augmentation. The intervention, initially described by extra-peritoneal laparotomy, can be performed by video-assisted surgery [244, 245] or by robot-assisted surgery [246] (LOE4). The detrusor can be dissected by laser [247] (LOE3). The area around the detrusorectomy can be protected using the omentum [248] or a striated muscle [249] (rectus abdominis muscle) to prevent perforation and retraction (LOE4).

Techniques using free-graft or pedicled de-epithelialized gastric patches [250, 251] require gastrointestinal tract surgery and were therefore not included in the present work. Furthermore, most of the previously published studies concerned children. All the studies are retrospective and with few patients. For children, most authors [248, 253-256] report poor results after surgery, both symptomatic and urodynamic, together with a risk of upper urinary tract impairment (LOE4). Two authors recently reported better results with certain technical adjustments, namely an extensive detrusorectomy [257] (LOE4) and rectus muscle hitch and backing [249] (LOE4). The last technique supposes a large dissection of the rectus muscle. Urothelium is then sutured to this muscle in the theoretical objective to prevent its retraction and shrinkage. Only three retrospective series are available for adults. The first, published by Stöhrer et al. in 1997 [205] (LOE3), reports interesting results for efficacy, with increased functional bladder capacity. However, the authors did not report mean follow-up and described a mixed population with 39 patients with neurogenic bladder and 11 patients without. The two other published series concerning adults [252, 253] did not confirm these findings but did confirm the marked superiority of enterocystoplasty with respect to both urinary symptoms and upper urinary tract impairment (LOE3). Detrusor myectomy achieves better results for idiopathic DO; nearly all patients (5 of 6) with neurogenic DO were not improved, with a mean follow-up of 79 months [252] (LOE3). There is little information on specific complications, but detrusorectomy is simpler and seems to present less risk than enterocystoplasty. A comparative retrospective study (LOE4) reported 20% complications for enterocystoplasty (infectious, digestive and parietal complications) against only 3% for detrusorectomy [253]. The rate of secondary rupture and/or perforation is poorly documented. An experimental animal study concluded that the bladder rupture pressure was slightly lower after detrusorectomy than after enterocystoplasty, thus potentially exposing the patient to an increased risk of rupture [259] (LOE4). Bladder augmentation using biomaterials

Research interest in the role of tissue engineering in bladder reconstruction is growing. This research appears to evolve along three axes [260]:

a. use of acellular natural or synthetic biomaterials: an acellular biomaterial graft is used as a tissue implant which becomes incorporated through the ingrowth of cells of the native host bladder
b. use of biomaterial scaffolds which have been pre-incubated with autologous cultured human urothelial and smooth muscle cells
c. composite cystoplasty, which combines the use of autologous cultured urothelial cells with a host pedicled and de-epitheliased smooth muscle segment.

Most publications concern preclinical studies [261-265] (LOE4). Several biomaterials have been used which can be grouped in 3 categories: (a) decellularized natural matrices produced from a variety of tissues; (b) matrices produced from natural extracted polymers (e.g., collagen, alginate, chitosan and hyaluronan); and (c) synthetic polymers including poly-glycolic acid (PGA) and poly-caprolactone (PCL) (see
reviews [260, 266]). These biomaterials can only be used after performing clam cystotomy since the area to be colonized should not be too large. It also appears that the use of biomaterials is associated with higher incidence of bladder lithiasis. The best studied natural materials are porcine intestinal submucosa (SIS, Cook) and bladder-derived acellular matrix [267, 277-282].

Results from only two pilot human studies have been fully published to-date [280, 281]. The former reported on neurological patients, the latter on non-neurogenic OAB patients. In a small prospective study of 7 young myelomeningocele patients (LOE 2-3), Atala [281] describes his technique, which consists of seeding patient’s urothelial and muscle cells on a biodegradable scaffold. After 7 weeks, this engineered artificial bladder could be implanted in patients. Although the small number of patients doesn’t allow definitive conclusions, a trend towards an improved bladder capacity and compliance was observed. It was also implied that patients who received cell-seeded collagen-coated PGA scaffolds wrapped in omentum as a vascular bed had the best outcomes. Encouraging results were also reported in 12 women with intractable non-neurogenic OAB who were submitted to bladder augmentation using an acellular matrix of porcine dermal collagen and elastin fibres (Pelvicol, Bard) [280] (LOE4). Significantly improved or cured incontinence was achieved in 67% of them at a 12-month follow-up. Finally, a recent review article [276] claims results in short report form from two small Phase II trials on patients with neurogenic bladders due to either spina bifida (paediatric patients) or SCI (adults). Success rates of 60% and 67% are reported for up to 2-year follow-ups, depicting patients with preoperative ‘normal bladder cycles’ as the best candidates for bladder augmentation with a tissue-engineered scaffold. Further studies, including larger trials are necessary to evaluate routine use of biomaterials.

**Recommendations**

- Any segment of the gastrointestinal tract may be used for bladder augmentation, but the ileum seems to give the best results in terms of ease of use, risk of complications and efficacy (B). Few data are available concerning gastrocystoplasty and ureterocystoplasty in adults (D)
- When the bladder suffers a significant compliance defect, supratrigonal cystectomy and reconstruction is preferable to clam cystoplasty (B).
- Bladder augmentation may solve low-grade vesicoureteric reflux. In the event of grade IV or V reflux, ureteric reimplantation may be necessary (C).
- Patients should be informed that the most frequent and serious complications are bladder calculi and perforation at the bladder/bowel junction, usually caused by over-pressure (B).

- Bladder augmentation may have sequelae such as intestinal transit disorder, and patients should be informed of this before surgery (C).
- The body of evidence concerning detrusor myomectomy in neurological patients is controversial. Therefore, detrusor myomectomy should not be recommended in these patients with impaired bladder function (D)
- Bladder augmentation using biomaterials or tissue engineering is promising, but the preliminary results need to be confirmed by larger studies (D)
- Due to risk of complications, regular follow up is needed (B)

**Cutaneous continent urinary diversion**

Keywords; Continent urinary diversion; vesicostomy; cystostomy; neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis

For certain patients, urethral catheterization can be or become, unacceptable or even impossible. The following list is not exhaustive, but describes the more frequent reasons:

- Functional limitations of the upper limbs (tetraplegia [295] unilateral or bilateral plexus problems, musculoskeletal trauma problems)
- Cognitive disorders (forgetfulness, lack of comprehension, refusal)
- Difficulties in terms of mobility and/or undressing (spasticity, upper SCI resulting in difficulty in maintaining the equilibrium of the trunk and or limited control of the upper limbs, obesity).
- Failure to reach the urethra independently (more common in women, compounded by the tilted pelvis and all other factors that cause mobility difficulties.)
- Urethral injuries (stenosis, fistulas, hyperesthesia), urethral pain.

In these situations, management requires careful consideration; in some, a continent cystostomy may be an option. The general principle is to permit the emptying of a full bladder, independently and easily, by IC through an efferent tube attached to the wall of the lower half of the abdomen. The absence of any leakage from the cystostomy is controlled by its own watertight system, associated with the return process of a capacitive and compliant reservoir. This will require careful selection of patient candidates, especially when there is any function impairment of the upper limbs (trauma to the spinal cord) [296-298] (LOE3).

Assessment is essential, and must include the motivation of the patient, capabilities for dressing and undressing, capability of catheterization in the planned stomal area, and tolerance for the time and potential
discomfort involved. In the case of cognitive difficulties that are too significant, if a severe upper limb dysfunction exists [295], or if compliance of the patient remains an impossible obstacle, continent diversion is not indicated. Impaired renal function can also be a contraindication [299].

In neuro-urology, techniques for heterotopic continent neo-reservoir (e.g. Koch pouch, Benchekroun, Mainz, Miami pouches) are seldom used initially. They can be offered to patients with VUR, with incontinence through the native urethra despite bladder enlargement, or when closure of the bladder neck will be needed (e.g. uretero-vaginal fistula).

**Results of the different types of cystostomy:**

The series are mainly retrospective (LOE 3) and frequently combine several techniques. This makes the analysis of the results difficult, but some major facts can be gleaned from them. The catheterizable tube must be able to penetrate the intact or enlarged bladder and it must be able to reach the abdominal wall through a direct pathway with easy access for the patient that has already been predetermined by pre-operative research. The pathway of the tube must be direct in order to facilitate self-catheterization. Techniques can be grouped in two major categories: simple tubes implanted with an anti-reflux system and intestinal loop invaginations.

a) Simple tubes: virtually any anatomical structure that is tubular or that can be tubularized and that is vascularized can be used to make a continent catheterizable tube [299] (LOE4). The two structures that are the simplest to use are:

- The appendix: Trans-appendicular cystostomy according to Mitrofanoff’s procedure [300] has long been the most used technique (LOE3). Different modifications have been proposed, especially to gain more length by removing a cecal cuff.

- A short, remodeled intestinal segment (small intestine, less frequently the sigmoid or right colon). Yang and Monti simple [301] (LOE3) or double technique and the Yang-Monti technique modified according to Casale in order to gain length by avoiding a double tube [302] (LOE3).

Other structures have been used in a more anecdotal manner, primarily in children: cecum and appendix monobloc [303] (LOE4), bladder [304] (LOE4), stomach [305] (LOE4), distal ureter [306] (LOE4), Meckel’s diverticulum [296, 307] (LOE4), or the preputial or clitoral skin [308] (LOE4).

For most authors, continence of the tube was achieved by implantation in the native bladder or in the augmentation via a submucosal path similar to that used in ureteral reimplantation for VUR. (LOE4). The submucosal path length must be at least 2cm, and is adapted to the bore of the tube (two to three times the diameter) [298] (LOE4). A posterior or pos-

</table>
The rate of stoma complications (16-60%) is dominated by the risk of stenosis, which is most often treatable by a simple dilation [318] (LOE3). Many authors emphasize the fact that this complication occurs most often in the year following surgery. However, Liard et al. [319] (LOE3) reported an elevated (65%) intervention rate at 20 years of monitoring. For most authors the rate of complications related to the tube continence was lower when the segment used was the appendix or intestines remodeled according to Yang-Monti (LOE3). However, these two plasties seem to have equivalent complication rates. Only Narayanaswamy et al. [320] (LOE3) reported higher rates for catheterization difficulty and reintervention with the Yang-Monti tube in comparison to the appendix. The Monti tubes in this study were double tubes in 68% (17/25) of cases, and the majority of the complications were related to the junction area for the two hemi-tubes and not to stoma stenosis. Therefore it seems that this lengthening method should be used with caution. If there is a problem with tube length, the method proposed by Casale [302] (LOE4) has the theoretical advantage of avoiding an anastomosis on the tube or a bent pathway at the junction of the two tubes.

The umbilical anastomosis site for the stoma may be related to an increased frequency of stoma stenosis [304, 321] (LOE3). The poorer vascularization of the umbilicus has been proposed as an explanation [321]. However, results on this point are contradictory with more recent studies [309].

b) Other types of continent urinary stoma:

Techniques are extremely varied. Two technical approaches can be broadly outlined here:

- Invaginated valves (Koch pocket, Benchekroun, Mainz), in which the continence mechanism is tied to the flattening of the invaginated valve by urine accumulated in the neo-reservoir;

- Ileal-caecal reservoirs, in which a portion of the ileum and the ileal-caecal valve are used as a continence mechanism (Indiana pouch, Charles-ton pouch, Miami pouch).

- A new technique using a pedicled cutaneous flap which is surgically elevated from a hairless area on the abdomen, tubularized and passed through the anterior abdominal wall directly into the bladder (The Daoud technique) [322].

Data in the literature do not allow a determination to be made as to the superiority of one type of stoma over the others. However, the catheterization difficulties seem to be lower with stomas that use the appendix, and the risk of lithiasis seems to be higher with the stomas constructed using metal staples [323] (LOE4). Several authors have also specifically reported results in neurological patients [312, 322, 324-329] (LOE3). Continence rates for the stoma vary between 63 and 100%. Complication rates for the stoma are between 10 and 23%.

Bladder outlet management; although prospective studies are missing, evidence from retrospective analyses (LOE2-3) suggest that continent diversion combined with bladder neck closure is superior in terms of functional outcomes to continent diversion with an open bladder neck, whilst having similar morbidity [330]. Another series reports primary continence rate following bladder neck closure and continent vesicostomy of 82% [331]. Both series report however on a mixed patient population.

**Recommendations:**

- Indication for cystostomy presumes a multidisciplinary evaluation involving the urologist and a neurologist or a reeducation doctor, as well as stomatherapy nurses or occupational therapists for estimating patient catheterization capabilities (A)

- Use of the appendix to carry out continent cystostomy is the standard method in children, but few long term data are available in adults (C). The appendix may have a short mesentery, so a reconfigured ileal segment is often needed.

- If the patient has undergone an appendicectomy, the use of a segment of the small intestine can be proposed, with slightly poorer short term results (C)

- Long term follow up of after continent cystostomy is needed to have a better idea of the long term results of the various procedures (C).

**6.15. Non-continent cutaneous urinary diversion**

Keywords; neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis; urinary diversion; ileovesicostomy; Bricker; ureterostomy; vesicostomy; ileal conduit

Non-continent cutaneous diversion refers to all methods used to divert urine, and where incontinence remains or where a system of extra-physiological continence is created, i.e. urine flow is continuous and requires a means of collecting urine attached to the skin. In the context of neurogenic bladder, these diversions make it possible to obtain low bladder pressure and to preserve the upper urinary tract. This type of surgery is a last resort for the many complications related to neurogenic bladder (and congenital anomalies of the lower urinary tract), in patients for whom other therapies have failed to help. Urinary diversion techniques, however, have been largely replaced by augmentation cystoplasty in the treatment of refractory neurogenic bladder, at least in some groups of neurological patients. The analysis of the US national database of patients with spina bifida between 1998-2005 demonstrated that 3,403 patients were submitted to augmentation cystoplasty as opposed to 772 treated with urinary diversion. Moreover, patients undergoing urinary diversion required more healthcare resources, with significantly longer hospital stays,
higher total charges and more use of home health care after discharge home [342].

Four techniques are described for non-continent urinary diversions for patients with neurological vesicoureteric disorders. In order of frequency these are: ileal conduit urinary diversion, ileovesicostomy, cystectomy and cutaneous ureterostomy.

**Ileal conduit urinary diversion**

Ileal conduit urinary diversion is the type of diversion most frequently performed on neurological patients with bladder dysfunction. Pre-operative location of the intended stoma site is crucial and must be adapted to the patient’s main position (wheelchair or bed); the stoma site must be easy to access for management. The ileal segment must be as short as possible to prevent stasis [343] (LOE3). There is a variant to this technique whereby a segment of jejunal loop is removed and a stoma made on the left hemi-abdomen. This technique can be proposed after irradiation of the pelvis minor, if the ileum has been impaired and a short loop must be used (about 10 cm) to avoid metabolic disorder (jejunal conduit syndrome: hyperkalaemia, hyponatraemia, hypochloraemia, acidosis) [344] (LOE3).

In neurological patients, ileal conduit urinary diversion by laparoscopy and by robot-assisted laparoscopy has been described [345-349] (LOE4). Patients seem to benefit from the procedure, though this remains to be confirmed in the medium and long-term [350] (LOE 2). Uretero-ureterostomy on conduit diversion has also been described in neurological transplant recipients in whom the donor ureter is too short to achieve a tension-free ureteroileal anastomosis [351]. Graft survival rates at mean 5.3 years follow-up was 83%.

Some series of neurological patients were evaluated to determine the onset of early and late complications [350, 352-357] (LOE2-3). The first study to use the recently introduced Clavien system reported on a series of multiple sclerosis patients (n=53), of whom 43% developed minor complications (Clavien grades I-II) and 11% major complications (Grades III-IV) [358]. Early series of children can be evaluated to determine the morphology of the upper urinary tract and renal function after urinary diversion over a long period (up to 20 years) [359-364] (LOE3). Despite complications, significant improvements in patients’ quality of life were recorded, in both retrospective [359] and prospective studies [350]. The latter, however, noted that only aspects of QOL associated with the limitations and constraints induced by urinary problems were improved, not the overall QOL.

Mortality is estimated between 0 and 3.4% (LOE2-3). The commonest early complication is intestinal obstruction (4 to 12.6%), usually reversible after prolonged intestinal drainage [350, 352, 353, 355-357] (LOE2-3). The risk of gastrointestinal fistula should also be taken into account (0 to 3.3%). As for enterocystoplasty, the current trend is to try to reduce nasogastric tube drainage time to a few hours [365] (LOE3). The most frequent medical complications encountered (3 to 8%) are febrile urinary infections and thrombo-embolism (2 to 3%; LOE2-3). Other major complications include: urinary fistula in 0.3 to 3.4% of patients which may be prevented by placing a ureteric catheter for about ten days (LOE3). This complication could be a risk factor for later uretero-ileal anastomosis stricture (LOE4).

The risk of long-term intestinal obstruction ranges between 5% and 7% (LOE3). Even when a short intestinal segment is used, some patients can experiment transient constipation or diarrhoea, which could adversely affect their quality of life [366] (LOE2).

Complications affecting the bladder left in situ. For the particular indication of neurological patients with bladder dysfunction, several authors have proposed not carrying out cystectomy so as to avoid potentially morbid surgery. At present, this is debatable for several reasons:

- There is a risk of pyocystis formation in the unused bladder (21-50%) [352, 353, 357, 367] (LOE3). Even where conservative treatments have been attempted (combining vesicular irrigation with antibiotherapy) [368] (LOE3), secondary cystectomy is then necessary in a high proportion [353, 359, 361]. For women, a surgical alternative is vaginovesicostomy, which appears to be effective [354, 361] (LOE4).
- The unused bladder frequently becomes infected and may become an "irritative thorn", especially in patients with spinal injury or multiple sclerosis (LOE 4) [353, 369].
- The risk of bladder neoplasia is higher in neurogenic patients, the principal risk factors being long-term indwelling catheterization (more than 8 years), bladder calculi and smoking [370-372] (LOE3). Moreover, screening by cystoscopy-biopsy is not effective [373, 374] (LOE3).
- Improvement of the cystectomy technique (noticeably laparoscopic cystectomy) has considerably reduced related morbidity [350, 375] (LOE2-3). Supratrigonal cystectomy can be performed in men, preserving the prostate and preventing any genital and sexual sequelae.

Upper urinary tract complications. Stenosis of the uretero-ileal anastomosis may occur in the medium and long term. This is very damaging to the upper urinary tract and requires regular monitoring. In contemporary series, it occurs in 2 to 7.8% of cases within 10 years [352-357] (LOE3). For cases followed for more than 10 years, the finding of 16.5 to 50% stenosis is essentially that of early paediatric series [359-364] (LOE3). Impairment of the upper urinary tract and renal function seems to be correlated mainly with stenosis of the uretero-ileal anastomosis, but also
with a long ileal graft and stomal stenosis leading to poor voiding and pyelonephritis [360] (LOE4). In the event of poor functioning of the uretero-ileal anastomosis, some authors suggest endoscopic dilation before further surgical repair of the anastomosis (LOE3) [356, 376-378]. Surgery however remains the reference treatment [378] (LOE3).

The risk of upper urinary tract lithiasis (3 to 31%) is always present in these patients (even without stenosis of the uretero-ileal anastomosis) [352, 353, 356, 357] (LOE3). Patient monitoring should include regular screening of the upper urinary tract to detect any lithiasis and to implement timely treatment (LOE 4). Chronic bacteriuria is frequent but should not be treated if asymptomatic. Both patients and attending physicians must be informed so as to avoid the administration of unnecessary antibiotics. However, the risk of febrile infection persists over the long term and may be predisposed by uretero-ileal stenosis (12 to 34%) [352, 353, 356, 357].

Stoma complications. These are relatively frequent (18.6 to 30%) and varied [353, 356, 357]. The risk of peristomal herniation is the most frequently reported (between 7.7 and 10%). Stomal stenosis may also occur. Stoma complications appear to occur more often in obese patients (LOE3) [379].

Some patients, usually adults who underwent surgery as children and who subsequently to recover a continent system, or who have had complications with their non-continent urinary diversion could ask for urinary diversion (380-384) (LOE3-4).

**Ileovesicostomy**

This technique was first described by Cordonnier in 1957 for treatment of three children suffering from myelomeningocele [385, 386] (LOE4). Its theoretical advantages are relative simplicity, the absence of dissection and suture of the ureter, thus preventing ureteral complications and the potential of restoring the integrity of the bladder (only one case described) [387] (LOE4). The surgery consists in removing a 10 cm ileal segment from about 15 to 20 cm above the ileocecal valve. One side of the segment is anastomosed to the dome of the bladder and the other to the skin halfway between the iliac spine and the umbilicus. A partial cystectomy is performed to reduce reservoir volume and possible urine stagnation. Surgical variants have been described with simple partial detubularization of the ileum before vesico-ileal suture [388], or the creation of a modified Boari flap on the bladder associated with partial detubularization of the ileum [387, 390-393] (LOE3). These improve drainage by reducing the ileal segment. Laparoscopic ileovesicostomy seems to be feasible [389, 394] (LOE4), and robotic ileovesicostomy has been described. A small, retrospective comparative study (LOE3) reported similar results in terms of continence and complications with the open surgery group, although a trend for less blood loss and shorter hospital stays was noted in the robotic group [395, 396].

One of the problems with ileovesicostomy, particularly in women, is the need for further surgery to prevent residual urinary leakage. All authors agree that this significantly prolongs surgery time. This further surgery may consist in closing the bladder neck or placing a suburethral tape [436, 438,443, 448, 449] (LOE3). Some authors propose performing this surgery later, where necessary [389] (LOE3).

Early complications are related to the underlying condition of these patients, which is often poor. No case of post-operative mortality has been reported in the published series [385, 387, 388, 390-393, 395-400] (LOE3). Other early complications were related to poor results of the surgery performed to render patients continent (4). Patients with this type of problem are the most likely to resort to cystectomy with ileal diversion (3 to 6%) [387, 397] (LOE3).

Late complications are summarized in Table 14

Only one series to date has more than five years of follow-up [400]. It should be noted that, despite reduction in complication rates, particularly those related to chronic upper tract infections and stone formation, none of the patients in this series remained complication-free [399]. The largest series to-date also report high complication rates (up to 74%), albeit reduced in comparison with preoperative rates [397]. The most frequent new adverse events appear to be poor emptying related to stenosis of the stoma or the ileovesical anastomosis. Only one group of authors specifically mention problems related to stoma equipment that occur in about 38% of patients [397] (LOE3). The incidence of renal or vesicular lithiasis can be as high as 25% in some series, and several authors report that affected patients had a history of lithiasis [399].

Renal function appears to be preserved with this procedure at least with a mean follow-up of five years (LOE 3) [387, 388, 390-393, 397, 398, 401]. No case of impaired renal function, or even post-operative uretero-hydronephrosis was reported. Two patients in a series with long-term follow-up developed a bladder tumour [393] (LOE4).

Vesicostomy was described by Blocksom in 1957 [402] and detailed subsequently by Lapides [403, 404]. The technique consists in constructing a bladder tube anastomosed to the skin by making a transverse subapicubic incision to reach the space of Retzius. The stoma is located half way between the umbilicus and the incision. The principal benefits simplicity and reversibility, particularly in children [405-411], making it possible to envisage temporary surgery to treat an acute urological problem. In pediatric series, an improvement in the symptoms of infection was reported, with 6 to 20% of patients suffering bladder calculi and 6 to 18% stomal stenosis. Hydrourephrosis improved or stabilized in most cases. The rate of end-stage renal failure varied between 6 and 18% for mean follow-ups of 6-7 years.

Nowadays, it is rare to conserve a vesicostomy long term. The long-term results of Lapides [404] (LOE3) are therefore all the more interesting. At two years of follow-up, there was no urinary infection, 16% poor drainage, 12% calculi, and renal function was preserved. At 10 years, however, end-stage renal failure, mainly due to calculi and repeated infection of the upper urinary tract, and mortality were reported [404, 412] (LOE3). Follow up at intervals ranging up to 20 years, showed the rate of chronic renal failure is around 16.6% [402-413] (LOE3).

Recently, percutaneous button vesicostomy placement under endoscopic control was proposed as a temporary continent alternative to Mitrofanoff in a series of 10 children with neurogenic bladders. The authors only discuss the feasibility of the procedure, not its efficacy [414].

Cutaneous ureterostomy

Cutaneous ureterostomy was first performed in the 1960s, to treat children with spina bifida and severe upper urinary tract impairment [415, 416]. The technique was also developed to treat malformative uropathies (exstrophy of the bladder and the posterior urethral valves) [416-419]. During this procedure, the ureters are anastomosed direct to the skin without using intervening gastrointestinal tract tissue. It is only feasible in the context of significant ureteric dilatation, and even then chronic stenting is often needed. The absence of gastrointestinal resection/ anastomosis avoids a major source of morbidity and mortality, but successfully achieving urine containment with appliances can cause considerable problems. In the absence of cystectomy, two short lateral incisions are made in the iliac fossa, at approximately 3-4 cm from the anterosuperior iliac spine. Direct retroperitoneal access is made and the two ureters located on the internal border of the psoas muscle or above the iliac vessels. It is important that the peri-ureteral region be spared and the ureter sectioned as low as possible. The ureter is then catheterized and raised to the skin. The stoma is formed by attaching the ureter to the skin, or by spatulating the sutured ureter on a V-shaped cutaneous incision (separate sutures with fine resorbable thread). Variants are described so as to obtain only one stoma: Y-transuretero-ureterostomy, implantation of both ureters in a single stoma, and implantation of a single ureter (ureter of the less functional kidney ligated, or even nephrectomy). The use of cutaneous plasties may remove the need for ureteral catheterization [420].

The main inconveniences are: cutaneous stenosis if the stoma is left unstented, upper urinary tract infections, and calcification around catheters. Moreover, it is frequently necessary to construct a double stoma. It is used in adults, usually in the context of palliative urinary diversion for those with obstructive pelvic cancer (bladder, uterus, rectum), and rarely in neurological patients [416-421]. Long-term results with a mean follow-up of 8 years are given hereafter: rates of stenosis between 8.7 to 11%, infections from 6.6 to 10% and calculi from 10 to 15.5%) [419, 421] (LOE3). Renal function was preserved for short follow-up times, but fatal end-stage renal failure occurred in up to 26.6% of children during long-term follow-up [418] (LOE3).

This technique is almost never used for neurological patients with bladder dysfunction anymore because conservative treatments (intermittent catheterization, urological endoscopy) have improved and the number of children suffering from spina bifida or presenting with complex malformation of the lower urinary tract has gradually lowered. Moreover, new urinary diversion techniques have been developed.

Recommendations:

- Non-continent urinary diversion is the last resort for patients with neurogenic bladder (A).
- Bladder should be removed during the procedure because of the risk of later complications at this site (B).
- It may be indicated for urological dysfunction or in the event of a motor handicap that prevents other modes of micturition (C).
- Ileal conduit urinary diversion has the best long-term results for non-continent diversion, if the following pre- and peri-operative precautions are taken (B):
  - Pre-operative identification of optimal location for the stoma site, with wheelchair test, if necessary.
  - Utilization of a short intestinal segment (10 cm maximum).
  - Minimal dissection of the ureters.
  - There are several reports of good results for ileovesicostomy, but the medium-term results need to be confirmed in the long term. Quality-of-life studies should also be performed (C).
- Vescostomy may be a useful temporary solution, particularly for children (D).
Central nervous system (CNS) disorders are common, and patients with these disorders frequently experience bowel symptoms. [1][2] In those individuals, bowel symptoms are associated with significant impairment of quality of life. [2][3] Chronic constipation is the commonest symptom of bowel dysfunction seen in the majority of individuals in spinal cord injury, and over one-third of patients with Parkinson’s disease (PD) and multiple sclerosis (MS).

2. PATHOPHYSIOLOGY

The digestive and excretory functions of the gastrointestinal tract are dependent on the interrelated physiological phenomena of gut transit and rectal evacuation. [4] Transit is under the complex regulatory interplay of the enteric nervous system and extrinsic autonomic innervation, whilst rectal evacuation depends on an interplay between conscious perception of rectal sensori-motor function and the internal and external anal sphincters. Excessively rapid transit and/or failure of the anorectal control mechanism can result in faecal incontinence, and it is easy to see how CNS disorders can result in bowel symptoms.

The level and extent of injury are the most important factors in determining bowel symptoms in both SCI and MS. Supraconal lesions (above the conus medullaris, where inhibitory input is lost) - slow whole gut transit and there is hypertonia (with consequent reduced rectal compliance) and hyperreflexia of the hindgut (i.e. distal to the splenic flexure). [5] The latter two abnormalities predispose to reflex defaecation and incontinence. By contrast, lesions within the conus or in the cauda equina (where excitatory sacral parasympathetic supply is lost) have rectal hypotonia and hyporeflexia predisposing to rectal impaction and overflow incontinence. [6]

In terms of extent of injury, since the striated external anal sphincter is under voluntary control from Onuf’s nucleus in the ventral horn of the sacral spinal cord, complete SCI results in loss of voluntary control of the anal sphincter is lost. Complete SCI has been shown to result in the most severe degree of bowel dysfunction. [5]

The pathophysiology of bowel dysfunction in patients with Parkinson’s disease is quite different. Dystonia of the striated muscles of the pelvic floor and external anal sphincter explains the defecatory dysfunction [6] which is associated with delayed colonic transit time secondary to central and peripheral neurodegeneration. [7]

3. ASSESSMENT

Current bowel symptomatology is assessed, regarding bowel frequency, stool consistency, faecal incontinence and manoeuvres needed to achieve bowel management. This information is usually gathered from standard patient and carer history. Use of diaries is especially valuable to reflect the chronic burden of these symptoms. [8] This can be supplemented by questionnaires, whether generic (Cleveland Constipation score, St Mark’s incontinence score or condition specific score has been developed for neurologic patients, the Neurogenic Bowel Dysfunction (NBD) Score.[9]

Digital rectal examination allows assessment of rectal filling, resting anal tone, ability to generate a voluntary contraction and also gives a crude assessment of anal sensitivity. The place of more interventional physiological or radiological transit investigations is not established, but may be appropriate if there is any co-morbidity (prior anal surgery, obstetric history, pelvic organ prolapse). Plainly, patients with alarm symptoms should have necessary colonic imaging performed. Alarm symptoms in this patient group are more difficult to recognise, but any worsening of established bowel dysfunction, weight or blood loss warrants investigation.

4. CONSERVATIVE TREATMENT

The primary aims of bowel care are twofold: firstly to achieve bowel evacuation without excessive toileting time and secondly to avoid fecal incontinence. The first step requires optimizing stool consistency with adequate fluid and fibre intake, and stimulating evacuation of stool on a regularly scheduled basis with digital rectal stimulation. A range of other non-invasive interventions may supplement this: Valsalva or manually-generated external pressure, oral medications – stool softeners, stimulant laxatives and prokinetic agents; diet modification; biofeedback – a re-education strategy to inform change in bowel function; electrical stimulation and functional magnetic stimulations. The key to successful bowel management is intensive patient education and training. If conservative bowel management fails, surgical management may be necessary.

4.1. Bowel program/bowel care [9]

Initial management for all subjects is medication review (especially bladder drugs such as antimusca-
of neurological diseases. [11] Long-term efficacy has been demonstrated in a variety of bowel programs. However, knowledge of bowel frequency prior to injury is important in deciding on the bowel program.

4.2. Specific techniques
Establishing a regular diet to optimize bowel motility is important and in general reducing fibre intake is helpful in improving the bloating and flatulence caused by slow whole-gut transit. Conversely, a higher fibre diet helps improve stool consistency and therefore prevent fecal soiling. Excessive quantities of caffeine, alcohol and foodstuffs containing the sweetener sorbitol can cause the stools to become looser and hence more difficult to manage.

Promoting a sense of privacy and comfort while exploiting gravity to achieve a successful bowel regime, is advised. Digital rectal stimulation (DRS) can be used to invoke a reflex contraction of the colon and rectum, and hence a bowel action, although caution is advised as it may cause local trauma and induce autonomic dysreflexia (AD) in SCI individuals. Finally, manual extraction of stool can be used and combined with a Valsalva maneuver to improve effectiveness.[8]

Chemical stimulants such as suppositories and enemas may supplement the above by causing a reflex contraction of the rectum. Implicitly, there is little point in using these agents when the rectum is empty on digital checking. Stimulants range in potency, from glycerine suppositories, through micro-enemas, to larger volume stimulant enemas.

4.3. Assistive techniques for defecation [10]
Abdominal massage with the heel of the palm, in a circular motion from right to left may help increase bowel transit and movement of content towards the rectum. In small controlled trials, positive effects were seen in patients with multiple sclerosis and with spinal cord injury. Anal stimulation with pulsed water irrigation to break up stool impactions and to stimulate peristalsis is a safe and effective method for individuals with SCI who develop impactions, or do not have an effective bowel routine.

Several studies have been published on transanal irrigation (TAI), with efficacy demonstrated in a variety of neurological diseases. [11] Long-term efficacy has been demonstrated, with associated health economic benefit. [12] Amongst factors correlating with positive outcome were neurogenic bowel, low rectal volume at urge to defecate, low maximal rectal capacity, and low anal squeeze pressure increment. A perforation rate of 1 in 500,000 has been suggested in long-term safety studies.[13]

4.4. Appliance/assistive techniques for faecal incontinence
Anal plugs are one option although previous studies have yielded conflicting results. Whilst anal plugs may provide a benefit to the majority of patients, it does not suit all eligible patients, with in situ plug retention being a problem for some.

Neuromodulation, electrostimulation or magnetic stimulation are techniques that offer an alternative intervention option for neurogenic bowel dysfunction in children and adults.

5. SURGICAL TREATMENT

The mainstay of current treatment in neurogenic faecal incontinence is adopting a conservative approach towards reversing the systemic effects and optimizing the mechanics of defecation through the use of laxatives and irrigation approaches. Surgery should be normally reserved for patients who have failed conservative therapy. This section focuses on specific aspects of faecal incontinence surgery in neurogenic patients. Options for surgical treatment of neurogenic bowel dysfunction are limited consisting of; 1) sacral nerve stimulation, 2) antegrade continent enema procedure, 3) dynamic graciloplasty, 4) artificial anal sphincter, 5) elective colostomy, 6) postanal repair.

Outcomes with these techniques are limited to uncontrolled studies.[14] Sacral nerve stimulation has been reported to restore continence in patients with intact muscle structure. The overview of the studies shows that electrical nerve stimulation is effective in partial spinal cord injury, however, there are no reports for complete spinal cord lesions. A 17-year experience with sacral deafferentation (SDAF) and implantation of sacral anterior root stimulator (SARS) showed improved continence in over 80% of individuals. [15]

The original antegrade continent enema procedure was developed by Malone et al. who reported successful results in five children with intractable faecal incontinence. [16] This procedure has been applied mainly to the paediatric population with neuropathic bowel dysfunction and anorectal anomaly, and successful outcome was achieved in 70-100%. Modifications have been reported including application among adult neurogenic patients with faecal incontinence, and similar success rates (83-100%) were reported. [17]

There are other more intrusive surgical procedures that have been applied to small numbers of patients with neurogenic faecal incontinence – defunct ones (such as dynamic graciloplasty) or extant ones like artificial anal sphincter. Definitive studies are not available in this population, and given the nature of referral practice are unlikely to ever be performed.

Retrospectively reported series on the effect of colostomy or ileostomy formation in SCI patients have shown significant improvements in average time...
spent on bowel care per week and quality of life. [18] The early and long-term complication rates are seen in the minority of patients, most frequently related to mucus discharge per rectum and diversion colitis, respectively. The decision about type of surgery depends on a multitude of factors related to manual dexterity, co-morbidity, carer availability and toilet set-up: as such careful patient counselling in individuals who have failed conservative therapies is the key to success. [17]

Conclusions

- In reflex bowel, digital rectal stimulation relaxes the external anal sphincter and increases peristaltic contractions by facilitating an excitatory anorectal (ano-colonic) reflex, and enhances bowel movement and evacuation
- Abdominal massage has beneficial effects on neurogenic bowel dysfunction, including defecation function and fecal incontinence
- Transanal irrigation is a safe method to improve constipation and faecal incontinence in individuals with neurogenic bowel dysfunction
- An anal plug can help control fecal incontinence in selected neurological patients
- Different forms of electrical stimulation seem promising for fecal incontinence and defecation management in neurologic patients
- To increase adherence rate with bowel care program/clinical practice guideline, implementation strategies should be addressed to care providers
- SNS is a minimally invasive procedure, and seems to be an option for faecal incontinence and constipation due to functional deficit of the anal sphincter without structural defect in incomplete neurogenic lesions
- Antegrade continence enema stomas are effective for controlling faecal incontinence and constipation associated with neurogenic bowel dysfunction especially in neuropathic children
- Elective stoma formation is an option for some SCI patients with medically refractory symptoms.

Recommendations

- Multi-faceted programs are the first approach to neurogenic bowel management and are supported by lower levels of evidence. They may consist of toileting, rectal stimulation (digital or with water stream), manual feces extraction, transanal irrigation and other assistive techniques
- Diet can help but multi fibre is not necessarily indicated in patients with upper motor neuron lesion
- Autonomic dysreflexia when using mechanical stimulation and assistive techniques can occur in neurologic patients with a high spinal cord lesion
- Studies on larger series with long term follow-up are needed to determine the role of SNS in the treatment of faecal incontinence associated with neurological lesions and identify those patients most likely to benefit

V. SPECIFIC NEUROLOGICAL DISEASES

1. DEMENTIAS

Methods. Using MEDLINE we identified English-language journal articles and reviews up to the date of the current Consultation, which were added to literature obtained for previous Consultations, looking for the keywords Alzheimer’s disease, vascular dementia, dementia with Lewy bodies, frontotemporal dementia, urinary incontinence, bladder dysfunction, management.

The dementias can be categorized according to clinical presentation, neuropathology and/or aetiology into four major dementia groupings, (I) the Alzheimer’s group (Alzheimer’s disease, AD); (II) the vascular group (including large and small vessel disease, particularly white matter disease); (III) the Parkinson’s group (including Parkinson’s disease dementia complex (PDD, being regarded as identical to DLB), and dementia with Lewy bodies (DLB), both being connoted as Lewy Body diseases); (IV) the frontotemporal group (including Pick’s disease and Semantic dementia) [1]. Normal pressure hydrocephalus (NPH) is a less common pathology, but nonetheless important.

1.1. Alzheimer’s disease

Epidemiology and prevalence

Alzheimer’s disease (AD) is the most common type of dementia in clinical and autopsy surveys. AD affects mostly elderly people. The symptoms include worsening of the memory, impairment of language and other cognitive functions (analytical thinking, abstract reasoning). Ultimately, there is loss of self-hygiene, eating, dressing and ambulatory abilities, incontinence and motor dysfunction. The onset of incontinence usually correlates with the disease progression (LOE 3) [2]. In other words, urinary incontinence inevitably occurs in the advanced stage of disease, while urinary incontinence is not common in the early stage of AD. This is in contrast with early occurrence of urinary urgency and incontinence in vascular dementia and dementia with Lewy bodies. The prevalence of incontinence in AD is between 23 % and 48 % (LOE 3) [3, 4]. However, most previous studies did
not mention the type of dementia concerning ‘frequency of urinary incontinence in dementia’. The prevalence of incontinence in dementia ranges from 10% (of out-patients) to more than 90% (of advanced, institutionalized individuals) (LOE 3) [5].

Pathology and disease-specific urinary tract problems

AD at the outset was identified by its unique pathology, the amyloid plaques and neurofibrillar tangles containing phosphorylated tau that Alzheimer referred to as “a clotting of fibrils…. in addition an extraordinary number of peculiar patches disseminated throughout the entire cortex.” Amyloid and tau can now be measured in vivo by positron emission tomography and/or examination of the cerebrospinal fluid (CSF). There is a familial occurrence of AD [3]. In such cases, mutations in the genes encoding amyloid precursor protein (APP); presenilin 1 (PSEN1), or presenilin 2 (PSEN2) are reported.

The clinical hallmark of AD is memory impairment. A sense of memory failure, detected by the patient or a close relative, is usually the presenting symptom. Motor and sensory symptoms are absent until late in the course of the disease. However, other cognitive domains, such as language, praxis and recognition skills, are affected even early in the presentation. AD has a gradual and progressive course, and duration is typically 10 years from diagnosis to death. The advent of central cholinesterase inhibitors and glutamate receptor antagonists has had a positive effect on the memory symptoms of AD [6-8].

In early stages of AD the prevalence of urgency incontinence is lower than in dementia with Lewy bodies [9, 10]. During stage III (advanced) AD, urinary and faecal incontinence occur due to loss of sphincter control [10]. In a study by Del Ser et al. (LOE 3) urinary incontinence was associated with severe cognitive decline in pure AD but usually preceded severe mental failure in patients with dementia due to diffuse Lewy body disease [10]. Nobili et al. (LOE 3) performed quantitative EEG in AD patients, finding that incontinence was predicted by alpha power in the right side [11]. In another study by Nobili et al. (LOE 3) the value of regional cerebral blood flow from a posterior temporal-inferior parietal area in each hemisphere predicted development of incontinence [12].

A brain computer tomography study done by Sugiyama et al. (LOE 3) in AD patients showed that the degree of brain atrophy was more severe in those with detrusor overactivity (DO) than those without it [13]. DO was found in 40-61% of their patients [13] (LOE 3). The incidence of DO in AD patients is low as compared with vascular dementia and dementia with Lewy bodies [9]. Haddad et al. (LOE 3) described two patients with vesicoureteral reflux, one of them showing buccosalivary, gastroesophageal, vesicoureteral, urethroprostatic and urethrovvesical reflex as a consequence of the neurologic dysfunction [14]. In a study of 144 patients with AD reporting urinary incontinence, the most common type of urinary incontinence was urgency urinary incontinence. Clinical Dementia Rating and Barthel’s Activities of Daily Living predicted the severity of detrusor overactivity in urodynamics [15].

Diagnosis and treatment

Franssen et al. (LOE 2) examined the occurrence of the following developmental reflexes: the tactile suck reflex, the palmar and plantar grasp reflexes, and the plantar extensor reflex in healthy elderly, cognitively and functionally mildly impaired patients, and patients with AD [16]. Prevalence of all five reflexes was more than 6 times higher for those categories that comprised doubly incontinent patients compared to continent individuals. The frequency of developmental reflexes rose sharply with the onset of progressive incontinence, suggesting its cortical origin. As demonstrated above, the development of incontinence in AD patients is associated with cognitive impairment and brain degeneration, suggesting its CNS origin. Therefore behavioural therapy, toilet training and prompted voiding would be appropriate treatment modalities for this type of incontinence.

Hutchinson et al. (LOE 3) suggested that caregivers of patients with AD should study the toileting behaviours. This would permit them to provide physical and cognitive assistance while attempting to avoid accidents and “catastrophic events” [6]. Tariot (LOE 4) stressed the necessity for taking into account different factors (like mobility, cognitive functions, general medical conditions), when planning treatment (also for incontinence) in AD patients [7]. Lancioni et al. reported three AD patients who could learn to use urine alarms [17] (LOE 4). Again the general guidelines should apply for choosing the best management of incontinence in AD patients. The treatment should be tailored to individual patient needs and disease status. There is insufficient evidence to support non-pharmacological and non-surgical conservative interventions, for the prevention or management of incontinence in community dwelling people with dementia [18] (LOE 1).

There is still some controversy that the central acetylcholinesterase (AChE)- inhibitors given by the neurologist might exacerbate urinary incontinence in those patients. Donepezil hydrochloride is a selective central AChE inhibitor, which decreases degradation of acetylcholine in the brain, then increasing the concentration of acetylcholine in the synaptic cleft [19]. This drug is widely used to ameliorate cognitive decline in patients with AD [20, 21] which is thought to be due to a decrease in cholinergic innervation of the cerebral cortex and the basal forebrain [22]. Since the bladder is innervated by the parasympathetic cholinergic nerves, neurogenic lower urinary tract (LUT) dysfunction occurs in a subset of patients with AD [5, 13].

Although donepezil may facilitate cholinergic neurotransmission in the CNS, common adverse effects of donepezil, such as nausea and abdominal discomfort, have been attributed to effects on the peripheral
nervous system (PNS) [20]. This peripheral influence may contribute to altered bladder function. However, according to Sakakibara et al. (2005) the patients with AD showed a slight increase in the bladder capacity, which cannot be explained by the PNS effects alone [23] (LOE 3). Although it is unknown to what extent central cholinergic circuits may participate in the regulation of micturition, recent experimental studies showed that lesions in the nucleus basalis Meynert in the basal forebrain (central cholinergic nucleus projecting fibres to the frontal/parietal cortex) give rise to decreased bladder capacity) [24]. In addition, improved cognitive status and alertness may well lead to proper initiative to hold urine. Central AChE inhibitors including donepezil hydrochloride, therefore, may have complex effects on the LUT function. It seems possible that donepezil could ameliorate cognitive function without serious adverse effects on the LUT function in patients with AD. This should be true also for other selective central AChE inhibitors. A large crossover cohort study used the Dutch PHARMO Record Linkage System, with 10 years of data on drug dispensing for over two million people. It suggested no firm association between AChE inhibitor treatment and risk of UI could be shown, except possibly during the first month of treatment [25] (LOE 2).

Many elderly patients and their caregivers seek medical care for dementia and overactive bladder (OAB) together. In order to answer this, recent clinical trials of a combination therapy of central AChE inhibitors and peripheral anti-cholinergics for ameliorating both cognition and incontinence are available. In 26 older individuals who had both cognitive problems and overactive bladder (AD in 8, vascular dementia in 5, a combination of AD and multiple cerebral infarction in 8, and others), Sakakibara et al. reported that addition of 20 mg/day propiverine, an anticholinergic agent, to 5 mg/day donepezil improved OAB without any cognitive change [26] (LOE 3). Sink and colleagues retrospectively studied 3536 nursing home residents who were taking central AChE inhibitors, in whom 10.6% were prescribed anticholinergics together [27]. They found no differences in cognitive function between groups of AChE inhibitors alone and AChE inhibitors with anticholinergics (LOE 3). Isik et al. demonstrated that patients with advanced Alzheimer’s Disease tolerated Trospium chloride without significant changes in MMSE (Mini-Mental Status Examination) scores [28] (LOE 3). The combined use of a ‘central’ AChE inhibitor and a ‘peripheral’ muscarinic receptor antagonist remains a matter of controversy and the Dementia Working group of the International Continence Society has put forward a recommendation that antimuscarinics that do not easily cross the blood brain barrier or are more selective for the M2/M3 receptors should only be used in patients with dementia reporting incontinence [29] (LOE 3). There is a study indicating that this combination would be pharmacologically sound as a site-directed therapy [30].

Guidance for further research

There is still no cure for AD, which is progressive and a type of dementia-associated disease. We are still lacking studies evaluating LUT disorders in AD. No systematic review has been performed regarding the possibilities of medical management (both pharmacological and behavioural) of incontinence. An open issue also remains the question of aggressive surgery for LUT problems in these patients. Whether we should offer surgical therapy for incontinence in patients with stress incontinence and progressive AD is so far unanswered.

Conclusions

- Detrusor overactivity seems to be the most common cause of incontinence in Alzheimer’s disease (AD) patients (LOE 3), while the incidence is low as compared with vascular dementia and dementia with Lewy bodies.
- The degree of functional incontinence is associated with cognitive impairment and brain degeneration (LOE 3).
- EEG studies, occurrence of developmental reflexes and regional blood flow studies can predict the development of incontinence in AD patients (LOE 3).
- Selective central AChE inhibitors ameliorate cognitive function without serious adverse effects on LUT functions in patients with AD (LOE 3).
- A combination therapy of central AChE inhibitors and peripheral anticholinergics for ameliorating both cognition and incontinence awaits further studies (LOE 3).

Recommendations

- The extensive and aggressive therapy of incontinence in AD patients should be reserved for those with good general status and ambulation (C).
- In the case of ambulatory patients, prompted voiding, behavioural therapy and oral anticholinergics seem to be the treatment of choice (C).

1.2. Vascular dementia

Epidemiology and prevalence

Vascular dementia is the second most common form of dementia after Alzheimer’s disease (AD) among the elderly. Pooled prevalence from eight European countries was 1.6% for vascular dementia in subjects older than 65, compared to a prevalence of 4.4% for AD (LOE 3) [31]. A meta-analysis of the European studies on the incidence of dementia showed vascular dementia constituted 17.6% of all incident dementia (LOE 3) [32].
Population-based MRI studies suggest that moderate white matter disease (WMD, a major cause of vascular dementia) affects around 10% (7.6–24%) of the general population of persons over 55 years of age [33], comparable to type 2 diabetes. WMD develops into three different geriatric syndromes; 1) vascular dementia (usually mild in the Mini-Mental State Examination and other general cognitive function), 2) vascular parkinsonism, and 3) so-called vascular incontinence, i.e. urinary frequency/urgency with or without incontinence [34]. Among these three syndromes, urinary and gait disorders are more prominent than dementia, and usually precede dementia. Comorbidity of Alzheimer’s disease (a degenerative disease) and WMD (a vascular disease) is not uncommon.

Vascular dementia may be the result of a single strategic infarct, particularly involving the thalamus and left angular gyrus, or multiple cortical or subcortical infarcts that produce WMD. There is an elevated risk for subsequent dementia in patients who have had a stroke in comparison to controls without any evidence of a stroke (LOE 2) [35]. Diabetes and hypertension are stronger risk factors for vascular dementia than for Alzheimer’s disease (LOE 3) [36]. The apolipoprotein e4 genotype is a risk factor for vascular dementia as well as AD (LOE 3) [37].

Pathology and disease-specific urinary tract problems

In patients with WMD, diffuse abnormalities are seen in the small deep perforating vessels of the hemispheric white matter, basal ganglia and brain stem. Pathological changes range from lipohyalinosis to fibrinoid necrosis and disintegration of small vessels. Disruption of the blood brain barrier is likely to precipitate or worsen progression of WMD [38] (LOE 3). Positron emission tomography imaging with 18F-fluoromisonidazole showed higher susceptibility to ischemia of white matter than gray matter in stroke cases [39]. Cortical WMD in MRI looks diffuse. However, within the brain, detailed pathology studies confirmed that the frontal lobe is most severely affected [40]. This is in line with documented frontal lobe atrophy on MRI volumetry, where glucose metabolism was also most severely reduced [41] (LOE 3). Corresponding to this, brain perfusion is most reduced in the frontal lobe of subjects with WMD [42] (LOE 3), a finding that remains to be fully explained. In patients with WMD reporting incontinence (“vascular incontinence”), performance on the frontal assessment battery suggests that performance on an inhibitory control task is decreased in patients with detrusor overactivity [43] (LOE 3).

The frontal cortex is an important higher center for micturition: damage to the prefrontal cortex, medial superior/middle frontal gyrus, anterior cingulate cortex, supplemental motor area and insula result in marked lower urinary tract dysfunction in humans [44] (LOE 3), corroborated by functional neuroimaging [45, 46] (LOE 3). Altered spinobulbospinal micturition reflex control may contribute to DO emergence in brain lesions [47] (LOE 3). Functional neuroimaging studies showed that the prefrontal cortex was deactivated in elderly subjects with urinary frequency/urgency [48] (LOE 3). Jirovec et al. (LOE 3) found that cognitive ability and mobility differ significantly between continent and incontinent patients [49]. When the variables were examined together, mobility emerged as the best predictor of the patient’s urine control, followed by cognitive impairment.

The prevalence of DO in WMD cases is reported as 70-91% of patients. In Sakakibara’s study, urodynamic studies in 33 subjects found DO more commonly in grade 1-4 white-matter lesions (82%) than grade 0 white-matter lesions (9%). Yoshimura et al. (LOE 3) found a 47% prevalence of DO which correlated with the presence of dementia [50].

Disease specific diagnosis and treatment

No specific diagnostic tests to evaluate dementia-related incontinence have been described. Since patients with dementia and incontinence usually have one or more concomitant diseases, the evaluation of the LUT functions should follow standard principles, bearing in mind that this is a population of frail elderly people. The treatment should start with modification of behaviour, and general rehabilitation targeted at making the patient more ambulatory. No other specific treatment in dementia has been described, however certain issues like prompted voiding, anticholinergic drugs and intermittent catheterization have been studied.

In a review of trials where prompted voiding was implemented, Eustice et al. (LOE 1) found that prompting increased self-initiated voiding and decreased incontinence episodes in the short-term [51]. A single small trial suggested that adding oxybutinin, reduced the number of incontinent episodes in the short-term. Suzuki et al. (LOE 3) found best results with the use of a portable chamber pot and induced urination in ambulatory patients; no improvement was seen in bedridden patients treated with anticholinergics [52]. Sugiyama et al. (LOE 3) studied the effects of anticholinergic therapy in patients aged 65 years or older, with and without dementia [53]. Urodynamic studies demonstrated significant increase of maximum bladder capacity in the dementia group and the non-dementia group. There was no significant difference in rate of objective improvement between both groups. On the other hand, rate of subjective improvement was significantly higher in the non-dementia group (40%) than in the dementia group (15%). Improvement of functional bladder parameters was not associated with better subjective symptoms in the dementia patients.

In voiding failure, intermittent catheterization (IC) is often feasible. Lieu et al. (LOE 3) found that carer-assisted clean IC is an effective and safe treatment option for persistent urinary retention in elderly female patients with cognitive impairment and other disabilities [31]. 54% of the patients were able to void
spontaneously and were continent after a median period of 6 weeks with a range of 1 to 40 weeks. 27% had significant improvement in the symptoms of urinary incontinence and the residual urine volumes became progressively smaller. 19% failed this treatment modality. The recovery of spontaneous voiding was influenced by the age of the patient, the carer performing the IC and the development of catheter-related UTI. 25% developed symptomatic UTI, leading to delay in the recovery of spontaneous voiding. UTI development was associated with the presence of pre-existing diabetes mellitus and predisposing common medical conditions, the person doing the catheterization, and the presence of dementia.

Ayonou et al. (LOE 3) studied a group of 13 patients with dementia who underwent transurethral resection of the prostate (TURP) [54]. Six patients reported good urination, 3 reported some improvement in urination but requiring IC, and 1 developed incontinence. No specific study addressing the issue of incontinence surgery in woman with dementia has been reported. However, it seems that incontinence surgery in patients with dementia should be reserved only for the cases with good ambulation and without concomitant functional disorders of micturition (overactive bladder, hypocontractile detrusor).

**Recommendations for further research**

Since dementia is not a homogeneous disease, a population study specifically reviewing disorders of lower urinary tract function is needed. A study evaluating different treatment modalities in patients with dementia (especially anticholinergic treatment for overactive bladder and surgical treatment for stress incontinence) is lacking.

**Conclusions**

- Incontinence occurs in 30-100 % of patients with dementia (LOE 3).
- The degree of incontinence is strongly associated with the patient’s general status and ambulation (LOE 3)
- There is no one major cause for incontinence in these patients; however overactive bladder is responsible for a significant proportion of incontinence (LOE 3)

**Recommendations**

- Intervventional therapy of incontinence in dementia should be reserved for patients with good general status and ambulation (C)
- In case of ambulatory patients, prompted voiding, rehabilitation and oral anticholinergics can be employed (C)
- Where there is a significant post-void residual, intermittent catheterization is the treatment of choice (B)

### 1.3. Dementia with Lewy bodies

**Epidemiology and prevalence**

Dementia with Lewy bodies (DLB) is thought to be the third most common type of dementia in the elderly, accounting for 10 – 15% of cases at autopsy. In population-based studies of subjects aged 65 and older, the prevalence of DLB was found to be 0.7% [55]. The epidemiology of DLB is sparse; age and gender distribution, and potential risk factors have yet to be defined.

**Pathology and disease-specific urinary tract problems**

DLB primarily affects the basal ganglia (as in Parkinson’s disease) and the cerebral cortex. Lewy bodies and Lewy neuritis are pathologic aggregations of alpha-synuclein (SNCA), a ubiquitously-expressed synaptic protein that has been implicated in vesicle production [56]. Lewy bodies also contain chaperone proteins and elements of the ubiquitin-proteasome system. Immunohistochemical staining for alpha-synuclein is the most sensitive and specific method for detecting Lewy bodies and can be used in a semi-quantitative grading of severity of Lewy-related pathology [57]. Alpha-synuclein can now be measured in vivo by positron emission tomography and/or in the cerebrospinal fluid.

Many patients with DLB also have Alzheimer’s disease pathology, which alters the clinical presentation. DLB patients who also have numerous neurofibrillary tangles display more core clinical features of AD [58]. Conversely, Lewy bodies also occur in more than half of patients with sporadic and early-onset AD [59]. The essential feature for a diagnosis of DLB is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Fluctuations (waxing and waning of cognition, functional abilities and arousal, from almost normal to markedly confused or hypersomnolent) are a core feature of dementia with Lewy bodies. In DLB, autonomic dysfunctions occur and are included as a supportive feature for clinical diagnosis [60].

Horimoto et al. (LOE 3) found 97% incidence of urinary incontinence amongst patients with DLB. From the urological point of view, patients with DLB tend to develop urgency and urgency incontinence more often than do patients with Parkinson’s disease (PD) or AD. Similar bladder capacity, detrusor pressure at maximum voiding, maximum urine flow, mean voided volume and post-void residual volume were found in each disease; DO was more prevalent in DLB than in PD and in AD [9]. Urinary symptoms were recorded in 35 % of patients with DLB, compared to 70 % in MSA and 25 % in PD patients. No detrusor-sphincter dyssynergia was observed. DLB patients with DO had significantly higher Hoehn and Yahr scores than did those without. Since the prevalence of frequency, urgency, urge incontinence and DO is markedly lower in AD than in DLB, LUTS may contribute to the differential diagnosis of these two entities.
Disease specific diagnosis and treatment

Since patients with Lewy Body disease and incontinence usually have one or more concomitant diseases, the evaluation of the LUT functions should follow the general rules, bearing in mind that this is most often a population of frail elderly people.

1.4. Frontotemporal dementia (FTD)

Epidemiology and prevalence

Prevalence studies of FTD give ranges of 3.6-15.0 per 100,000 [61]. There is a high familial occurrence of FTD [62]. In such cases, a combination with parkinsonism, and rarely amyotrophic lateral sclerosis, also occurs. The distribution of FTD is equal between men and women. The mean duration of illness from onset to death is 4-6 years, with a range of 2-20 years.

Pathology and disease-specific urinary tract problems

Frontotemporal dementia (FTD), also known as Pick's disease, encompasses a diverse group of clinical and pathological disorders. There are several distinct clinical presentations, most commonly behavioral changes, but a language disorder, usually in the form of a progressive non-fluent aphasia, can be the main presenting sign. The most common clinical presentation of FTD is characterized by profound changes in personality and social conduct, including a decline in manners and social skills that are incongruent with the patient's premorbid behaviour. Affected patients lack emotional warmth, empathy and sympathy and are indifferent to others.

MRI of patients with FTD often shows atrophy in the frontal and temporal lobes (LOE 2), which may be asymmetric [63]. At autopsy, markedly gross atrophy of the frontal and temporal lobes is seen in FTD. On histologic examination the salient features include neuronal loss, micro-vacuolization and astrocytes gliosis centred on cortical layer II. Molecular pathology of FTD has identified four subtypes:

- classical Pick's disease (Pick body with accumulation of 3-repeat tau);
- mutations in the MAPT (microtubule-associated protein tau) gene;
- accumulation of TDP-43 (TAR DNA binding protein-43) with mutations in the PGRN (progranulin) gene; and,
- accumulation of FUS (fused in sarcoma) protein

There are no published data on LUTS in patients with FTD, but due to the cognitive state these patients have incontinence, either because they forget to take down clothes when they go into the toilet, or they have difficulty finding the toilet, or they may urinate in inappropriate places. Moreover, they may be affected by constipation, diarrhoea or faecal incontinence.

Diagnosis and treatment

There are no studies which show the significance of LUTS in patients with fronto-temporal dementia. The importance of cortical regulation for social control of urinary habits needs evaluation.

Conclusions

- There are no studies available which show the significance of LUTS in patients with fronto-temporal dementia
- Since the underlying pathology is gross atrophy of frontal and temporal lobes, autonomic dysfunction including LUTS can be anticipated, but further research is needed

Recommendations

- The recommendations do not differ from those for other types of dementia

2. CONSTIPATION AND FAECAL INCONTINENCE IN DEMENTIA

Only one paper was retrieved related to the influence of dementia on the prevalence of faecal incontinence [64]. This evaluated a random sample (n = 485) of the population of 85-year-olds from Gothenburg, Sweden. Prevalence of urinary and faecal incontinence and dementia were 38%, 17% and 29% respectively. Dementia-affected men (50%) and women (60%) were more often incontinent than non-affected men (18%) and women (36%). Faecal incontinence was more prevalent in dementia (34/8% versus 6/7%): both urinary and faecal incontinence were more prevalent in demented women (43% and 20% respectively) than in men (27% and 11%). The prevalence of urinary and faecal incontinence and dementia were higher in residents of a nursing home or hospital (74%, 51% and 92% respectively) than subjects living at home (32%, 9% and 18%): of the dementia residents in an institution, 78% were incontinent compared with 37% living at home.

No specific paper was found on the management of faecal incontinence in people with dementia. Patients may benefit from a bowel habit training programme, which also includes management of constipation with non-pharmacologic (such as exercise and fibre) and pharmacologic measures.

Conclusions

- Although faecal incontinence is prevalent in people with dementia, no paper was found dealing with the disease-specific management of faecal incontinence (LOE3)
Normal-pressure hydrocephalus (NPH) is characterized by a clinical presentation of gait disturbance, memory deficit, and urinary incontinence, combined with dilated cerebral ventricles and normal cerebrospinal fluid (CSF) pressure [65]. The clinical triad of this disorder is very much akin to those of vascular dementia or white matter disease (WMD), and should be considered before performing brain imaging in relevant patients. The syndrome was first described by Hakim and Adams in 1965 [66]. The effectiveness of the diversion of CSF flow by shunt operation in treating this syndrome is well documented [65] (LOE 2). Population-based MRI studies suggest that the incidence of NPH, or asymptomatic ventriculomegaly with features of idiopathic normal pressure hydrocephalus on MRI (AVIM), is around 1% (0.51-2.9%) in the general population of persons over 65 years of age [67], being estimated as one-tenth of WMD (LOE 3).

3. NORMAL PRESSURE HYDROCEPHALUS

LUTS in NPH include urinary urgency and frequency (OAB). Sakakibara et al. found urinary symptoms in 93% of 42 idiopathic NPH patients [68] (LOE 3). These symptoms included storage symptoms in 93% of patients (Nocturia 64%; urinary urgency, 64%; urgency urinary incontinence, 57%; increased daytime frequency, 36%) and voiding/ post mic Tory symptoms in 71% (hesitancy 50%; prolongation /poor flow, 50%; sensation of post-void residual, 29%; straining, 21%; intermittency, 14%). In some patients urinary urgency /frequency preceded urinary incontinence. Among the clinical triad of NPH, urinary incontinence was regarded a late symptom, but gait disturbance and OAB can be the early manifestation of NPH. Urodynamic findings of 42 NPH patients included low Qmax (<10 cm/s) in 40%; increased post-void residual (>30 ml) in 43% (average PVR volume 42.1 ml); low volume at first sensation (< 100 ml) in 33%; decreased bladder capacity (< 200 ml) in 57%; and DO in 95% of patients [68] (LOE 3). Although case series are often small (4-12 cases), DO is common (63-100%) [69] [70] (LOE 4). The high prevalence of DO suggests altered brain autonomic control in NPH [71].

3.1. Pathology and disease-specific urinary tract problems

Since there is a surgical shunt therapy for NPH, early diagnosis of NPH in patients with OAB is important. In addition to OAB with/without urinary incontinence, patients with NPH commonly have gait disorder (parkinsonian and wide-based gait) and dementia that is milder than Alzheimer’s disease. Differential diagnosis should include vascular dementia or white matter disease. If the shunt surgery failed, or was not applied to individuals with particular reasons (such as dementia), medical management (pharmacological and behavioural) of incontinence is put in place. However, no systematic review has been performed regarding the medical management of urinary incontinence in NPH.

Urodynamic findings of 42 NPH patients included low Qmax (<10 cm/s) in 40%; increased post-void residual (>30 ml) in 43% (average PVR volume 42.1 ml); low volume at first sensation (< 100 ml) in 33%; decreased bladder capacity (< 200 ml) in 57%; and DO in 95% of patients [68] (LOE 3). Although case series are often small (4-12 cases), DO is common (63-100%) [69] [70] (LOE 4). The high prevalence of DO suggests altered brain autonomic control in NPH [71].

3.2. Diagnosis

Diagnosis of NPH may comprise:

- Clinical manifestations in NPH mimic those of vascular dementia or white matter disease (LOE 3)
- Urinary urgency and increased urinary frequency may precede urinary incontinence in NPH (LOE 3)
- Detrusor overactivity seems to be the most common cause of incontinence in NPH patients (LOE 3).

Conclusions

- Definite; improved clinical symptoms by ventriculoperitoneal shunt surgery, etc.

Functional neuroimaging in normal volunteers has shown that the anterior cingulate, prefrontal cortex and insula are activated in response to bladder filling as compared to an empty bladder [47]. Although NPH is a diffuse brain disease with dilated ventricles, hypoperfusion in the frontal lobe has been documented in NPH patients using PET [72], single-photon emission computed tomography (SPECT) [73], and perfusion-weighted MRI [74] (LOE 3). Therefore, the frontal lobe is thought to be the anatomical substrate for urinary urgency and incontinence in NPH. According to the study by Sakakibara et al, using 97 NPH patients and [123I]-iodoamphetamine (IMP)-SPECT statistical mapping, there was a significant decrease in tracer activity in the right-side-dominant bilateral frontal cortex and the left inferior temporal gyrus in the severe urinary dysfunction group (p<0.05) [75]. The findings indicate that there is a link between right frontal hypoperfusion and urinary dysfunction in NPH. Importantly, bladder dysfunction and frontal lobe hypoperfusion in NPH can improve after shunt surgery. Recovery rate of OAB and urinary incontinence in NPH ranges from 20-80% [65] (LOE 4). After shunt surgery, bladder recovery is related to an increase in mid-cingulate perfusion [76] (LOE 3).

Recommendations

- Studies should be undertaken to ascertain management strategies for constipation and faecal incontinence in dementia
4. MULTIPLE SYSTEM ATROPHY

Multiple system atrophy (MSA) is an uncommon but well-recognized disease entity that both neurologists and urologists may encounter. The term MSA was introduced by Graham and Oppenheimer in 1969 to describe a disorder of unknown cause affecting extrapyramidal, cerebellar, and autonomic pathways [77]. MSA includes the disorders previously called striatoniagral degeneration (SND), sporadic olivopontocerebellar atrophy (OPCA), and Shy–Drager syndrome. The discovery in 1989 of glial cytoplasmic inclusions in the brains of patients with MSA provided a pathological marker for the disorder (akin to Lewy bodies in idiopathic Parkinson’s disease (IPD)) and confirmed that SND, OPCA, and Shy–Drager syndrome are the same disease with differing clinical presentations. Immunocytochemistry showed that the glial cytoplasmic inclusions of MSA are ubiquitin-, tau-, and alpha-synuclein (SNCA)-positive, possibly representing a cytoskeletal alteration in glial cells that results in neuronal degeneration. SNCA is a presynaptic neuronal protein encoded by the SNCA gene located on chromosome 4. This protein appears to play a role in dopamine and other neurotransmitter metabolism, vesicle trafficking, modification of synaptic transmission, and regulation of membrane permeability. In contrast, pathologically increased expression and abnormal conformation of SNCA are reported to reduce neurotransmitter release by inhibiting synaptic vesicle re-clustering after endocytosis. Familial occurrence is estimated to account for 1.6% of all cases, and data on such cases are being accumulated to identify candidate genes for this disorder, including SNCA, MAPT (microtubule-associated protein tau), etc.

Autonomic failure (postural hypotension and urinary dysfunction) is fundamental to the diagnosis of MSA: it is diagnosed when the criteria of either postural hypotension (systolic blood pressure fall > 30 mmHg or diastolic > 15 mmHg) or urinary dysfunction (persistent, involuntary urinary incontinence/incomplete bladder emptying) or both are fulfilled, along with poorly levodopa-responsive parkinsonism or cerebellar dysfunction [78]. Based on the major motor deficits, MSA can be classified as MSA-P (parkinsonism-predominant) or MSA-C (cerebellar-predominant) [77]. Clinical differential diagnosis between MSA-P, the most common clinical form, and IPD is difficult even for specialists. However, the lack of one-side dominance and resting tremor, poor response to levodopa, and rapid progression are all red flags indicating MSA. MSA-C can mostly be distinguished from hereditary spinocerebellar ataxias, although some individuals with such disorders do not have apparent redity. Autonomic failure (AF) is almost invariably present and can be an initial manifestation (AF-MSA) [79]. Autonomic failure occurs in other neurodegenerative diseases, for example in a subset of patients with IPD (AF-PD), as well as in pure autonomic failure (PAF), both of which are considered Lewy body diseases.

This section reviews the current concepts of urinary dysfunction in MSA, with particular reference to urinary symptoms, (video-)urodynamic assessment and sphincter electromyography (EMG), and patient management.

4.1. Pathology and disease-specific LUT problems

Both overactive bladder and large post-void residuals occur in MSA. The second consensus statement on the diagnosis of MSA recognizes that the disease frequently begins with bladder dysfunction (although erectile dysfunction usually precedes that complaint). Patients may present with urinary incontinence, urinary retention, or a combination of incontinence and incomplete bladder emptying [78]. It is important that other common causes of poor bladder control are excluded by a urologist or uro-gynaecologist before the disorder is attributed to the neurological condition [80]. The prevalence of troublesome urinary symptoms in 256 patients with MSA compared with 158 aged matched control subjects [81] showed that MSA patients had significantly higher increased daytime frequency (45% of women, 43% of men), night time frequency (65%, 69%), urinary urgency (64% of men), and urgency incontinence (75%, 66%) than did the controls. They also had more hesitancy of micturition (62%, 73%), prolonged poor stream (71%, 81%), urgency incontinence (61%, 47%), or the need to strain to void (48%, 55%). Of particular importance is that the quality of life (QOL) index in the MSA group was significantly higher (i.e. worse) in MSA patients for bladder dysfunction (70%, 76%) than that in controls. Many of them show large post-void residual urine volume > 100 ml. Therefore both overactive bladder and large post-void residuals are common in MSA.

In MSA, urinary dysfunction precedes postural hypotension. Of various symptoms of autonomic failure (erectile dysfunction, urinary dysfunction, postural hypotension, respiratory stridor) in patients with MSA, urinary dysfunction has attracted less attention.
than postural hypotension, although urinary dysfunction may result in recurrent urinary tract infection and cause morbidity. In addition, urinary incontinence results in impaired self-esteem, stress on the caregiver, and considerable financial cost. Postural hypotension was pointed out first in AF-MSA, which turned out to be a marker of autonomic involvement in this disorder. Both of the original two patients discussed by Shy and Drager had urinary frequency, incontinence, and urinary retention [82]. Other variants (MSA-P and MSA-C) rarely develop postural hypotension in their early stage. However, in the original reports, three of four patients with MSA-P showed voiding difficulty, retention, and urinary incontinence [83].

Thus, what are the most common and earliest autonomic features of MSA? In a study of 121 patients with MSA [84], urinary symptoms (96%) were more common than orthostatic symptoms (43%). The most frequent urinary symptom was difficulty voiding in 79% of the patients, followed by nocturnal urinary frequency in 74%. Other symptoms included urgency in 63%, urgency incontinence in 63%, diurnal urinary frequency in 45%, nocturnal enuresis in 19%, and urinary retention in 8%. The most frequent orthostatic symptom was postural faintness in 43%, followed by blurred vision in 38% and syncope in 19%. These figures are similar to findings reported by other centres [85, 86], and indicate that urinary dysfunction is a more common and often earlier manifestation than postural hypotension in MSA. Many factors might be involved in this phenomenon. Reports of focal lesions have shown that postural hypotension occurs in lesions below the medulla, whereas urinary dysfunction occurs in lesions at many sites in the neuraxis. MSA lesions involve the pons, the hypothalamus, and the basal ganglia, all of which might affect LUT function, as described below.

Urinary dysfunction also precedes motor disorder. Approximately 60% of patients with MSA develop urinary symptoms either prior to or at the time of presentation with the motor disorder [84]. This indicates that many of these patients seek urological advice early in the course of their disease. Since the severity of urinary symptoms is severe enough for surgical intervention, male patients with MSA may undergo urological surgery for prostatic outflow obstruction before the correct diagnosis has been made. The results of such surgery are often transient or unfavourable because of the progressive nature of this disease. Male erectile dysfunction is often the first presentation [84, 87], possibly preceding the occurrence of urinary dysfunction in MSA. The urologist confronted with a patient showing these features should be cautious about embarking on an operative approach. The neurologist encountering a patient with marked urinary symptoms might consider future investigation by brain magnetic resonance imaging (MRI) and sphincter EMG. Since motor disorders in MSA mostly mimic those in IPD, the urogenital distinction between these two diseases is worth considering, although a number of earlier studies on ‘Parkinson’s disease and the bladder’ might inadvertently have included patients with MSA. The prevalence rate of urinary dysfunction and urgency incontinence in MSA is higher than that reported in IPD. In addition, urinary dysfunction is never the initial presentation in IPD.

4.2. Disease specific diagnosis

Since MSA is a neurodegenerative disease that affects multiple brain regions, patients may have a wide range of urodynamic abnormalities that change with progression of the illness. Videourodynamics and sphincter EMG enable assessment of lumbosacral cord functions, which help distinguish MSA from other parkinsonian disorders.

Filling phase abnormalities include overactivity in 33–100% and uninhibited external sphincter relaxation in 33% of MSA [88-90]. Detrusor overactivity seems to be the major cause of urgency incontinence in patients with MSA, and may be associated with uninhibited sphincter relaxation.

Cerebral diseases can lead to a loss of the brain’s inhibitory influence on the spino-bulbo-spatial micturition reflex. The information that arises from the lower urinary tract reaches the periaqueductal gray matter (PAG), then goes down to the pontine micturition center (PMC), an area identical to, or just adjacent to, the locus ceruleus, which then activates the descending pathway to the sacral preganglionic neurons innervating the bladder. The basal ganglia are thought to be one of the higher centers for micturition, since lesions of this area lead to bladder overactivity. Positron emission tomography (PET) studies have shown that the hypothalamus, PAG, midline pons, and cingulate cortex are activated during urinary filling. The central pathology of MSA includes neuronal loss of neuromelanin-containing cells in the locus ceruleus [91] and the nigrostriatal dopaminergic system (‘putaminal slit sign’) [92] and cerebellum, and to a lesser extent in the ponto-medullary raphe (‘pontine cross sign’) [92, 93] and the frontal cortex [94, 95]. Experimental studies have suggested that the raphe modulates micturition function [96], and also that the cerebellum controls micturition function [97]. A single photon emission computed tomography (SPECT) study has shown that in the urinary storage and micturition phases, but not in the resting phase, activation of the cerebellar vermis was significantly lower in MSA patients than in control subjects [98]. These areas seem to be relevant for the occurrence of bladder overactivity and uninhibited sphincter relaxation in MSA patients.

Incomplete bladder emptying is a significant feature in MSA. In fact, 47% of patients with MSA had postvoid residuals (PVR) > 100 ml, whereas no patients with IPD had such levels [88]. The mean PVR volume was 71 ml in the first year, 129 ml in the second year (which exceeded the threshold volume for the start of clean intermittent catheterization (CIC)), and 170 ml in the fifth year from the onset of illness [99]. Pressure-flow analysis showed that bladder underactivity (a weak detrusor contraction) during voiding is more...
common in MSA (71% in women and 63% in men) than in IPD (66% in women and 40% in men) [88]. The mean bladder outlet obstruction index (Abrams Griffiths number) are smaller in patients with MSA (12 in women and 28 in men) than in those with IPD (40 in women and 43) [88]. Detrusor-external sphincter dyssynergia is present in 47% of MSA patients [88]. A subset of patients with MSA has bladder overactivity during storage and underactivity during voiding (detrusor hyperactivity with impaired contractile function, DHIC) [100]. The exact mechanism of this phenomenon has yet to be ascertained. However, it has been recognized that the central mechanisms underlying bladder filling and voiding are distinct from each other; i.e. the area promoting micturition is located in the PMC and the frontal cortex, whereas that promoting urinary storage is in the pontine storage center, basal ganglia, raphe, and frontal cortex. Lesions in these areas may cause various combinations of urinary filling and voiding disorders, such as DHIC.

The role of the sympathetic nervous system may be important, and a key feature could be an open bladder neck, which can suggest sympathetic denervation. The bladder neck, also known as the internal (smooth) urethral sphincter, is a component in the maintenance of continence that is innervated by the sympathetic hypogastric nerve. Videourodynamics study is an established method for evaluating bladder neck function. In normal subjects, the bladder neck is closed throughout filling so as to avoid leaking. However, an open bladder neck is found in 46–100% of MSA patients and in 23–31% of PD patients, and an open bladder neck at the start of bladder filling, even without the accompaniment of bladder overactivity, was noted in no PD patients but in 53% of MSA patients (p < 0.01) [88]. Because open bladder neck is common in patients with myelodysplasia or a lower thoracic cord lesion at T12-L2 (where the sympathetic thoracolumbar intermediolateral [IML] nuclei are located) and is reproduced by systemic or intrarethral application of alpha1-adrenergic blockers [101], it is likely that an open bladder neck reflects the loss of sympathetic innervation.

Neurogenic changes in the sphincter EMG may suggest somatic denervation. A distinguishing pathology in MSA is neuronal cell loss in the Onuf’s nucleus, a group of anterior horn cells in the sacral spinal cord [92]. External anal sphincter (EAS)-electromyography (EMG) results for over 600 MSA patients have been reported, with abnormality rates of more than 70% in many studies [102, 103]. Abnormalities have also been recorded in the bulbocavernous muscles in MSA [104]. A particular importance is not to miss the late components [105].

In a study of 84 probable MSA cases, 62% exhibited neurogenic change [106]. The prevalence was relatively low, presumably because up to 25% of patients had a disease duration of 1 year or less. In such early cases, the diagnosis of MSA should be made with extreme caution. In addition to the clinical diagnostic criteria, we usually add an imaging study and we perform gene analysis to the extent possible. The prevalence of neurogenic change was 52% in the first year after disease onset, which increased to 83% by the fifth year. Therefore, as expected, it is apparent that the involvement of Onuf’s nucleus in MSA is time-dependent; and EAS-MUP abnormalities can distinguish MSA from idiopathic PD and other diseases in the first 5 years after disease onset. Receiver-operating characteristic analysis of sphincter EMG showed high diagnostic power in terms of the duration of motor unit potential (MUP) analysis [103].

In the early stages of illness, the prevalence of neurogenic change in MSA does not seem to be high. It is possible that some MSA patients never develop neurogenic change during the course of their illness. Wenning et al. (1994) reported 3 patients with normal EAS-EMG and a postmortem confirmation of MSA [85]. Therefore, a negative result does exclude a diagnosis of MSA. Paviour et al. (2005) reported that among 30 sets of clinical data and postmortem confirmation in MSA cases with a duration of more than 5 years, 24 (80%) had normal EAS-EMG, 5 (17%) had a borderline result, and only 1 had a normal EMG [107]. Neurogenic change does not correlate directly with a clinically obvious functional deficit, although urinary incontinence is more severe in the patients with neurogenic change than in those without it.

Prevalence of neurogenic change increases with the severity of gait disturbance (wheel chair bound) [106]. However, neurogenic change was not related to postural hypotension (reflecting adrenergic nerve dysfunction); erectile dysfunction in men (presumably reflecting cholinergic and nitrergic nerve dysfunction); detrusor overactivity (reflecting the central type of detrusor dysfunction); constipation (presumably reflecting both peripheral and central types of autonomic and somatic dysfunction); or gender [106]. The neurogenic change in EAS-MUP was slightly more common in those with detrusor-sphincter dyssynergia (DSD). It has also been suggested that not only suprasacral pathology, but also sacral/peripheral lesions can produce DSD [108]. Although denervation can be found in the other skeletal muscles in MSA, it occurs much earlier in the external sphincter muscles [109]. This is in contrast to amyotrophic lateral sclerosis, where denervation occurs in most advanced cases (respirator bound).

The neural sites responsible for cardiovascular autonomic failure in MSA are mostly central, in contrast to the peripheral lesions in PAF [80]. However, 31–45% of patients with MSA also have low-compliance detrusor, defined as a maximum bladder capacity/tonic detrusor pressure increase <20 ml/cmH2O [84]. Low-compliance detrusor is known to occur in patients with spina bifida or in animals with experimental cauda equina lesions, most probably reflecting neuronal loss of bladder preganglionic neurons in the sacral IML nucleus and their fibers (pelvic nerve). Repeated urodynamic studies in MSA patients show...
that the cystometrogram changes from bladder overactivity to low-compliance or atonic detrusor, and from negative to positive betanecdol supersensitivity [84]. Nineteen percent of MSA patients show denervation supersensitivity of the detrusor, indicating peripheral changes [84]. As the disease progresses, symptoms may change from urinary urgency and frequency to those due to incomplete bladder emptying. These findings suggest that the responsible sites of the bladder cholinergic disorder may change from the ‘center’ (supra-nuclear) to the ‘periphery’ (nuclear sacral IML and/or infra-nuclear) during the course of the illness. Since MSA primarily affects the preganglionic neurons in the autonomic nervous system [80], bladder findings that suggest postganglionic lesions might reflect trans-synaptic degeneration of the cholinergic fibers.

Besides bladder disorders, patients with MSA may have nocturnal polyuria, which results in nocturnal urinary frequency and morning hypotension. A postmortem study revealed the degeneration of AVP neurons in the supra-chiasmatic nucleus in MSA [104], leading to impairment of the circadian rhythm of the plasma AVP concentration in MSA [110, 111]. In addition, daytime postural hypotension may cause nocturnal polyuria in patients with MSA [112]. This is probably due to a combination of factors that include compensatory supine hypertension at night, leading to increased glomerular filtration.

4.3  Disease specific management

More than half of patients with MSA have urinary dysfunction either prior to or at the time of presentation with motor disorder. Since many of these patients develop incomplete bladder emptying, they may be misdiagnosed as having prostatic hypertrophy. In fact, the results of urological surgery are rarely favourable, since bladder underactivity contributes more to voiding difficulty than does outflow obstruction. Therefore, it is important to avoid inappropriate urological surgery in patients with MSA [80]. A conservative approach with medical measures to manage urinary problems can be effective.

Estimation of the PVR volume is a simple and useful test in patients with MSA; even if their urinary complaints are solely urinary urgency/frequency, they may be unaware that their bladders do not empty completely. If the patient has a significant PVR and is symptomatic, this aspect of the problem should be managed using CIC performed by either the patient or the caregiver. However, in patients with advanced disease and severe neurological disability, a permanent indwelling catheter, either transurethral or suprapubic, or urosheath drainage may be required.

If OAB/DO is present, anticholinergic medication such as tolterodine, oxybutynin, propiverine, or propanethione may be indicated. However, anticholinergic side-effects, particularly dry mouth (probably mediated by M3 receptors) and constipation (M3 receptors), may limit their use in a proportion of the patients. A subset of patients with MSA may develop mild cognitive decline at an advanced stage of the disease. Since the use of anticholinergic drugs carries a risk of cognitive impairment (M1 receptors) [113], caution is needed. Anticholinergic drugs ameliorate urgency and frequency, but conceivably could reduce bladder contractility during voiding. Therefore, PVR should be measured and the medication should be withdrawn or CIC should be added if there is significant residual. If night-time urinary urgency/frequency is the problem, overnight bladder drainage may be considered [99].

Interactions can arise between drugs to treat bladder, postural hypotension, and motor disorders. Since incomplete bladder emptying in patients with MSA is due mostly to bladder underactivity, drugs acting on outflow obstruction are unlikely to benefit all patients. However, in some patients, alpha-adrenergic blockers may be effective in lessening PVR volumes, due probably to detrusor-sphincter dyssynergia [114]. Uro-selective blockers such as tamsulosin and naftopidil may be chosen, in the hope they have fewer side-effects such as postural hypotension. Importantly, the drugs most commonly used to treat postural hypotension in MSA are adrenergic agonists. Administration of amezinium, an adrenergic drug, may increase PVR volume and the risk of retention [115]. Amezinium most probably stimulates the alpha receptors, both in the vascular wall (alpha1 receptors, particularly in the elderly [116]) and the proximal urethra (alpha1A-adrenergic receptors).

Pyridostigmine, an acetylcholinesterase inhibitor, can be effective in lessening PVR volumes [117]. Pyridostigmine also lessens postural hypotension, presumably by enhancing nicotinic acetylcholine receptor transmission in the sympathetic ganglia [118, 119].

Dopaminergic receptors: whether centrally acting drugs, such as pergolide (a dopaminergic D1 selective receptor agonist) for parkinsonism, might ameliorate urinary dysfunction in MSA has not been fully studied. Early untreated IPD patients with mild urgency and frequency tend to benefit from levodopa (D1/2) treatment. However, levodopa may augment bladder overactivity in IPD patients. Since D7 selective stimulation inhibits the micturition reflex whereas D2 selective stimulation facilitates it, the balance of these stimulations may explain the various effects of the drugs. Levodopa (D1/2) and its metabolites, such as norepinephrine (noradrenaline), may also contract the bladder neck by stimulating alpha1 adrenergic receptors [115].

Desmopressin is a potent analogue of AVP used in the treatment of diabetes insipidus due to a loss of posterior pituitary AVP secretion. Mathias et al. [111] used 2–4 μg of intramuscular desmopressin in patients with autonomic failure including MSA. 5 μg of intranasal desmopressin once a night in MSA patients with impaired circadian rhythm of AVP and nocturnal polyuria also appears to be beneficial [120]. This small dose of desmopressin is unlikely to
cause adverse effects, but hyponatremia and signs of cardiac failure should be checked for regularly. Desmopressin could also ameliorate morning hypotension resulting from the abnormal loss of body fluid at night [111].

Micturition syncope: Well-known triggers for syncope in MSA include: 1) standing (postural syncope), 2) eating (post-prandial syncope), and 3) exercise (post-exertional syncope) [80]. In addition, syncope in patients with MSA may also be triggered by 4) voiding (micturition syncope) [121]. The detailed link between the bladder and the cardiovascular system is still uncertain in this condition. However, particularly in patients who use abdominal straining when voiding, CIC could lessen micturition syncope.

Recent studies suggest that bladder management may directly, or indirectly, affect survival of MSA [122, 123]. Coon et al. suggested that while the initial onset with autonomic symptoms was not associated with shortened overall survival, early autonomic symptoms in disease course, particularly bladder symptoms and severe urinary symptoms (requiring urinary catheterization), negatively affected survival [122]. Since MSA is a progressive disease that leads to urinary retention, early differential diagnosis from Parkinson’s disease is necessary in terms of catheterization [124].

Conclusions:

- Urinary dysfunction is a prominent autonomic feature in patients with MSA, and it is more common (above 90%) and occurs earlier than postural hypotension in this disorder (LOE3).
- In contrast to idiopathic Parkinson’s disease, MSA patients have more marked urinary dysfunction, which consists of both marked urinary incontinence and post-void residuals >100 ml (LOE1,2).
- Videourodynamic and sphincter EMG analyses are important tools for understanding the extent of these dysfunctions and for determining both the diagnosis and management of the disorders (LOE3).
- The common finding is detrusor overactivity, which accounts for urinary urgency and increased frequency (LOE3).
- Detrusor-sphincter dyssynergia, open bladder neck at the start of bladder filling (internal sphincter denervation), and neurogenic sphincter EMG (external sphincter denervation) are all characteristics of MSA (LOE2).
- These features may reflect pathological lesions in the basal ganglia, pontine tegmentum, raphe, intermediolateral cell column, and sacral Onuf’s nuclei (LOE4).
- During the course of the disease, the pathophysiological balance shifts from central to peripheral, with bladder emptying disorder coming to predominate (LOE3).

Recommendations:

- Clinical features of MSA may mimic those of IPD, and the potential impact on treatment outcomes should be considered if there is any doubt about the underlying diagnosis (A).
- MSA is a progressive disorder and impaired detrusor contractility is common. Therefore it is important to avoid inappropriate urological surgery in patients with MSA (B/C).
- A conservative approach with medical measures in MSA patients includes anticholinergics for urinary urgency and frequency, desmopressin for nocturnal polyuria, uro-selective alpha-blockers and cholinergic stimulants for voiding difficulty, and CIC (clean, intermittent catheterization) for large PVR (post-void residual) (B).

4.4. Faecal incontinence

Lower gastrointestinal tract (LGIT) dysfunction is also common in patients with MSA. Sakakibara et al. [125] (LOE2) performed a bowel questionnaire in 15 patients with MSA and in 10 age-matched healthy control subjects. The MSA group showed decreased bowel frequency (<3 times a week) in 9, difficulty in expulsion in 11, and faecal incontinence in 3; the control group showed decreased bowel frequency in only 2, mild difficulty in expulsion in 2, faecal incontinence in none. Therefore, constipation is the major bowel dysfunction in this disorder, although in advanced stages faecal incontinence is not uncommon. Studies on the mechanism of bowel problems in this disorder are scarce. Stocchi et al. [126] (LOE2) performed anorectal manometry in 16 patients with MSA; 13 patients showed paradoxical anal sphincter contraction on fictive straining. Bardoux et al. [127] (LOE3-4) reported a case of a faecally incontinent patient due to MSA, who showed inability of anal squeezing. Sakakibara et al. [125] (LOE2) performed colonic transit time, sphincter electromyography (EMG) and rectoanal videomanometry in 15 patients with MSA and 10 age-matched healthy control subjects. Compared with the control subjects, MSA patients had significantly prolonged colonic transit time in the rectosigmoid segment and total colon. Sphincter EMG showed neurogenic motor unit potentials in none of control subjects but in 93% of MSA. In the resting state, MSA patients showed a lower anal squeeze pressure (external sphincter weakness) and a smaller increase in abdominal pressure on coughing. During rectal filling, MSA patients showed smaller amplitude in phasic rectal contraction, which was accompanied by an increase in anal pressure that normally decreased, together with leaking in 3 patients. During defecation, most MSA patients could not defecate completely, with larger post-defecation residuals. MSA patients had weak abdominal straining, smaller rectal contraction on defecation and larger anal contraction on defecation (paradoxical sphincter contraction on defecation, or anismus),
though these differences were not statistically significant.

Constipation in MSA most probably results from slow colonic transit, decreased phasic rectal contraction and weak abdominal straining, whereas faecal incontinence results from weak anal sphincter due to denervation. The responsible sites for these dysfunctions are still not known. However, as described in idiopathic Parkinson’s disease, they most probably reflect lesions of both central and peripheral nervous systems that regulate the LGIT.

LGIT functional disturbance is often preceded by LUT dysfunction in MSA patients. Abnormalities in colonic transit time and rectoanal videomanometry in MSA were mostly similar to those in idiopathic Parkinson’s disease, except for the sphincter denervation and resultant faecal incontinence in MSA.

When treatment of the bowel disorder in MSA is planned, use of objective parameters is recommended in order to clarify the action of drugs. A few such studies are available: Eichhorn and Oertel [128] (LOE3) gave polyethylene glycol 3350, an osmotic agent with high water binding capacity, in 2 patients with MSA, and found an improvement in stool frequency and difficult defecation in both patients. Similarly, Sakakibara et al. [129] (LOE2) measured colonic transit time in 4 patients with MSA. After administration of calcium polycarbophil, an osmotic and highly bulking agent, colonic transit time of total and the right segment shortened significantly. Liu et al. [130] (LOE2) performed colonic transit time and rectoanal videomanometry in 7 patients with MSA. After administration of mosapride citrate, a novel selective 5-HT4 receptor agonist, the patients showed a shortened total and rectosigmoid segment colonic transit time, lessened first sensation and an augmented amplitude in phasic rectal contraction. During defecation, mosapride augmented the amplitude in rectal contraction and lessened the volume of post-defecation residuals significantly.

Similar results were obtained in a study by Sakakibara et al. [131] (LOE2), in which dietary herb extract Dai-Kenchu-To, one active component of which is hydroxy-beta-sanshool (5-HT3 receptor agonistic action), was prescribed.

MSA is a slowly progressive disease currently without cure. More research is needed to evaluate the pathophysiology of LGIT dysfunction, and to evaluate the effects of different drug treatment modalities.

Conclusions

- Patients with multiple system atrophy have often abnormal bowel function (LOE2).
- The most common bowel disturbances are slow colonic transit, decreased phasic rectal contraction and weak abdominal straining; faecal incontinence results from weak anal sphincter, due to denervation (LOE2).
- Bowel dysfunction, such as constipation, is common and has significant impact on quality of life of patients with multiple system atrophy (LOE3).
- More studies on neurologic bowel dysfunction and management in patients with multiple system atrophy are needed.

5. PARKINSON’S DISEASE

5.1. Urinary incontinence

Parkinson’s disease (PD) is a movement disorder due to degeneration of dopaminergic neurons in the substantia nigra and a loss of dopamine-containing nerve terminals in the basal ganglia. Degeneration of the nigrostriatal pathway is accompanied by decreases in corresponding biochemical markers, including dopamine, tyrosine hydroxylase, dopamine metabolites, and dopamine transporter. These central nervous system changes also have influence on autonomic function; the most common problems are gastrointestinal (constipation), perspiratory (hypohidrosis) and urinary system.

LUT dysfunction in PD was estimated to occur in 37-71% in uncontrolled studies. Among these, in a study of Hattori et al. [132] (LOE3), 60% of PD patients had urinary symptoms, which could be divided in the following categories: storage LUTS in 28%, voiding in 11%, and both types in 21%. The prevalence of urinary symptoms correlated with severity of the disease, but not with the duration of illness. Gray et al. [133] (LOE3) reported that LUT functional disturbances in PD are not disease-specific and only correlated with age. In control-based studies [134-137] (LOE2) the prevalence of LUT symptoms (LUTS) was found to be 27-64%, and significantly higher than healthy controls. The majority of patients had onset of the bladder dysfunction after the appearance of motor disorder. Even patients with low disability may report LUTS, though this may not cause impairment of quality of life [138]. In one study, urinary incontinence in PD frequently occurred in conjunction with faecal incontinence, whereas no significant relation was observed between bladder and sexual dysfunction. Bladder dysfunction substantially affects the quality of life in patients with PD. Bladder dysfunction in PD correlates with neurological disability, and stage of disease, both suggesting a relationship between dopaminergic degeneration and LUTS. LUTS was more common in a group of PD patients with older age, as in healthy populations. Among LUTS, nocturia (night-time urinary frequency) is the most prevalent symptom (>60%) [136, 137] (LOE2). Patients also complained of urinary urgency (33-54%), daytime frequency (16-36%), and urinary incontinence in 28% of males and 28% of females. These figures are almost the same in untreated, early PD patients [138]. Although
less common than storage symptoms, PD patients also report voiding symptoms. In the study by Sakakibara et al. [139] (LOE2), PD patients had significantly higher rates of delay in initiating urination (44% of men), prolongation/poor stream (70% of men), and straining (28% of women) compared with the control group. However, despite the voiding symptoms, PD patients have low post-void residuals. Impaired detrusor contractility is reported in urodynamic studies in PD and is related to the degree of motor impairment [140].

**Pathology and disease-specific urinary tract problems**

The net effect of the basal ganglia on micturition is thought to be inhibitory [141]; in PD, the bladder becomes overactive. Functional neuroimaging during bladder filling resulted in activation in the globus pallidus of normal volunteers and in the putamen in PD patients with detrusor overactivity. In contrast, dopamine transporter imaging (indicating brain dopamine neurons) was decreased in PD patients with urinary dysfunction than in those without it [142]. The micturition reflex is under the influences of nigrostriatal dopamine (both inhibitory in D1 and facilitatory in D2) and GABA (inhibitory). Deep brain stimulation in the subthalamic nucleus results in amelioration of motor disorder as well as increased bladder capacity and decreased post-void residuals [143] (LOE2). Therefore, urinary dysfunction in PD could reflect degeneration of the nigrostriatal dopaminergic cells associated with specific motor disorders. In addition to the nigrostriatal dopaminergic projection, the ventral tegmental area (VTA, the A10 cell group)-limbic cortex and the hypothalamic (the A11 cell group)-spinal cord are involved in urinary dysfunction in PD.

In a study of PD and multiple system atrophy (MSA) patients, Sakakibara et al. [88] (LOE2) found urinary symptoms in 72% of PD patients. They were mostly attributed to DO (81%) and external sphincter relaxation problems (33%). During micturition, PD patients did not demonstrate DSD, but impaired detrusor contractility was observed in 66% of women and 40% of men. In addition, patients with PD had partial bladder outlet obstruction, e.g. mean bladder outlet obstruction index was 43 in men. Nevertheless, average volume of post-void residuals in PD was only 18 ml. Similar observations were reported by Defreitas et al. [144] (LOE2).

**Specific diagnosis and treatment**

In the differential diagnosis of PD and parkinsonian-type MSA, large post-void residuals, open bladder neck, and neurogenic change in sphincter motor unit potentials are common in MSA [80, 88] (LOE2), whereas they are rarely seen in clinically typical PD [145]. However, PD with dementia, or dementia with Lewy bodies, may have large post-void residuals and neurogenic change in the sphincter motor unit potentials [146], thereby mimicking MSA (LOE3). Bladder dysfunction in PD parallels other autonomic dysfunctions [147], cardiac denervation [148], and falls [149] (LOE3). Nocturnal polyuria is an important cause for nocturia and therefore patients reporting nocturia should fill in a bladder diary.

Guidelines now exist for the management of bladder dysfunction in PD [124]. Levodopa and other antiparkinson medication may affect bladder function in PD. To date the results are not consistent and the responses are not straightforward. Some reports have shown storage-facilitating effects of dopaminergic drugs. Kuno et al. [150] (LOE3) showed that change of bromocriptine to pergolide (D1<2 agonist) brought lessening of nocturia. Others have shown voiding-facilitating effects. In early PD [151] (LOE2) and advanced PD with the on-off phenomenon [152] (LOE2), a single-dose of levodopa exacerbates DO in the filling phase, but also improves bladder emptying through increased detrusor contractility. We still do not know the reasons for the discrepancy between different studies.

There are several factors underlying the complex bladder behaviour in PD. Post-synaptic dopamine D1 (excitatory) and D2 (inhibitory) receptors have a millimolar affinity to dopamine, whereas dendritic D2 (inhibitory) autoreceptors have a picomolar affinity to dopamine. Therefore, when levodopa is administered externally, it may first stimulate dendritic D2 autoreceptors, which might suppress the nigral cells and facilitate the micturition reflex. In cases of PD under long-term treatment with levodopa, dopamine receptors are down-regulated. Bladder overactivity might also involve an activation of D2 receptors in the spinal cord [153] (LOE2). In addition, in experimental animals, single doses of apomorphine showed a biphasic effect [154] (LOE2).

Deep brain stimulation (DBS) is a treatment option in advanced PD. The subthalamic nucleus (STN) is regarded as the key area in the indirect pathway, which is dominant in the parkinsonian state. DBS inhibits many cells within the STN, probably due to depolarization block and release of GABA from activation of inhibitory afferent terminals. In the STN, neuronal firings related to the micturition cycle have been observed in cats [155] (LOE2). DBS increases bladder capacity, facilitated bladder afferent pathways, and augmented activity of the prefrontal cortex in the brain of PD patients [156] (LOE2). In a cohort of 107 patients with advanced PD, patients treated with STN DBS reported the same degree of LUT symptoms compared to patients treated with either conventional oral medication therapy or an apomorphine pump, however had significantly less nocturia [157]. Acute urinary retention has been reported in two patients after subthalamic nucleus DBS [158] and detrusor overactivity has been reported following pedunculopontine nucleus DBS [159] (LOE3).

A double-blind, randomized, placebo-controlled study evaluated solifenacin 5-10 mg /day in 23 pa-

SPECIFIC NEUROLOGICAL DISEASES | 1193
patients with PD and LUT symptoms. A significant improvement in the number of micturitions per 24 h period was observed in the solifenacin group compared to placebo at a mean dose of 6 mg/day. In the open label phase, the number of urinary incontinence episodes per 24 h period, as well as the number of nocturia episodes, decreased [160] (LOE2). A prospective evaluation of 33 men with PD reporting LUT symptoms taking doxazosin demonstrated a significant improvement in LUT symptoms, LUT-related quality of life and flow rates, though the response to treatment was dependent on the severity of neurological disability [161] (LOE 3).

A systematic review of anticholinergic use (centrally acting) to treat PD was done by Katzschlager et al. [162] (LOE I). Cognitive adverse events of anticholinergics are a concern, particularly in elderly PD patients. This was first described in 1997 by Donnellan et al. in PD patients with overactive bladder [113] (LOE 3). They gave oxybutynin in four patients, who subsequently developed dementia, which reversed after discontinuation of oxybutynin. Factors underlying the cognitive effects of these medications include: 1) central muscarinic receptor affinity, e.g. high M1-receptor selectivity; and 2) easy penetration of the blood-brain barrier (BBB), e.g. high lipid solubility; a neutral charge or low degree of ionization; and a less bulky (number of rotatable bonds<5) and smaller molecular size (<450Da) [163] (LOE 2). Regarding BBB penetration, most anticholinergics have a molecular size between 300-400Da. Oxybutynin can readily penetrate the CNS, since it has high lipophilicity and neutrality, while anticholinergics have less marked lipophilicity or neutrality. Trospium, a quaternary amine, has a particularly high polarity.

Intradetrusor injections of onabotulinumtoxinA is a promising treatment for managing intractable DO in patients with PD and small case series have demonstrated improvement in clinical and urodynamic parameters [164-166] (LOE3). However the concern is urinary retention that may arise following treatment and the potential need to require catheterisation. This seems to be related to the dosage used and reports of incomplete bladder emptying and catheterisation is reported more when using 200 units compared to 100 units [164, 165].

Tibial nerve stimulation (TNS) has been shown to be effective in short term management of OAB symptoms in patients with PD. Acute percutaneous TNS (PTNS) has been reported to increase functional bladder capacity in PD, and following chronic stimulation urinary frequency and urgency urinary incontinence reduced [167]. However, long term outcomes in PD are lacking. Transcutaneous tibial nerve stimulation (TTNS) was found effective in the treatment of LUTS in 13 patients with PD, with benefits in urinary urgency and nocturia episodes, as well as urodynamic parameters [168]. The number of patients reported having Sacral nerve modulation is insufficient to draw any conclusions [169].

As in MSA, a very important issue in PD affected patients is the indication for pelvic surgery. Myers et al. [170] (LOE2) found that women with PD and LUT complaints have a lower maximum cystometric capacity and a higher rate of DO at lower bladder volumes in comparison with non-neurologic controls. Therefore surgery for stress incontinence in women with PD should be performed only when no significant DO is present, since this type of surgery can evoke or aggravate DO and subsequent urgency incontinence. Roth et al. reported outcomes of 23 patients with PD undergoing transurethral prostate resection for benign prostatic obstruction, emphasizing the importance of careful evaluation before any decision on intervention [171].

**Conclusions**

- In Parkinson’s disease, LUT symptoms are associated with degeneration of dopaminergic neurotransmission (LOE2).
- The most common LUT disturbances are detrusor overactivity during storage, and impaired detrusor contractility during voiding (LOE2).
- The effect of levodopa on LUTS in PD patients remains to be fully elucidated (LOE3).

**Recommendations**

- Detrusor overactivity in PD patients can be treated with antimuscarinic drugs (B).
- For voiding failure with significant post void residual, the treatment of choice is intermittent catheterization (B).
- OnabotulinumtoxinA is a promising treatment for managing intractable DO in PD, which is associated with a risk for urinary retention and the need for catheterisation. (C )
- LUT surgery for patients with Parkinson’s symptoms is an option where MSA is excluded, provided evaluation is detailed (C).
- Stress incontinence surgery should not be offered to patients with significant detrusor overactivity (C).

**5.2. Constipation and faecal incontinence**

Lower gastrointestinal tract (LGIT) dysfunction is common in Parkinson’s disease (PD). In control-based studies, the incidence of decreased stool frequency (< 3 times a week) in PD patients ranges from 20% to 81%, difficulty in stool expulsion 57-67%, and diarrhoea 21% [172, 173] (LOE2). All of these values are significantly higher than in the normal population (range, decreased stool frequency, 0-33%; difficulty in stool expulsion, 26-28%; diarrhoea, 10%). Faecal incontinence affects 10-24% in PD [172, 174] (LOE2). Therefore, constipation is the most prominent LGIT symptom in patients with PD. Indeed, PD is a risk fac-
tor for elderly nursing home residents to have constipation. Bowel dysfunction affects the quality of life in patients with PD. The rate of dissatisfaction for bowel dysfunction (59%) is significantly higher than for urinary (28%) or sexual dysfunction (29%), although the prevalence rate of all three dysfunctions is almost the same (more than 60%). The rate of dissatisfaction for the bowel dysfunction in PD is also significantly higher than in healthy controls (16%) [174] (LOE2).

Difficulty in expulsion and diarrhoea are more common in the higher grade of Hoehn and Yahr staging, suggesting a relationship between dopaminergic degeneration and LGIT symptoms. Faecal incontinence in PD occurs commonly with urinary incontinence, whereas no significant relation has been seen between bowel and sexual dysfunction. Constipation in PD is often associated with a low coefficient of variation in electrocardiographic R to R intervals [175] (LOE3). The findings indicate that parasympathetic dysfunction might underlie these abnormalities.

Intestinal pseudo-obstruction (IPO), also called paralytic ileus, is the most severe presentation of constipation in patients with PD and constitutes a medical emergency. Occurrence of IPO/volvulus is reported to be rare, emergency IPO needs hospitalization and may lead to a poor outcome. Therefore, preventative treatment of constipation, including consideration of prokinetic drugs is necessary, particularly in elderly PD patients.

There seems to be an association between the frequency of bowel movements and the future risk of developing PD [177, 178] (LOE1). This observation is in line with the pathological staging of PD by Braak et al. [179] (LOE1), in which disease process in the central nervous system starts earlier in the dorsal motor vagal nucleus than in the substantia nigra in PD. From a clinical perspective, it is of particular relevance that patients may see gastroenterologists or physicians first because of their bowel dysfunction, prior to a correct diagnosis of PD being made. Therefore, constipation as the initial presentation of PD is akin to urinary dysfunction as the initial presentation of multiple system atrophy.

Pathology and disease-specific problems

The enteric nervous system generates the peristalsis responsible for bowel content transit. The components of peristalsis are contraction on the oral side of the bolus, and relaxation on the caudal side. Cholinergic receptors have a major role in the contraction proximally. The strength of cholinergic transmission is regulated by opposing receptors; serotonin 5-HT4 receptor-mediating excitation and dopamine D2 receptor-mediating inhibition. Post-mortem studies of bowel in PD have shown decrease in dopaminergic myenteric neurons and the appearance of Lewy bodies along the proximal-distal axis, being most frequent in the lower oesophagus, but scarce in the rectum [180-182] (LOE2). Thus PD affects not only the central, but also the peripheral (enteric) nervous system.

LGIT function primarily consists of [1] colonic transport of the bowel content to the anorectum, [2] transient storage in the anorectum, and [3] defecation. In PD, constipation results primarily from decreased transport and/or disturbed anorectal evacuation. Faecal incontinence may result from disturbed anorectal reservoir function, or overflow secondary to constipation. Previous reports have shown that total colonic transit time (CTT) is increased beyond the normal threshold in 80% of PD patients, which translates into an increased average CTT ranging from 44 hours to 130 hours [172, 174] [139, 141, 151] (LOE2), and 89 hours in de novo PD patients [48] (LOE2), all of which are significantly longer than the CTT in controls (range, 20-39 hours). Prolonged CTT has also been documented in PD patients without subjective constipation. Slow colonic transit is the major cause of decreased stool frequency. The slow colonic transit is likely to reflect a decrease in slow waves and spike activities of the colon [147].

In resting anal manometry, the anal pressure of PD patients is low or normal [172, 174, 183] (LOE2). The resting anal pressure may reflect sympathetic innervation in the internal anal sphincter, since lesions or anaesthetic blocks at T12-L3 (where the sympathetic preganglionic neurons are located) substantially lessen the anal pressure. Similarly, most PD patients have normal anal pressure increase on squeezing. This finding corresponds to a lack of neurogenic changes in the external sphincter EMG. Nevertheless, latent anal sphincter dysfunction may explain the faecal incontinence that occurs in most advanced cases. In slow-filling rectoanal videomanometry, PD patients had the same rectal volume at first sensation and a maximum desire to defecate, and the same rectal compliance as control subjects [90, 174] (LOE2). In contrast to the bladder, the normal rectum shows spontaneous phasic contraction. However, the amplitude of the spontaneous phasic rectal contraction in PD patients is significantly less than that in control subjects. The decreased spontaneous phasic rectal contraction may share the same aetiology with the altered CTT.

During defecation, healthy subjects utilize the final wave of spontaneous phasic rectal contractions. However, rectal contraction on defecation in PD patients is smaller than that in controls [174] (LOE2). In addition, abdominal straining is weaker in PD patients. Paradoxical anal sphincter contraction on defecation (PSCD), or anismus, is observed in studies using sphincter EMG, radiography, and anal pressure measurement. The mechanism of the impaired straining in PD may include rigidity and reduced contractility of the axial muscles, and a failure of coordinated glottis closure. However, neuronal degeneration in the brain of PD patients relevant to straining is yet to be clarified. Mathers et al. [184] consider PSCD a focal dystonia. Dysfunction in the supraspinal descend-
ing pathway to the external sphincter may be a con-
tributing factor. Apomorphine was shown to lessen PSCD [184] (LOE2). This effect was not antagonized by domperidone, which does not penetrate the BBB, suggesting that CNS pathology may contribute to PSCD.

**Disease-specific diagnosis and treatment**

Insoluble dietary fibers produced an improvement in stool consistency and an increase in stool frequency in PD, which paralleled an improvement in levodopa absorption [185] (LOE3). Dietary fibers such as psyllium [186] (LOE2) and polyethylene glycol 3350 [128] (LOE2), or bulking and highly hydrophilic agent polycarbophil [129] (LOE2), improve constipation in neurodegenerative disorders, including PD. Although psyllium does not alter CTT or anorectal parameters in PD patients, polycarbophil shortens the total CTT, particularly in the proximal bowel segments.

It is possible that levodopa and other antiparkinson medication may affect bowel function in PD. Endogen-
ous dopamine is thought to inhibit intestinal motility via D2 receptors. Tateno and Sakakibara performed the quantitative lower-gastrointestinal autonomic test (QL-GAT, a combination of colonic transit and manometry) in 19 early, untreated PD patients before and after administration of 200 mg/day of levodopa [187]. Levodopa augmented rectal contraction, less-
ened paradoxical anal sphincter contraction on defe-
cation (PSCD, anismus), and thereby ameliorated an-
orectal constipation, without apparent adverse ef-
fects. This might be brought about by both peripheral and central dopaminergic stimulation.

Since levodopa is absorbed from the small intestine, bowel dysfunction in PD may interfere with levodopa absorption, worsen the motor disorder, or even lead to malignant syndrome [173, 188] (LOE3/4). Domper-
idone, a peripheral D2 receptor antagonist that does not cross the blood-brain barrier, causes a mean 12% increase in peak plasma levodopa concentrations that occurs a mean of 10 min earlier than when levo-
dopa is given alone [189] (LOE3).

The selective 5-HT 4 receptor agonist cisapride [190], though no longer licensed, and newer agents such as mosapride [130] (LOE2) and tegaserod [191] significa-
cantly reduce CTT and ameliorate constipation in PD. Mosapride shortened total CTT (particularly the cau-
dal segment), and augmented the amplitude in rectal contraction during defecation in patients with PD [130]. Notably, improvement of parkinsonism is more significant with pergolide-mosapride than with per-
golide-domperidone, presumably reflecting better levodopa absorption. Similar results were obtained in PD by dietary herb extract Dai-Kenchu-To, one active component of which is hydroxy-beta-sanshool (5-HT3 receptor agonistic action) [131] (LOE2). A series has shown a role for Botulinum toxin A injections into the puborectalis muscle [192] (LOE3).

**Conclusions**

- Patients with PD often have abnormal anorectal function (LOE2).
- The most common bowel disturbances in PD are slow colonic transit, decreased phasic rectal con-
traction, weak abdominal straining, and paradox-
ical sphincter contraction on defecation (anismus) (LOE2).
- Bowel dysfunction such as constipation is com-
mon and has significant impact on quality of life of PD patients (LOE2).

**Recommendations**

- More studies on management of neurologic bowel dysfunction in PD are needed.

### 6. CEREBRAL LESIONS AND CEREBROVASCULAR ACCIDENTS

Lower urinary tract dysfunction (LUTD) may be an in-
tegrated part of the neurological syndrome (i.e. a neu-ogenic LUT dysfunction, most often urinary inconti-
nence (UI)). LUTD may also be a consequence of asso-
ciated deficits; particularly motor and cognitive dys-
function may lead to UI, which in this case is called “functional”. Both neurogenic and functional UI may be combined. Patients themselves, however, rarely link the LUT symptoms to the neurological disorder. Correlation between specific LUT symptom (LUTS) and the lesion site caused by stroke has initially been studied by post mortem or surgical specimens. But with improving modalities of imaging, it becomes possible to correlate symptoms with smaller, more dis-
crete abnormalities. As a rather new insight, slow, dif-
fuse brain ischemia (white matter lesion) recently emerged as a significant factor to produce overactive bladder (OAB) in the elderly. Finally, management of LUTD in stroke is reviewed.

#### 6.1. Stroke

LUTD in stroke may be a consequence of direct in-
volveinent of neural structures which are part of the brain neural control of LUT. The consequence is, as will be discussed later, in most events the overactive bladder syndrome (OAB; i.e. urgency and frequency of micturition, and urge UI). Furthermore, there often is a functional component (immobility and loss of ini-
tiative/cognition) [193].

Stroke, a major form of cerebrovascular disease (CVD), is a common brain disease that preferentially affects the elderly. LUTD significantly affects quality of life in post-stroke patients [194]. Reports of the prevalence of LUTS in patients with stroke, except for UI, have been scarce. Sakakibara et al. [195] re-
ported on the bladder symptoms of 72 patients who had been admitted with an acute hemispheric stroke
in a neurology department. When assessed at 3 months, 53% were found to have significant LUTS. The commonest problem was nocturnal urinary frequency (36%), then urgency UI (29%) and difficulty in voiding (25%); urinary retention was seen in 6%. Britain et al. [196] reported an incidence of post-stroke LUTS as 64% (in 423 subjects) that was higher than in a control normal population (32%). The major urinary symptoms were: nocturia (49%), UI (33%), urgency (19%), frequency (15%), straining (3.5%) and pain (2.5%). In 1248 stroke patients, Williams et al. [197] found that 83.6% of survivors reported one or more abnormal LUTS at 3 months, nocturia being the most frequent (79.1%), followed by UI (43.5%; urgency type 37.0%, stress type 20.6%) and urinary frequency (17.5%). Thomas et al. [198] reported UI in 40-60% of patients admitted to hospital after a stroke, with 25% still having problems on hospital discharge, and around 15% remaining incontinent at one year. Amelioration of UI in 25-45% of the patients may reflect amelioration of neurological involvement. It is postulated that the micturition reflex is under tonic (mainly inhibitory) influence of the PMC in stroke rats.

Studies reporting on stroke localization and LUTD stress the importance of the frontal lobe, and there are no clear reports of bladder dysfunction as a consequence of a single/focal deficit in the parietal, temporal or occipital lobe. Lesions of the anteromedial frontal lobe, its descending pathways and the basal ganglia may be important for bladder dysfunction in stroke patients. Khan et al. [200, 201] reported on post-stroke patients with LUTS, and the majority of patients had frontal cortex and/or internal capsular lesions. Bogousslavsky and Regli noted UI in 22% (6 of 23 cases) of anterior cerebral artery infarction that affects the frontal lobe [202]. Sakakibara and colleagues [195], analysing 72 post-stroke patients irrespective of the presence of LUTS, found a significant correlation between the occurrence of a urinary disturbance and hemiparesis and a negative correlation with hemianopia, brain imaging techniques confirming a more anterior location of brain lesions in the former group. Woessner et al. reported a urinary-incontinent patient whose stroke was localized in the cortical motor area of the bladder/sphincter [203].

Considering LUT neural control one expects LUTD also in brainstem infarcts. An analysis of LUTS of 39 patients who had had brainstem strokes showed that it was dorsally situated lesions that resulted in disturbance of micturition [204]. Forty-nine percent of all the patients had LUTS; nocturnal urinary frequency and voiding difficulty in 28%, urinary retention in 21% and UI in 8%. The problems were more common in those following haemorrhage, possibly because the damage was usually bilateral. MR scanning showed that the responsible lesions were in the pontine reticular nucleus and the reticular formation, adjacent to the medial parabrachial nucleus and the locus coeruleus. A correlation was found between LUTS and sensory disturbance, abnormal eye movement and inco-ordination. Lateral medullary infarction (Wallenberg syndrome) has been reported to produce voiding difficulty and DSD [205]. In another case, the lesion seemed to extend to basal medulla that produced hemiparesis [206]. Brain stem stroke cases suggested the region is located in the dorsolateral pons including the pontine reticular nucleus and the reticular formation, adjacent to the medial parabrachial nucleus and the locus ceruleus [207]. Yum et al. [208] analysed 30 brainstem infarction cases. They found LUTS in 70% of patients, comprising 46.7% storage disorder and 23.3% emptying disorder. In their series of patients, emptying disorder was more common in medullary lesion (55.6%) than pontine lesion (9.5%). Storage disorder was found only in pontine lesion (61.9%).

There are few reports on LUTD related to other brain areas. Cerebellar stroke has been reported to cause LUTD (detrusor overactivity) [209]. UI is seen in 13% (2/16) of right and 33% (10/30) of left anterior cerebral artery infarctions [210]. Sakakibara et al., however, did not see a clear relationship between stroke laterality and LUTS [195]. Similar findings were reported by others [211]. In contrast, Ersöz et al. [212] divided their post stroke patients with LUTD into infarction and haemorrhage. The infarction group had large bladder capacity (250.3 ml) and larger post-void residual urine volume (136.1 ml) than haemorrhage group (194.9 ml, 29.5 ml, respectively), indicating a more severe bladder dysfunction. Han et al. [213] found that the infarction group had more detrusor overactivity but less detrusor underactivity (70.7%, 29.3% respectively) than the haemorrhage group (34.65, 65.4% respectively).

Khan et al. [200, 201] demonstrated detrusor overactivity (DO) in 79% of 33 post stroke patients with LUT symptoms. None of them had detrusor-sphincter dyssynergia (DSD) on voiding. The mechanism of DO seems not to be uniform; certainly DO has been described in patients with different locations of lesions in CNS, but is also seen in patients without (obvious) neurological involvement. It is postulated that the micturition reflex is under tonic (mainly inhibitory) influences [214, 215] by the central cholinergic pathway [216] and the fronto-nigro-striatal, dopamine D1-GABAergic direct pathway [139]. Furthermore, it is postulated that in patients with brain lesions DO is an exaggerated spino-bulbo-spinal micturition reflex; PMC normally promotes micturition, and without inhibition, DO develops [141, 214, 215]. The exaggerated micturition reflex is abolished after chemical lesioning of the PMC in stroke rats.

Consequent urodynamic studies showed a more varied picture: in 19 poststroke UI patients Gelber et al. [217] reported DO in 37%, underactive detrusor in 21%, and detrusor-sphincter dyssynergia in 5%. In an urodynamic study of 27 symptomatic stroke patients [218] DO was seen in 40.7% and detrusor areflexia in 3.7%. Similarly, a study of 38 symptomatic stroke
men by Nitti et al. [219] showed DO in 82% and outlet obstruction in 63%. In 57 poststroke patients, Natsume [220] also found detrusor underactivity in 35% men and 43% women; and most of them had so-called detrusor hyperactivity with impaired contraction (DHIC). In contrast to the pathophysiology of DO, little is known about the pathophysiology of ‘brain shock’ and DHIC [100]. Within the brain, it is known that there are both micturition-inhibiting and micturition-promoting areas. The latter includes A10 ventral tegmental area (VTA)-mesolimbic dopaminergic pathway, D2-subthalamic indirect pathway, and the glutamatergic pontine micturition center (PMC) adjacent to the locus ceruleus and sacral cholinergic preganglionic cells [139]. These pathways might also be involved in many brain diseases affecting the frontal lobe. Gupta et al. [221] found DO in 90% and DSD in 27.5% in their 40 patients with post-stroke UI. Urodynamics in 11 symptomatic patients with brainstem lesions showed DO in 8 (73%), low compliance detrusor in 1 (9%), acontractile detrusor in 3 (27%), non-relaxing sphincter on voiding in 5 (45%) and uninhibited sphincter relaxation in 3 (27%). No statistically significant correlation could be demonstrated between any particular lesion site and urodynamic findings [222].

Early UI following a stroke is a specific indicator of poor prognosis. Wade and Langton-Hewer analysed the symptoms of 532 patients seen within seven days of their stroke and found that the presence of UI appeared to be a more powerful prognostic indicator for poor survival and eventual functional dependence than was a depressed level of consciousness [223]. Others have also reported that the outcome was better in those who remained or became dry [224, 225]. Rotar et al. [226] demonstrated post-stroke UI is a predictor of greater mortality not only at the end of the first week, but also at 6 months and 12 months after stroke.

Gelber et al. [217] found that post-stroke UI was associated with large infarcts, aphasia, cognitive impairment, and functional disability. Nyberg and Gustafson [227] noted a strong link between easy fall and UI. van Kuijk et al. [228] reported that among 143 post-stroke patients, activity of daily living (modified Barthel index) and discharge rate to their own home were negatively related with UI. Landi et al. [229] reported that among 355 poststroke patients, functional (mobility and activity of daily living) decline is related with UI. Pettersen and Wyller [230, 231], among 355 poststroke patients, noted a relation between UI and poor mobility. Paolucci et al. [232] and Daviet et al. [233] reported that, not only immobility and dementia, but also unilateral spatial neglect (mostly due to right hemispheric lesion) strongly correlates with UI after stroke. It seems likely that UI is a strong predicting factor for poor prognosis of stroke for a number of reasons: the same lesion might cause neurogenic bladder dysfunction (neurogenic UI), motor or cognitive impairment (functional UI), or both; falls, gait difficulty and cognitive decline are all marked in severe, bilateral brain lesions; finally UI may secondarily cause psychological depression and also generally interfere with rehabilitation and quality of life.

6.2. White matter lesions and urinary incontinence in the elderly

Urinary incontinence (UI) is a major concern in geriatric populations, which have grown rapidly in recent decades. In addition, the incidence of urinary frequency/urgency (OAB), with or without UI, is high in the general population over 40 years old and it increases significantly with age. It is widely acknowledged that urinary frequency and poor bladder control have a negative impact on the quality of life, that LUTD in elderly persons adds to their caregivers’ burden, and that LUTD is an important factor leading to institutionalization. The mechanisms underlying OAB and UI in the frail elderly are multi-factorial; the factors may include age-related changes in the bladder itself or central nervous system changes innervating the bladder.

Atherosclerosis and subsequent ischemia of the bladder occurs in patients with pelvic peripheral vascular disease. Atherosclerosis is a systemic condition which also affects cerebral arteries supplying the brain. Cerebral white matter disease (WMD) is a common chronic bilateral ischemic brain disease in the elderly. WMD progresses insidiously, and the likelihood of WMD increases significantly with age. It has been proposed that WMD is the pathoanatomical substrate in the brain aetiology of OAB. Thus, it is proposed that WMD leads to three different geriatric syndromes; vascular dementia, vascular parkinsonism, and ‘vascular incontinence’ [234].

In relation to the cerebral vascular component in vascular incontinence, Sakakibara and colleagues [235] investigated 63 subjects (mean age 73 years) with varying degrees of cerebral WMD or leukoaraiosis. Magnetic resonance imaging (MRI)-defined WMD was graded on a scale of 0 to 4. The prevalence of nighttime urinary frequency in cases of grade 1 WMD was 60%; grade 2, 58%; grade 3, 93%; and grade 4, 91%, respectively, giving an overall prevalence of nighttime urinary frequency of around 75%, which was a more common and earlier feature than UI (40%). Of particular importance was the fact that OAB was not always accompanied by gait disorder or dementia (Grade 1 of WMD), so that it appeared that OAB might be the first clinical manifestation of the observed WMD [236]. Detrusor overactivity (DO) is the major underlying urodynamic observation of vascular incontinence. The incidence of DO in WMD cases is reported as 70%–91% of patients. In Sakakibara’s study [235], urodynamic studies were performed in 33 of the subjects. They found that subjects with grade 1–4 WMD had DO significantly more commonly (82%) than those with grade 0 WMD (9%). Post-micturition residuals, low compliance, DSD and uninhibited sphincter relaxation were also more common in grade 1–4 WMD than in grade 0 WMD, though not significantly so.
Population-based MRI studies suggest that the incidence of moderate WMD (periventricular WMD grade >4/9 and subcortical white matter volume >1.5 mL) is approx. 10% (7.6%–24%) in the general population of individuals over 55 years of age. WMD can develop into three different geriatric syndromes: [1] vascular dementia; [2] vascular parkinsonism; and [3] ‘vascular incontinence’ [235, 236]. These three syndromes can present in any combination, but clinically, urinary and gait disorders are more prominent than dementia, and usually precede dementia.

Two studies have shown significant relationship between OAB/UI with WMD [236, 237]. Tadic and Griffiths [236] studied 25 older women (age 71.5 + −7.5 years) with urgency UI, and they reported that bladder responses to bladder filling during self-reported ‘urgency’ were most prominent in the frontal regions. Regional activations became more prominent with increased global WMD. Looking at the fiber tracts, the main effect activations and deactivations were superimposed with anterior thalamic radiation and superior longitudinal fasciculus. These results indicated that WMD, particularly the anterior portion, is clearly related to OAB in cognitively intact, elderly persons.

A survey was carried out to look at relationship between DO and higher brain function in 40 WMD patients with OAB (age 60–89 years) [43]. DO was independent of general cognitive status (the mean MMSE score or any of its subdomains). In contrast, the presence of DO was significantly associated with the inhibitory control subdomain in the FAB test. This finding is in agreement with the fact that brain perfusion is most severely reduced in the frontal lobe of subjects with WMD [238]. What exactly this finding means is a matter of debate. One explanation might be that the bladder is under general inhibitory control concerning decision-making [239] and emotion [240] by the prefrontal cortex. In patients with WMD, this neural network might be impaired, leading to both frontal cortex-related behaviour changes and DO.

Both age-related WMD (also called vascular dementia) and Alzheimer’s disease (AD) are common causes of elderly dementia, and are known to be independent risks for OAB/UI. A survey was carried out among 49 mild/moderate dementia patients irrespective of OAB (mean age, 76 years), including AD alone in 9, AD+WMD in 15, and WMD alone in 25 [241]. OAB was most common in WMD alone. Therefore, WMD is a more significant contributor to OAB and UI than AD in elderly dementia patients. It should be mentioned that in WMD, LUTD occurs independently of dementia. The pathological mechanisms for LUTD in AD and WMD remain obscure. However, a single-photon emission computed tomography (SPECT) study showed that frontal hypoperfusion is common in WMD, whereas parietal-temporal hypoperfusion is common in AD [238]. This is in accordance with the finding that in AD, dementia is the predominating symptom, and early UI is extremely rare [242].

6.3. Management of LUTD in stroke patients

An approach for the care of patients with LUTD in brain diseases is applied as a general LUTD treatment regimen, which should depend on the pathophysiology and be individualized. As discussed above, UI in brain diseases can be divided into two types: neurogenic UI (OAB wet) and functional UI (immobility and loss of initiative/cognition). These two types of UI may occur together. However, management of two types of UI differs significantly. Management of neurogenic UI includes anticholinergic drugs to treat bladder directly, and management of functional UI includes behavioural therapy (timed/prompted voiding with physical assistance; bladder/pelvic floor training) and drugs to treat gait (Parkinson’s disease drugs) as well as cognition (Alzheimer’s disease drugs) that further facilitate continence.

In 2005, Thomas et al. [198] undertook meta-analysis of interventions aimed at reducing the occurrence of post-stroke UI. Seven trials with a total of 399 participants were included. Four trials tested an intervention against usual care, including acupuncture, timed voiding, and two types of specialist professional intervention. One cross-over trial tested an intervention (oestrogen) against placebo. One trial tested a combined intervention (sensory-motor biofeedback plus timed voiding) against a single component intervention (timed voiding alone). One trial tested a specific intervention (oxybutynin) against another intervention (timed voiding). The interpretation was that there was insufficient data. A review of behavioural therapies for post-stroke UI was done by Dumoulin et al. [243]. Tibæk et al. [244] reported on effectiveness of pelvic muscle training in 24 women with post-stroke UI (irrespective of type of UI) with a randomized, controlled and blinded study.

In contrast to the intervention of functional UI (due to immobility and loss of initiative/cognition), drug trials for OAB wet in patients with brain diseases are scarce. Propiverine, an anticholinergic, has been used to treat idiopathic as well as neurogenic DO including brain diseases [245]. Sakakibara et al. [246] used an anticholinergic drug imidafenacin in 62 OAB patients following brain diseases, including 29 with WMD. They found an improvement of OAB after 0.2 mg/day imidafenacin, without cognitive decline. Another study used tolerodine in 13 OAB patients following brain diseases, including five with WMD. They showed an improvement of OAB with 4mg/ day tolerodine [247]. The addition of propiverine (a peripheral anticholinergic) to donepezil (a central acetylcholinesterase inhibitor) ameliorates OAB without worsening cognitive function in elderly OAB patients with dementia [248]. Mirabegron, a novel selective adrenergic beta-3 receptor agonist, seems to be promising for lessening DO, with fewer central side effects [249].

For ameliorating post-stroke UI, alternative/ complementary therapies have also been studied. Electro-
applied to post stroke UI. Kuo [252] applied 200U suburothelial injection of botulinum-A toxin in 24 patients with DO due to stroke in 12 and suprasacral spinal cord diseases in 12. He found 91.6% achievement of continence in spinal cord diseases but 50% achievement in stroke. Newer modalities such as botulinum toxin have been applied to post stroke UI. Kuo [252] applied 200U suburothelial injection of botulinum-A toxin in 24 patients with DO due to stroke in 12 and suprasacral spinal cord diseases in 12. He found 91.6% achievement of continence in spinal cord diseases but 50% achievement in stroke.

Transcranial magnetic stimulation at the motor area or the prefrontal cortex was able to lessen DO in multiple sclerosis [253] and Parkinson’s disease [254]. In stroke, no similar studies are available.

Conclusions

- Incidence of lower urinary tract dysfunction (LUTD) in stroke patients ranges from 14-53%, principally due to overactive bladder (OAB), being higher when involving the frontal cortex (LOE3).
- White matter disease (WMD) is a chronic, bilateral form of cerebrovascular disease, leading to the high prevalence of OAB (LOE3).
- Since WMD is common particularly in elderly, WMD might be one of anatomical substrates for elderly OAB. (LOE4)
- Neuroimaging studies have shown relationship between LUTD and the frontal cortex in stroke and WMD that regulate the micturition reflex.
- Data on other brain diseases, particularly affecting deep brain structures, are limited. A small infarct affecting the brainstem leads to either OAB or urinary retention. (LOE4)
- Neuroimaging studies have shown relationship between LUTD and the periaqueductal gray and the pontine micturition center that directly relay and modulate the micturition reflex.
- Urinary incontinence (UI) in stroke/WMD can be divided into two types: neurogenic UI (OAB wet) and functional UI (immobility and loss of initiative/cognition). These two types of UI may occur together, but management differs substantially. (LOE3).
- Management of neurogenic UI/OAB includes anticholinergic drugs that do not penetrate the blood-brain barrier easily or beta 3 adrenergic agonists (LOE3).
- Management of functional UI includes behavioural therapy (timed/prompted voiding with physical assistance; bladder/pelvic floor training) and drugs to treat gait as well as cognition that facilitate continence (LOE4), in order to maximize the quality of life in stroke patients.

### Recommendations

- Urinary incontinence (UI) in stroke/WMD should be divided into two types: neurogenic UI (OAB wet) and functional UI (immobility and loss of initiative/cognition) (A).
- Neurogenic UI/OAB needs anticholinergic drugs that do not penetrate the blood-brain barrier easily. (B).
- Functional UI needs behavioural therapy (A).

#### 7. MENINGITIS-RETENTION SYNDROME

Meningitis retention syndrome (MRS) is one of the diseases that could cause a relatively uncommon urinary retention in childhood, young adults, and in women [255]. Spina bifida occulta/ tethered cord syndrome is one such disorder known to lead to urinary retention without marked neurological abnormalities, except for saddle anaesthesia. Fowler’s syndrome is another disorder that causes urinary retention, particularly in neurologically-intact young women, and isolated urethral sphincter hypertonicity underlies this condition. Benign inflammatory nervous diseases also cause acute urinary retention, in which patients lack apparent urethral outlet obstruction, but exhibit only minor neurological as well as cerebrospinal fluid (CSF) abnormalities. Based on the mechanism of urinary retention, these disorders can be divided into two subgroups: disorder of the peripheral nervous system (PNS) (e.g. sacral herpes, with unilateral sacral pain, sensory signs and often skin rashes in the same area); and disorder of the central nervous system (CNS) (e.g. meningitis-retention syndrome), with fever, headache, stiff neck, and minor pyramidal signs). Previously the latter condition has been only occasionally reported, but now it is recognized as a specific category [256, 257], which is considered to be a very mild form of acute disseminated encephalomyelopathy (ADEM). True prevalence of MRS has not been fully investigated due to the rarity of the condition.

It is postulated that ADEM appears after vaccination or after exanthematous infections, and serological and pathological studies have suggested that ADEM is of parainfectious/ autoimmune origin [258]. Antecedent/ comorbid infections are diverse, e.g. human herpes virus 6 [259]. A combination of signs of encephalitis (e.g. disturbance of consciousness, epilepsy, and hemiparesis), signs of myelitis (e.g., sensory disturbance below the level of the lesion, spastic paraplegia, whereby flaccid paraplegia may occur in the initial shock stage), and lower urinary tract (LUT) / bowel dysfunction typically occur in patients with ADEM. Lesions observed in brain MRI are usually confined to the white matter. Lesions in the spinal
cord involving the conus are also seen. CSF pleocytosis, increased protein, mildly decreased glucose content, increased myelin basic protein (MBP)/oligoclonal bands, and a lack of increased viral titres, are all features of this disease.

Patients with ADEM commonly exhibit LUT dysfunction [260, 261], which varies from urinary retention to urgency incontinence. LUT dysfunction appears to be related to pyramidal tract involvement, and most probably reflects the severity of the spinal cord lesion. Urodynamic findings have included detrusor overactivity in the storage phase, brisk bulbocavernous reflex, and DSD (reflective of a suprasacral spinal cord lesion); detrusor areflexia in the voiding phase (reflective of either acute spinal shock or conus lesion); and neurogenic sphincter EMG in one of four patients studied (reflective of a conus lesion). The responsible lesion sites in cases of LUT dysfunction have appeared to be the cervico-thoracic spinal cord, and, to a lesser extent, the conus [262] and possibly the spinal nerve roots in patients with ADEM. In addition, cases of ADEM presented with LUT dysfunction as the only remaining consequence of the disease, thus suggesting that LUT innervation was selectively vulnerable in these cases. It is also reported that cases of ADEM/parainfectious myelitis initially presented with urinary retention [263] or leaves urinary retention as the sole sequel [264].

Although aseptic meningitis is a common neurological disorder, a combination of aseptic meningitis and acute urinary retention (MRS) has not been previously well recognized. The clinical manifestations of Sakakibara’s three cases [256] are mostly the same as those of the six reported cases in the literature (including cases written in Japanese). The clinical manifestations of MRS cases differ markedly from those of the six reported cases in the literature (in particular, four of the patients had apparent muscle atrophy/weakness in the lumbo-sacral segment); Wallerian degeneration of the spinal afferent axons in ADEM, antecedent/comorbid infections or conditions with MRS include angiostrongylus cantonensis [266], Epstein Barr virus [267], and herbal medicine use [268], whereas such antecedent influences are not apparent in the remaining cases [269].

Urodynamic study results have shown that all patients examined had detrusor areflexia, which results in an inability to contract the bladder on voiding, and some patients had an unrelaxing sphincter. Detrusor areflexia originates from various lesion sites along the neural axis; most commonly, peripheral lesions are observed. However, CNS lesions that affect the spinal cord or the brain can also cause detrusor areflexia, which is particularly seen in the acute shock phase of patients with transverse myelitis (often immune-mediated) or ADEM. A case report described repeated urodynamic studies in one patient, in which an initially areflexic detrusor became overactive after a 4-month period, suggesting an upper motor neuron bladder dysfunction [270]. As described above, encephalitic features are absent in patients with MRS. However, three MRS patients (including Sakakibara’s cases 1 and 3) showed the brisk lower extremity reflexes suggestive of mild myelitis. In one of Sakakibara’s cases, MBP was increased, which is suggestive of CNS demyelination. Therefore, it appears possible that MRS is a very mild variant of ADEM, which selectively affects LUT innervation.

Arriving at a diagnosis is easy when a combination of aseptic meningitis and acute urinary retention is confirmed, although such a diagnosis should be made both urologically and neurologically, in order to exclude sacral herpes, a benign variant of Guillain-Barre syndrome (inflammatory radiculitis), typical ADEM, myelitis with leg weakness [271], herpetic brainstem encephalitis, chemical meningitis, focal subarachnoid bleeding, and other common causes of neurogenic urinary retention (e.g., diabetic neuropathy, lumbar spondylitis, etc.). For the differential diagnosis, detailed history, brain/spinal MRI and nerve conduction study are necessary.

The term “Elsberg syndrome” has been occasionally used, which is rather vaguely assigned to sacral myeloradiculitis of undetermined aetiology, sacral herpes, sacral vasculitic neuropathy, possible MRS, possible ADEM, or conus infarction. However, in contrast to the majority of “Elsberg syndrome” cases, Kennedy, Elsberg, and Lambert (1913) reported five cases of pathology-demonstrated cauda equina radiculitis. Clinical pictures of these cases were characterized by rare CSF abnormalities (only one of the four cases described showed an increased cell count as well as increased protein levels); no clinical meningitis; subacute/chronic course (in one case the course of disease was subacute: 3 months, but in the remaining four cases, the course of disease was chronic: 4.5-36 months); the patients presented with typical cauda equina motor-sensory-autonomic syndrome (in particular, four of the patients had apparent muscle atrophy/weakness in the lumbar-sacral segment); Wallerian degeneration of the spinal afferent axons; and finally, spinal cord involvement of the conus was also seen.
tracts; and mild upper motor neuron signs. The authors assumed that the aetiology of these cases was either inflammatory or toxic. The exact cause of these five cases remains uncertain, although clinical pictures of these cases resemble, at least in part, those of paraneoplastic or autoimmune lumbosacral radiculoplexus neuropathy [272]. Clinical features of sacral herpes or MRS differ markedly from those of Kennedy’s cases.

7.2. Disease specific management

Since MRS has a benign and self-remitting course (i.e., a duration of 2-10 weeks), the effectiveness of immune treatments (e.g., steroid pulse therapy) remains unclear, although such treatments may shorten the duration of the disease. Management of the acute urinary retention is necessary to avoid bladder injury due to overdistension (LOE4).

Since MRS is rare, true prevalence has not been fully investigated and evaluation of this is warranted in future research. Similarly, in order to shorten the urinary retention period, the effectiveness of immune treatments (e.g. steroid pulse therapy) in MRS remains unclear, and future research is desirable.

Conclusions

- Meningitis-retention syndrome, with fever, headache, stiff neck, and minor pyramidal signs, is thought to be a very mild form of acute disseminated encephalomyelopathy (ADEM) encountered by both urologists and neurologists (LOE 2)
- Initially the bladder is areflexic, but soon becomes normal or overactive during the course of the disorder. (LOE 2)

Recommendation

- Management of the acute urinary retention is necessary to avoid bladder injury due to overdistension in patients with MRS (B)

8. ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)

Acute disseminated encephalomyelitis (ADEM), also known as post-infectious encephalomyelitis, is a demyelinating central nervous system (CNS) disorder that usually follows infection, or more rarely vaccination [273]. ADEM can be confused for MS; indeed, the early symptoms of ADEM are similar to an acute relapse of MS. Presence of constitutional symptoms such as fever and headache, and the simultaneous involvement of various parts of the CNS may help differentiate this condition from MS. However, it can be difficult to distinguish the two, and the only sure way is follow up and the observation of any relapses over time.

ADEM is a disease that is characterized by an inflammatory reaction and demyelination in the brain and spinal cord. In contrast to MS, there is a tendency for perivenous localization of pathological changes [274]. Bladder dysfunction is common in ADEM. In a consecutive series of sixty one patients with ADEM, 20 (33%) had evidence of LUTD [261].

Lesions in the cerebral and spinal cord white matter result in LUTD. Both voiding and storage symptoms are reported in ADEM, however the pattern of bladder dysfunction depends upon the time point at which they are assessed. In the acute stage, Panicker et al. reported that voiding dysfunction is more common; in their series of 20 patients, 16 were in urinary retention [261]. Urodynamics demonstrated detrusor overactivity in four patients and underactivity in four patients. Incontinence was reported more often in patients with frontoparietal white matter changes in MR imaging (LOE 3/4). In the series of Sakakibara et al., patients were followed up for 3 to 38 months, and seven of nine patients with retention were able to pass urine once again, five had difficulty in voiding and four developed urinary frequency or urgency incontinence. Motor unit analysis of the external sphincter revealed polyphasic neurogenic changes in only one of four patients. They also observed that bladder disturbances in ADEM seemed to be as common and severe as in MS [260] (LOE 3/4). LUTD is common especially in patients with lower limb pyramidal involvement [261].

Management of LUTS is essentially supportive. Patients complaining of LUTS should have their post-void residual checked regularly during the progressive phase of ADEM. If retaining urine, an indwelling catheter may be preferable during the acute phase. The need for catheterisation should be reviewed regularly as voiding dysfunction often recovers. If suitable, IC could be considered. Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic medication, once it is confirmed they are not retaining urine.

For future research, there are currently only limited studies evaluating the natural history of LUTD in ADEM and patients should be followed up to assess lower and upper urinary tract changes with time. There is a dearth of information about the role of botulinum toxin or sacral neuromodulation in this condition.

Conclusions

- In the acute phase of ADEM, LUTS may be seen in a third of patients (LOE3/4).
- Both voiding and storage dysfunction are observed in ADEM (LOE3/4).
- Recovery of LUT functions occurs, along with the recovery of motor weakness (LOE3/4).
Recommendations

- Patients with ADEM and bladder symptoms should be managed according to their symptoms, and the findings on urodynamic tests, particularly post-void residual (C).
- LUTS can change as the disease stabilises; re-evaluation during follow-up is therefore recommended (C).
- Patients with overactive bladder symptoms are likely to benefit from antimuscarinic pharmacotherapy, once they are shown not to be retaining urine.

9. SPINAL CANAL STENOSIS

It is not uncommon to develop pelvic floor dysfunction including urinary symptoms in patients with spinal canal stenosis (SCS). It is thought about half of the patients with intractable leg pain in spinal canal stenosis will have urinary difficulty with high post-void residual (PVR) and reduced flow rate and/or incontinence indicating effects on the cauda equina. Such symptoms, including urinary incontinence usually improve after surgical decompression.

One third of patients with achondroplasia developed SCS [275], especially at the lumbar level, and 77% of these had urinary incontinence. According to Johnsson and Sass [276] in the County of South Jutland, Denmark during a 5-year period (1996-2000), the annual incidence of SCS was 272 per million inhabitants. Of 340 cases diagnosed with SCS during that period, only one patient presented with acute cauda equina syndrome. This was a 74-year-old woman with SCS from L2 to L4, who presented with urinary retention and faecal incontinence (FI) for the preceding 24 hours; after urgent surgery she recovered from her anal sphincter paresis within 5 days and from her bladder paresis within 5 weeks.

Goh and colleagues [277] carried out a comprehensive retrospective review of the clinical features, radiological changes and outcome of 75 patients with radiologically diagnosed lumbar SCS; imaging of the lumbar spine showed that moderate to severe central spinal stenosis correlated with complaints of weakness and abnormal motor power on clinical examination. The commonest symptom was numbness or tingling of the legs. According to the study of Inui[4] 58.8% of the 34 patients were diagnosed with neuropathic bladder; however there was no difference in the cross-sectional area of dural sac between those with and without neurogenic bladder dysfunction in patients with lumbar SCS. Nonetheless, the anteroposterior diameter of the dura was shorter in those with bladder dysfunction, and a critical size for the dural sac of patients was reported as 8 mm.

Usually signs and symptoms of compressive neuropathy of multiple lumbar and sacral roots is an indication for surgical intervention, but relatively unknown as a post-operative complication [278]. Four years after diagnosis, 65% had undergone surgical decompression; a third of patients felt that their symptoms had improved while a quarter felt that they had worsened. Imran and Halim [279] reported a 63-year-old man who developed acute cauda equina syndrome due to fat graft compression after decompressive laminectomy, posterior instrumented fusion with pedicle screw fixation for spinal stenosis of L5 and S1 vertebral levels and free fat grafting to cover the exposed dura; three days postoperatively, gradual neurological deficit started with sensory loss and weakness of the affected dermatomes and myotomes followed by FI on the 12th postoperative day; and immediate removal of the fat graft resulted in recovery from cauda equina syndrome. Another case was reported by Tubbs [280]; a Caucasian girl who had idiopathic growth hormone deficiency and Klippel-Feil and Duane’s syndromes with symptomatic stenosis of the first cervical vertebrae presented with episodes of loss of tone with subsequent falling, facial cyanosis, UI, hand weakness, and difficulties with swallowing; following suboccipital craniectomy and the removal of the posterior arch of the atlas, her symptoms were resolved and UI improved.

9.1. Disease specific diagnosis

To demonstrate narrowing of the lumbar canal with compression of the cauda equina, CT or MRI is often recommended, to reveal either bony or soft tissue compression [281]. Miyata and colleagues [282] studied the relationship between bladder function and roentgenographic changes in the spinal canals of ossification of posterior longitudinal ligament (OPLL) patients. CO₂-filling cystometry, uroflowmetry and PVR were measured and the vertical extent of OPLL and the degree of SCS was estimated by X-ray films and CT. The occurrence of abnormal detrusor activity had no relationship to the degree of canal stenosis, while the occurrence of an areflexic or underactive detrusor correlated with the vertical extent of OPLL. Yamanishi et al. [283] found DO in 14 lumbar canal stenosis patients (29%) and most of them had voiding symptoms and had storage symptoms which seemed to be caused by the irritation of sacral roots.

9.2. Disease specific management

Of 10 patients followed up after surgical decompression, DO disappeared in 5 patients, improved in 1 patient and remained unchanged in 4 patients [283]. Lee and colleagues [284] did an expansive cervical laminoplasty in patients with non-traumatic cervical spondylolisthesis with myelopathy and found that age greater than 80 years at the time of presentation, duration of symptoms more than 18 months prior to surgery, preoperative bowel or bladder dysfunction, and lower-extremity dysfunction were associated with poorer surgical outcome.
There can be some confusion related to this syndrome. An anatomical discrepancy lies in the fact that the vertebrae and the nerve roots do not correspond all the way down to sacrum. The spinal cord terminates at the level of L1 vertebrae and there is thick column of nerves below this level resembling a horse tail, hence the term “cauda equina” has been coined to describe this arrangement. Damage to these nerve roots produces a characteristic pattern of symptoms called the cauda equina syndrome, which can entail pelvic floor dysfunction in all 3 compartments (including bladder, bowel, sexual abnormalities).

Central lumbar disc prolapse compresses sacral nerve fibers to and from the bladder, the large bowel, the anal and urethral sphincters, and the pelvic floor. Cauda equina syndrome due to central lumbar disc prolapse is relatively rare, the incidence being from 1 to 5% of all prolapsed lumbar disc [285-287]. An annual incidence of 3.4 per million and a prevalence of 8.9 per 100,000 population has been reported. It has been suggested that damage to cauda equina is more common in middle aged men whilst in younger patients it was the conus lesion that was more prevalent [288].

The common causes of cauda equina syndrome are summarised in Table 15 (below). It is thought that spinal fracture in young men, disc herniations in middle aged and spinal operations in elderly are the main factors leading to cauda equina syndrome (CES) [288].

### Conclusions

- Patients with spinal stenosis, especially at lumbar levels, may present with bladder and bowel involvement – urinary retention/ incontinence and faecal incontinence (LOE 3/4)
- Lumbar canal stenosis may cause either detrusor underactivity/acontractility or overactivity (LOE 3)
- Imaging helps diagnose spinal stenosis, while urodynamic study categorises neurogenic bladder dysfunction (LOE 3/4)
- Acute symptoms of incontinence or urinary retention may recover after decompression of spinal stenosis (LOE 3/4)

### Recommendations

- Surgical decompression is recommended in patients with spinal stenosis having acute symptoms of urinary retention/incontinence and faecal incontinence (A)

### 10. CAUDA EQUINA SYNDROME

There can be a diverse presentation of CES. This includes low-back pain, bilateral sciatica, saddle anaesthesia, and urinary retention, loss of urethral sensation as well as constipation and erectile dysfunction [286, 289]. Those patients with cauda equina syndrome usually have some sensory disturbance in the sacral dermatomes. A retrospective cohort study with prospective clinical follow-up showed that bowel dysfunction at presentation was associated with sexual problems at follow-up [290].

The most common urinary symptom associated with lumbar disc prolapse is acute urinary retention [291]. At the onset, acontractile detrusor with impaired bladder sensation is a typical urodynamic finding [291, 292]. Severe denervation of pelvic floor [291] and external urethral sphincter is also frequently demonstrated. Detrusor overactivity may occur [283, 291]. Urinary disorders usually follow or accompany more obvious neurologic symptoms, such as lumbar pain and perineal sensory disturbances that prompt the appropriate diagnosis. However, sometimes voiding disturbances may be the only or the first symptom of this condition, which makes it more difficult to diagnose. There can be associated bowel disturbances that might be either constipation or faecal incontinence [288].

The presence of sexual dysfunction can be particularly disabling. There is impairment of sexual sensations and this is associated with erectile dysfunction. However, a combination of these two leads to orgasmic dysfunction which becomes the most bothersome symptom in this group of patients [293].

### 10.2 Disease specific diagnosis

There should be a high index of suspicion in patients who present with the features described above. The presentation can be either in an acute or chronic setting. The acute symptoms manifest generally after disc herniation or post surgery. The classical presentation includes severe sudden bilateral back pain radiating down both lower limbs with numbness and tingling in saddle region and loss of bladder function. However, only a fifth of patients present with these

### 10.1 Pathology and disease specific LUT problems

There can be a diverse presentation of CES. This includes low-back pain, bilateral sciatica, saddle anaesthesia, and urinary retention, loss of urethral sensation as well as constipation and erectile dysfunction [286, 289]. Those patients with cauda equina syndrome usually have some sensory disturbance in the sacral dermatomes. A retrospective cohort study with prospective clinical follow-up showed that bowel dysfunction at presentation was associated with sexual problems at follow-up [290].
classical symptoms [294], as in the majority low back pain, sacral sensory loss and some urinary symptoms are more prevalent. Similar to acute presentation, the symptoms are the same in chronic presentation, though the onset is more insidious.

All patients should undergo a detailed neuro-urologic examination. This includes assessment of sensory, motor and reflexes of lower limbs and anal reflexes [288, 295]. There should be an assessment of post void residual. An urgent MRI assessment is recommended in all patients who present with new onset urinary symptoms concomitantly with lumbar back pain or sciatica, because it is impossible in a significant proportion of patients to exclude the diagnosis of prolapsed intervertebral disc in the context of referral with suspected cauda equina syndrome.

In chronic setting the same investigations are required, though probably not with the same urgency. There might be a need to undertake electrophysiological studies to confirm the diagnosis. Additionally urodynamics and anal manometry might be required to establish the bladder and bowel dysfunction respectively [296].

10.3. Disease specific management

Emergency surgical decompression has been reported to increase the chance of satisfactory neurological recovery in patients with cauda equina syndrome due to central lumbar disc prolapse [297-299]. In a meta-analysis of surgical outcomes, a significant improvement in sensory and motor deficits as well as urinary and rectal function occurred in patients who underwent the surgery within 48 hours, compared with those who had the surgery more than 48 hours after the onset of the cauda equina syndrome [299]. Although there is still a controversy [290], most other reports support the concept that decompression performed within 48 hours of onset of this syndrome resulted in improved functional outcomes [287, 300]. However, acontractile detrusor is usually irreversible, even after immediate decompression [301, 302], although many patients can empty their bladder postoperatively, this may achieved only by straining or changing voiding postures [302]. In contrast to bladder dysfunction, urethral function shows a better recovery after surgery [303].

The management of pelvic floor dysfunction in an established CES patient requires careful support. The patient needs to start self-catheterization if there is significant residual urine. The patient should be encouraged to relax to pass urine and avoid straining. They need to be monitored with urodynamics owing to the unpredictable nature of recovery [304]. Similar to bladder, the bowel management needs to be optimised according to the individual patient dysfunction. The constipation is relatively easier to control compared to faecal incontinence [296]. The erectile dysfunction can be treated with oral medications but there is no specific treatment available for sensory impairment.

The patients could be put in touch with support groups like www.caudaequina.org

10.4. Research for Cauda Equina Syndrome

For future research, good epidemiological studies on the occurrence of pelvic floor dysfunction are needed. This is increasingly relevant with the advent of new, minimally invasive treatment options for disc prolapse.

Conclusions

- Cauda equina syndrome is a relatively rare complication of lumbar disc prolapse (LOE 3)
- Bladder and bowel manifestations of lumbar disc prolapse include: urinary retention, loss of sensory functions, decreased sexual functions (LOE 3)

Recommendations

- Emergency surgical decompression is the treatment of choice: the optimum timing is considered to be within 48 hours (Grade B/C)
- Full recovery of lower urinary tract functions, including bladder contractility, is unreliable (Grade C)

11. TRANSVERSE MYELITIS

This is a clinical syndrome characterized by an immune mediated process leading to neural injury in the spinal cord. There can be a varied presentation with weakness, sensor alterations and autonomic dysfunction. It can also present as part of a multifocal disease of nervous system. Transverse Myelitis (TM) is reported to have an incidence of 1-4 new cases per million, with bimodal peaks between the ages of 10 and 19 years and 30 and 39 years. There is no sex or familial predisposition.

TM is commonly parainfectious. It can occur in connective tissue diseases, infective myelitis, and idiopathic inflammatory demyelinating disorders including MS. It is thought that only true spinal inflammatory processes should be designated myelitis. Myelitis may selectively affect different parts of the nervous system. The inflammatory distribution is termed poliomyelitis when it is confined to the gray matter and leukomyelitis if it affects the white matter. When the entire thickness of the spinal cord is involved, it is called TM. TM can clinically be divided into acute or subacute depending upon the speed of onset of symptoms and signs. These can affect any of the motor, sensory or autonomic nerves. As a general rule there is well defined upper border of sensory impairment.
Lumbar puncture and spinal MRI will usually show signs of acute inflammation. At the height of inflammatory condition about half of patients lose all movements of their legs with almost all having bladder dysfunction. The bladder symptoms are generally a combination of storage and voiding with urgency, difficulty to empty. Additionally, there can be associated bowel dysfunction. The Transverse Myelitis Consortium Working Group has proposed diagnostic criteria looking at motor, sensory, and autonomic dysfunction [305]. The diagnostic criteria include presence of symptoms attributable to spinal cord inflammation, a defined sensory level, and presence of immunoglobulin G with progression to nadir between 4 hours and 21 days. They also proposed a set of exclusion criteria including a history of previous radiation, and abnormal arterial flow patterns of imaging suggestive of another neurologic disease.

TM can present with a diverse array of clinical neurological manifestations. Bladder dysfunction is common and may be the only consequence of TM. Ganesan and Borzyskowski [306] described urinary tract dysfunction after TM in 10 children, with ages ranging from 8 months to 16 years. Nine of 10 children had voiding symptoms and all developed storage symptoms within a month of presentation. Videourodynamic showed a combination of detrusor overactivity and detrusor sphincter dyssynergia (DSD) in most patients. With a median follow-up of 36 months, all had residual bladder dysfunction, with only four being asymptomatic. The degree of bladder recovery was not related to the motor recovery.

In another study Cheng et al. [307] reviewed the long-term urological outcome of 5 children with TM over 15 years. The median length of follow-up was 5 years (2–10 years). Four children recovered completely from paresis; two had no urinary symptoms with normal voiding. However, follow-up urodynamics 3 years later revealed that four out of the five children, including one without any urinary symptom, had residual bladder dysfunction.

Leroy-Malherbe and colleagues [308] studied 21 children at the mean age of 8 years. Bladder dysfunction was present in 85% at presentation. Complete regressive course was noted in 38% of patients, minor sequelae in 39%, and major sequelae after 6 months in 23%. No upper tract deterioration was noted after 3 years. Factors of favourable prognosis were early motor function recovery and early management of bladder dysfunction.

Kalita et al. [309] evaluated voiding abnormalities in TM and correlated these with evoked potentials, MRI, and urodynamic findings. Patients with TM had a neurological examination and tibial somatosensory evoked potential (SSEP) and motor evoked potential studies in the lower limbs. Urodynamic studies showed an acontractile or hypocontractile bladder in 10, detrusor overactivity with poor compliance in two, and DSD in three. Persistent abnormalities included detrusor overactivity, dysynergia, and acontractile bladder. The urodynamic abnormalities correlated with muscle tone and reflex changes but not with sensory or motor evoked potentials or MRI signal changes.

Sakakibara et al. [310] reported 10 patients with TM. Seven patients had urinary retention and three patients had voiding difficulties within 1 month after the onset of the disease. At 40 months of mean follow-up 9 still had mixed urinary symptoms.

Berger et al. [311] found abnormal detrusor function in all six patients with TM. Computerized tomography scans and myelograms were inconclusive and CSF studies were normal. On recovery the functional outcomes were uniformly good. Bladder abnormalities persisted despite motor recovery. Urodynamic studies revealed DSD in six patients with 2 revealing detrusor overactivity. Sexual dysfunction was reported by 3 men. The authors concluded that prolonged bladder and sexual dysfunction may persist despite a systemic neurological recovery. They recommend urodynamics for initial and follow-up management.

The clinical manifestations of TM is described as a dysfunction of motor, sensory, and autonomic pathways [312]. At maximum deficit, 50% of patients had completely paraplegia with almost all having some degree of bladder dysfunction.

11.1. Treatment of bladder dysfunction in TM

The management of bladder dysfunction is tailored to the abnormality present. The detrusor overactivity and DSD is treated with a combination of antimuscarinics and self catheterization. Persistent overactivity can be controlled with Botulinum toxin A. Monitoring should be undertaken with urodynamics and the management adjusted accordingly.

In longitudinal case series, broadly one-third of patients recovered with little or no long-term sequelae, one-third are left with moderate degree of permanent disability, and one-third has severe disabilities. The predictor of poor outcome is thought to be rapid progression of symptoms, back pain and spinal shock. In a follow-up study Bourre [313, 314] reported on 85 cases to evaluate the rate of conversion to MS as well as predictive factors of long-term disability during a mean follow-up of 8.7 years. They confirmed that presence of oligoclonal bands in the CSF and brain MRI abnormalities increases the risk for conversion to MS. Long-term follow-up of urological function is recommended for all patients with TM.

Conclusions

• Transverse myelitis is an immune mediated process leading to neural injury in spinal cord

• There can be a varied presentation, with weakness, sensor alterations and autonomic dysfunction (LOE 2). It can also present as part of a multifocal disease of nervous system (LOE 2)
Autonomic dysfunction is a frequently overlooked complication. Cardiovascular autonomic dysfunction is recognized in up to 60% of GBS patients [317]. However, bladder and bowel dysfunction occurs much less often. Indeed, the presence of bladder or bowel symptoms at the onset of disease, or their persistence, casts doubt on the diagnosis, so that other conditions, such as spinal cord disease, need to be excluded. During the acute phase, it is often difficult to assess LUTD specifically due to neurological dysfunction. Patients are often catheterized as part of their general nursing care to monitor water balance or maintain hygiene [316]. Furthermore, patients may be on medications such as opiates and tricyclic antidepressants, which in themselves can affect bladder and bowel functions. In the largest study to date, Sakakibara et al. [318] studied 65 patients with definite GBS (meeting clinical and neurophysiological criteria) and LUTD was observed in 27.7% (LOE3/4). This figure is similar to that quoted by Guillain and others in the early papers [319]. The condition is characteristically a symmetrical radiculo-neuropathy predominantly due to demyelination (Acute Inflammatory De-myelinating Polyradiculoneuropathy, AIDP), but also there are subtypes where axonal damage prevails (Acute Motor Axonal Neuropathy, AMAN). There is a dearth of systematic studies evaluating LUTD in GBS. In a few reports [320, 321], detrusor areflexia and disturbed bladder sensation were the common findings, and a non-relaxing urethral sphincter was also seen (LOE3/4). In the study by Sakakibara et al. [318], patients most commonly reported voiding symptoms in 24.6%, including urinary retention in 9.2%. Storage symptoms were noted in 7.7%, urinary urgency in 7.7%. None of the patients in this study became incontinent. Urinary dysfunction was more common in AIDP (39%) than AMAN (19%), although the prevalence of urinary retention was almost the same (ADIP, 7%; AMAN, 11%). Factors that were associated with bladder symptoms included age, severity of motor weakness (Hughes motor grade) and concurrent bowel dysfunction. When patients were followed up, improvement in bladder symptoms paralleled improvement in motor weakness. Interestingly, there was no correlation between the presence of cardiovascular autonomic dysfunction and bladder dysfunction.

Urodynamic studies performed within eight weeks of disease (n=9) showed variable results, demonstrating detrusor underactivity (n=2), DO (n=3), both DO and underactivity (n=5) and non relaxing urethral sphincter (n=2). Three patients had an elevated post void residual and one patient had reduced bladder sensations [318] (LOE3/4). Their results were similar to the urodynamic findings from Gabavac et al. [321](LOE3/4).

Urinary dysfunction in patients with GBS tends to appear after the onset of motor weakness. However, in two patients with axonal GBS, it was reported that voiding difficulty and motor weakness appeared almost simultaneously [322, 323] (LOE3/4). A close relationship between severity of GBS and bladder dysfunction has been reported (LOE3/4). Lichtenefeld [324] (LOE3/4) has reported urinary retention in one-third of patients requiring ventilator assistance. Even though up to 11% of GBS patients may develop urinary retention at the peak of motor weakness, it will

12. NEUROPATHIES AND MUSCLE DISORDERS

12.1. Guillain Barre syndrome

Since the eradication of poliomyelitis, Guillain-Barré syndrome (GBS) has become the most common cause for acute, flaccid paralytic disease in many parts of the world [315]. It presents as a rapidly progressing ascending areflexic motor paralysis, with or without sensory and autonomic dysfunction. Following an initial acute progressive phase, which by definition reaches a nadir within four weeks, there is a plateau phase and finally a recovery phase. Symmetrical limb weakness is the common presentation, however there may be in addition cranial nerve and respiratory muscle weakness. The disorder affects children and adults of all ages and both sexes. GBS is amenable to treatment with intravenous immunoglobulin or plasma exchange. However despite this, 4% to 15% of patients die from this syndrome, most often due to cardiovascular autonomic disturbances, respiratory compromise or aspiration. Nearly 20% have persistent disability [316].

Autonomic dysfunction is a frequently-overlooked complication. Cardiovascular autonomic dysfunction is recognized in up to 60% of GBS patients [317]. However, bladder and bowel dysfunction occurs much less often. Indeed, the presence of bladder or bowel symptoms at the onset of disease, or their persistence, casts doubt on the diagnosis, so that other conditions, such as spinal cord disease, need to be excluded. During the acute phase, it is often difficult to assess LUTD specifically due to neurological dysfunction. Patients are often catheterized as part of their general nursing care to monitor water balance or maintain hygiene [316]. Furthermore, patients may be on medications such as opiates and tricyclic antidepressants, which in themselves can affect bladder and bowel functions. In the largest study to date, Sakakibara et al. [318] studied 65 patients with definite GBS (meeting clinical and neurophysiological criteria) and LUTD was observed in 27.7% (LOE3/4). This figure is similar to that quoted by Guillain and others in the early papers [319]. The condition is characteristically a symmetrical radiculo-neuropathy predominantly due to demyelination (Acute Inflammatory De-myelinating Polyradiculoneuropathy, AIDP), but also there are subtypes where axonal damage prevails (Acute Motor Axonal Neuropathy, AMAN). There is a dearth of systematic studies evaluating LUTD in GBS. In a few reports [320, 321], detrusor areflexia and disturbed bladder sensation were the common findings, and a non-relaxing urethral sphincter was also seen (LOE3/4). In the study by Sakakibara et al. [318], patients most commonly reported voiding symptoms in 24.6%, including urinary retention in 9.2%. Storage symptoms were noted in 7.7%, urinary urgency in 7.7%. None of the patients in this study became incontinent. Urinary dysfunction was more common in AIDP (39%) than AMAN (19%), although the prevalence of urinary retention was almost the same (ADIP, 7%; AMAN, 11%). Factors that were associated with bladder symptoms included age, severity of motor weakness (Hughes motor grade) and concurrent bowel dysfunction. When patients were followed up, improvement in bladder symptoms paralleled improvement in motor weakness. Interestingly, there was no correlation between the presence of cardiovascular autonomic dysfunction and bladder dysfunction.

Urodynamic studies performed within eight weeks of disease (n=9) showed variable results, demonstrating detrusor underactivity (n=2), DO (n=3), both DO and underactivity (n=5) and non relaxing urethral sphincter (n=2). Three patients had an elevated post void residual and one patient had reduced bladder sensations [318] (LOE3/4). Their results were similar to the urodynamic findings from Gabavac et al. [321](LOE3/4).

Urinary dysfunction in patients with GBS tends to appear after the onset of motor weakness. However, in two patients with axonal GBS, it was reported that voiding difficulty and motor weakness appeared almost simultaneously [322, 323] (LOE3/4). A close relationship between severity of GBS and bladder dysfunction has been reported (LOE3/4). Lichtenefeld [324] (LOE3/4) has reported urinary retention in one-third of patients requiring ventilator assistance. Even though up to 11% of GBS patients may develop urinary retention at the peak of motor weakness, it will
most often improve along with other neurological signs after supportive patient management, with or without immunomodulation. However, bladder dysfunction can persist and is reported that urinary retention failed to recover for 10 months, even after a patient (with axonal GBS) regained the ability to walk [323] (LOE3/4).

GBS primarily affects the large myelinated fibers, but pathological studies have demonstrated moderate to severe loss of small myelinated fibers and inflammatory cell infiltration in the lumbosacral spinal roots, sympathetic chain, and spinal cord [315]. It has been postulated that LUTD in GBS may be arising from inflammatory or immunologically mediated damage of the autonomic fibres of the lumbosacral nerves [315] (LOE3/4). Contrast magnetic resonance imaging (MRI) has demonstrated enhancement of the nerve roots of the cauda equina in GBS [325] (LOE3/4). The possible mechanism for DO might be abnormal spontaneous depolarisations in demyelinated nerve fibres, and impairment of inhibitory spinal cord interneurons, both of which can result in lumbosacral autonomic hyperactivity [326] (LOE3/4).

12.2. Treatment of bladder dysfunction after GBS

Management of LUTS is essentially supportive. Patients complaining of LUTS should have their post-void residual checked regularly during the progressive phase of the disease. If retaining urine, an indwelling catheter may be preferable during the acute phase. The need for catheterisation should be reviewed regularly as voiding dysfunction can recover in parallel to recovery of motor weakness, but in some cases this might be delayed. If suitable, IC should be considered. Wosnitzer et al. reported a successful case of sacral neuromodulation for urinary retention that persisted 18 months after GBS [327] (LOE3/4). Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic medication once it is shown they are not retaining urine. Of specific consideration to GBS is the side effect of tachycardia, as many patients may have concomitant cardiovascular autonomic dysfunction. Follow-up and further research

There are only limited studies evaluating the natural history of LUTD in GBS and long-term follow-up studies of patients are required. Studies evaluating the correlation between LUTD and other evidence for autonomic dysfunction (such as cardiovascular autonomic dysfunction) should be specifically evaluated.

Conclusions

- In the acute phase of GBS, about 25% of patients demonstrate LUT functional problems (LOE3/4).
- Both voiding and storage dysfunction are observed in GBS (LOE3/4).
- Recovery of LUT function occurs along with the recovery of motor weakness. However, in rare cases it might take months (LOE3/4).

Recommendations

- Recovery of LUT functions is expected in GBS; supportive care, including an indwelling catheter or IC, is the treatment of choice for urinary retention (C).
- Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic, once they are shown not to be retaining urine.
- A systematic evaluation of LUTD during the acute phase and recovery following GBS is required to optimize therapy (C).

12.3. Bowel Dysfunction in GBS

Bowel dysfunction occurs less commonly in GBS, in up to 15% of patients [328] (LOE3/4). Adynamic ileus was noted in 17 out of 114 GBS patients. However, cardiovascular symptoms coincided with ileus in only 5 patients, suggesting a different pathophysiology for these two manifestations of autonomic dysfunction. Indeed in 4 patients, mechanical ventilation and immobilization was implicated. In 8 patients, pre-existing conditions such as prior abdominal surgery or incremental doses of opiates could also be linked to ileus. However, case reports by Gazulla Abio et al. (LOE3/4) [329], Sawai et al. (LOE3/4) [322] and Nowe et al. (LOE3/4) [330] have also shown that paralytic ileus can be the initial presenting symptom in GBS.

There is a lack of good systematic studies on bowel disorders in GBS during the acute and chronic phase of GBS. However, there are some reports suggesting an involvement of bowel autonomic fibres in GBS. Sawai et al. (LOE3/4) [322] performed a detailed bowel function test in a 47-old man with acute motor axonal neuropathy (AMAN) type of GBS who presented with ileus (also called intestinal pseudo-obstruction) by an abdominal X-ray. Sitzmarks showed prolonged total colonic transit time (86.4 hours; normal 16.0-48.0), suggesting slow transit constipation. Pathological studies of GBS have revealed moderate to severe loss of small myelinated fibers and inflammatory cell infiltration in the lumbosacral spinal roots, sympathetic chain, and spinal cord. Therefore, involvement of bowel autonomic fibers might also occur in GBS.

Adynamic ileus or intestinal pseudo-obstruction occurs in up to 15% of patients during a course of GBS, particularly in those with severe motor dysfunction. Recovery of bowel function usually occurs along with the recovery of motor weakness in GBS, after an intensive immune therapy including intravenous immunoglobulin. There is still a lack of a detailed functional evaluation of the bowel in GBS patients. Such studies are needed in order to optimize the therapy in the future.
Conclusions

- About 15% of patients demonstrate bowel functional problems particularly in the acute phase, but they can also be presenting symptoms (LOE3/4).
- Constipation and intestinal pseudo-obstruction are observed in GBS (LOE3/4).
- Recovery of bowel function usually occurs, along with the recovery of motor weakness.

Recommendation

- Supportive care, including laxatives or enemas, is the treatment of choice (C).

13. FAMILIAL AMYLOID POLYNEUROPATHY

Familial Amyloid Polyneuropathy (FAP) is a rare autosomal dominant neuropathy affecting predominantly the peripheral autonomic nerves. Neuropathy starts insidiously in the lower limbs and is characterised by lancinating pains, numbness and impaired temperature sensations.

Autonomic manifestations are common and may be the initial manifestation in nearly 25% of patients (LOE3/4). These include erectile dysfunction, orthostatic hypotension, bladder dysfunction, distal anhydrosis and abnormal pupils. LUTS generally appear early on and are present in 50% of patients within the first three years of the disease. Patients most often present with voiding dysfunction and incontinence (LOE3/4). Often, however, bladder dysfunction may be asymptomatic and uncovered only during investigations. Urodynamic studies have demonstrated reduced bladder sensations, underactive detrusor, poor urinary flow and an open bladder neck. There may be failure of relaxation of the smooth and striated sphincters as well. Ultrasound scans of the bladder may show bladder wall thickening, a finding which becomes more prominent as the disease progresses, and may represent either amyloid deposition in the bladder wall or detrusor hypertrophy secondary to functional obstruction (LOE3/4). 10% of patients with FAP type I may proceed to end stage renal disease and bladder diaries may demonstrate global polyuria. Bladder dysfunction is likely to be due to small nerve fibre damage and deposition of amyloid substance in the detrusor muscle.

Treatment of bladder dysfunction in FAP requires that patients should be followed up regularly, as over-distention is likely to contribute to bladder dysfunction. In the early stage of disease, post-void residual urine will often be less than 100 ml and bladder scheduling and double voiding is often sufficient. However when bladder emptying deteriorates, intermittent catheterization is required. Lower gastrointestinal dysfunction results in alternating constipation and diarrhea. This occurs concomitantly with other manifestations such as episodic nausea, vomiting, and malnutrition. Anorectal physiology studies have demonstrated prolonged colonic transit time, low anal pressure at rest and loss of spontaneous phasic rectal contractions during squeeze, suggesting an enteric neuropathy (LOE3/4).

Liver transplantation remains the only potentially curative treatment and gastrointestinal symptoms improve in about half of cases (LOE3/4). Studies suggest that bladder dysfunction does not improve following transplantation (LOE3/4). Interestingly, the occurrence of urinary incontinence pre-operatively appears to predict higher post-operative mortality (LOE3/4).

14. FAMILIAL DYSAUTONOMIA

Familial dysautonomia (FD) or Riley-Day syndrome is the best known of the hereditary sensory and autonomic neuropathies (HSAN). This autosomal recessive condition is characterised by autonomic and small fibre sensory dysfunction.

LUTD occurs in this condition and patients most often present with incontinence, which is mainly stress incontinence, but also overactive bladder symptoms. The limitation of using antimuscarinics is that it can exacerbate an already dry mouth from the underlying autonomic neuropathy. Less often, patients may have voiding dysfunction manifesting with hesitancy for micturition and high post-void residual volumes, and may be predisposed to recurrent urinary tract infections (LOE3/4).

15. CHARCOT-MARIE-TOOTH DISEASE

In a questionnaire based study, bladder and bowel complaints were significantly higher in patients with Charcot-Marie-Tooth disease compared to healthy controls (LOE3/4). Lower urinary tract dysfunction has been reported in a family with proximal lower limb weakness, where it manifested as loss of bladder sensations and urinary retention with detrusor underactivity demonstrated in urodynamics. A hypotonic bladder was reported in urodynamics in a patient with parasympathetic dominant autonomic dysfunction in Charcot-Marie-Tooth Disease Type 2J with the MPZ Thr124Met Mutation (LOE3/4).
16. AUTONOMIC NEUROPATHIES

A number of autonomic conditions can lead to pelvic floor dysfunction in general and bladder dysfunction in particular. Some conditions are:

1. Acute Idiopathic Autonomic Neuropathy. Bladder dysfunction is well recognized in acute idiopathic autonomic neuropathy (acute pandysautonomia). Acute onset autonomic dysfunction is the hallmark, and is thought to be due to lesions of the pre- and postganglionic sympathetic and parasympathetic fibres. Urinary retention and voiding difficulty are common and cystometry demonstrates detrusor areflexia. Bladder dysfunction tends to resolve earlier than other features of autonomic dysfunction, such as orthostatic hypotension. Constipation is common (LOE3/4).

2. Autoimmune Autonomic Ganglionopathy. Presentation is with rapid onset of severe autonomic failure: orthostatic hypotension, gastrointestinal dysmotility, anhidrosis, bladder dysfunction, erectile dysfunction and sicca symptoms. Impaired gastrointestinal motility manifesting as gastroparesis and severe constipation is reported in nearly 70% of patients. Bladder dysfunction generally manifests with voiding difficulty and incomplete emptying. Severity and distribution of autonomic dysfunction appear to depend upon the level of antibody titers (LOE3/4). Roughly 50–60% of patients with Autoimmune Autonomic Ganglionopathy have circulating antibodies to the α3 subunit of the ganglionic acetylcholine receptor (ACHR) in the acute or subacute stage.

3. Pure Autonomic Failure. PAF is a degenerative postganglionic autonomic disorder. Nocturia and voiding dysfunction are common and bladder emptying is often affected. Bladder diaries may demonstrate nocturnal polyuria. Urodynamics may however demonstrate detrusor overactivity in some patients (LOE3/4). Bladder dysfunction in PAF appears to be as common as, but less severe than, MSA and this could possibly reflect slower progression of the disease (LOE3/4). Constipation is common.

17. DISORDERS OF THE NEUROMUSCULAR JUNCTION

Widespread autonomic dysfunction is a hallmark of Lambert-Eaton myasthenic syndrome (LEMS). This is associated with antibodies to voltage-gated calcium channel (VGCC) of the P/Q-type and patients can present with erectile dysfunction, constipation and bladder dysfunction (LOE3/4).

In the more common disorder of the neuromuscular junction, myasthenia gravis, LUTS are rare. This is presumably because the auto-antibodies are directed against the nicotinic acetylcholine receptors, rather than the muscarinic. However voiding difficulties have been reported and urodynamic studies have revealed detrusor underactivity in these patients. In fact, voiding dysfunction may herald a new diagnosis of myasthenia or an exacerbation of the disease process (LOE3/4). The proposed mechanism is involvement of acetylcholine receptors in the detrusor muscle or pelvic ganglia. Ganglionic acetylcholine receptor antibodies may be present in some patients (LOE3/4). Urinary incontinence is a listed side effect of anticholinesterase medications which are used in treating myaesthenia gravis (British National Formulary [online]), though in clinical practice this is rarely observed. Intestinal pseudo-obstruction has been reported in patients of myasthenia gravis with subacute autonomic failure.

18. MUSCLE DISORDERS

18.1. Muscular Dystrophies

Case series in boys with Duchenne Muscular Dystrophy (DMD) [344] have reported the occurrence of overactive bladder symptoms, and DO has been demonstrated in urodynamics. Symptoms improve with antimuscarinic medications in Becker’s muscular dystrophy [345]. The exact mechanism for DO is uncertain, though it is likely to be due to a disturbance of neural control rather than myopathy of the detrusor or external sphincter. Patients may have severe scoliosis as a consequence of their muscle disorder and this, as well as spinal fusion surgery for correcting scoliosis, can contribute to LUTS because of spinal cord compression. The commonest genito-urinary complaints reported in a population based study of males with Duchenne and Becker muscular dystrophy were urinary tract infections, voiding dysfunction (most commonly urinary retention) and renal calculi [346].

Urological and gastrointestinal dysfunction are reported by patients with dystroglycanopathies more commonly than household controls and can negatively impact quality of life [347]. Myotonic dystrophy (MD) is an autosomal dominant disorder caused by unstable trinucleotide repeat expansions. Urinary and bowel complaints are commonly reported, more often in women [348]. The commonest bowel complaint is constipation, however most disabling is fecal incontinence. EMG has demonstrated myotonia and myopathic changes in the external anal sphincter. Bowel incontinence is often refractory to treatment and procainamide (300 mg twice a day) has been proposed as a treatment option [349]. Constipation is usually treated with prokinetics, laxatives and enemas. Bladder dysfunction is variable and less often reported with detrusor overactivity or atonia being documented in urodynamics [350] (LOE3/4).
18.2. Mitochondrial cytopathy

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is a rare autosomal recessive disorder characterized by gastrointestinal, extracranial, peripheral nerve and cerebral white matter involvement. The gastrointestinal disease manifests with intermittent diarrhea and pseudo-obstruction. Mitochondrial DNA abnormalities and/or thymidine phosphorylase mutations in the proper clinical setting are diagnostic [351]. Bowel dysmotility has also been reported in Wolfram syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness, acronym DIDMOAD) [352]. LUTD has been described and may be associated with urinary retention and dilated upper urinary tracts [352] (LOE3/4).

Conclusions

- Lower urinary tract and bowel dysfunction can occur in a variety of neuromuscular disorders (LOE3/4).
- Both voiding and storage dysfunction are observed in these conditions (LOE3/4).

Recommendations

- Patients with neuromuscular disorders with bladder symptoms should be managed according to their symptoms and the findings of urodynamic tests (C).
- LUT and bowel dysfunction can change as these diseases progress and therefore follow-up is recommended (C).

19. PERIPHERAL NEUROPATHY DUE TO IATROGENIC LESIONS (FOCAL NEUROPATHY)

Surgical procedures in the abdomen and pelvis can lead to a variety of pelvic floor dysfunctions. This can occur from damage to the nerves innervating the pelvic organs, anywhere in the course of these nerves through the cauda equina, the spinal nerve roots, the sacral plexus, or to the various individual nerves that arise from the plexus. Most injuries to these nerves are iatrogenic. Extensive pelvic surgery, such as abdomino-perineal resection for rectal cancer, radical hysterectomy, and aorto-iliac surgery are all likely to damage the pelvic parasympathetic nerves to the bladder and genitalia. Of course this listing is not complete and almost any surgery in the pelvis could damage some nerves e.g. adenomectomy, radical prostatectomy, prolapse surgery. Additionally, pelvic irradiation, apart from directly affecting the irradiated tissue, could cause damage to the adjacent nerve fibers, resulting in altered functions. A variety of types of voiding, erectile and fecal dysfunctions can result.

19.1. Hysterectomy (simple and radical)

It is difficult to attribute certain dysfunctions to neuronal damage alone, since hysterectomy directly affects static and dynamic functions of the pelvic structures. Parys et al. [353] (LOE 3) studied 126 women after simple hysterectomy. The results show that 47.0% had DO, 36.7% had urethral obstruction and 24.8% stress incontinence. Sekido et al. [354] (LOE 3) described 9 women treated with radical hysterectomy more than 10 years before the study. Voiding symptoms and/or urinary incontinence were observed in 7 patients. Cystometry revealed impaired bladder sensation, detrusor acontractility, straining on voiding, and impaired relaxation of the sphincter in all investigated patients. In addition, decreased bladder compliance was observed in 5 patients. Axelsen [355, 356] (LOE 2) studied 100 women after radical hysterectomy and found that those women who reported incontinence had lower urethral pressure. In a prospective study of over 1000 women Jackson et al. found hysterectomy to be an independent risk factor of incontinence [357] (LOE 2). Ploiti et al. analysed literature between 1952 and 2010 and found that in studies with follow up longer than 12 months, 34% of patients demonstrated DO and lowered compliance [358] (LOE 2).

The introduction of nerve sparing hysterectomy appeared to reduce urinary and sexual dysfunctions in comparison with the standard radical hysterectomy. It was found that autonomic nerve preservation significantly improved morbidity 6 months after treatment [359-362] (LOE 3). There is, however, significant lack of long term observations of patients after radical hysterectomy in terms of lower urinary tract neurogenic dysfunctions.

19.2. Abdominoperineal resection and total mesorectal excision

Retrospective analysis of 52 patients after abdominoperineal resection was performed by Eickenberg et al. [363] (LOE 3). Neurologic bladder dysfunction of various degrees was found in 50% but represented a long-term problem in only 10%. Baumgartner et al. [364], (LOE 3) studied 86 consecutive cases of abdominoperineal resection and described 11 cases of various functional problems of micturition. These reports lack specific tests of LUT functions and are not prospective. At 1 year follow up, dysuria incidence is higher after abdominoperineal resection than after anterior resection [364] (LOE 3).

Curative total mesorectal excision with autonomic nerve preservation can be done with high rates of preservation of such function. Pocard et al. [365] (LOE 3) investigated 20 patients (13 men, 7 women) following curative total mesorectal excision with autonomic nerve preservation for rectal cancer. There was no difference in preoperative and postoperative LUT function, International Prostate Symptom Score or urodynamic results, nor in the results of the quality of urinary function questionnaire. Sexual function and

SPECIFIC NEUROLOGICAL DISEASES | 1211
potency were also unchanged in these men. The authors conclude that autonomic nerve preservation is possible and does not impair urinary and sexual function. Kim et al. [366] (LOE 3) also showed relative safety in preserving sexual and voiding dysfunction in total mesorectal excision with pelvic autonomic nerve preservation. Evaluation was based on uroflowmetry, voided volumes and residual volume, while symptoms were evaluated with the IPSS. There were significant differences in maximum urinary flow rate and voided volume, but no differences in residual volume before and after surgery. The IPPS increased after surgery from 6.2 +/- 5.8 to 9.8 +/- 5.9 (p < 0.05).

Similar results were reported by Turaldo et al. [367] (LOE 3) evaluating incidence and pathogenesis of LUT dysfunction after surgical treatment of rectal cancer in a series of 219 patients with normal urinary function pre-operatively. In the immediate follow-up, only 17 patients with dysfunction were observed, 14 stage II, 2 at stage III and 1 at stage IV according to Astler-Koller classification; six months later only 8 patients reported urinary dysfunction and 1 required catheterisation. However no urodynamic studies were performed. There was no correlation of LUT dysfunction with staging, radiotherapy, size of tumour, or surgical technique. However, worse functional results were observed in patients who underwent abdomino-perineal resection.

Lim et al. found that not only surgery but also pre-operative intervention could cause lower urinary tract and anorectal dysfunctions [368]. The maximum resting anal pressures were unchanged after chemoradiation, but the maximum squeeze anal pressures were reduced. They concluded that pre-operative chemoradiation for rectal cancer carries a significant risk of pudendal neuropathy, which might contribute to the incidence of fecal incontinence after restorative proctectomy for rectal cancer [368] (LOE 3). However Langer et al. found that the surgery mostly responsible, not the pre-operative radiotherapy [369] (LOE 3).

Focal injury to peripheral innervation of the bladder and/or sphincter results in decentralization or denervation of the above mentioned organs. Therefore detrusor hypocontractility (acontractility) and/or sphincteric deficiency will be the result of such damage. This in turn will result in impaired bladder emptying and/or stress incontinence. No prospective studies referring specifically to the problem of functional disturbances of the LUT in focal iatrogenic neuronal injury in patients after hysterectomy or colorectal surgery have been performed.

Iatrogenic faecal incontinence can be caused by sphincter damage caused by surgery for ano-rectal problems, trauma, fistulae and abscesses. Vaginal delivery can cause not only sphincteric, but also neuronal damage to the innervation of the anal sphincter [370] (LOE 3). There is a significant paucity of epidemiological data regarding fecal incontinence after pelvic surgery. Anorectal reflexes and anorectal manometry may predict recovery of function [371] (LOE 3). An experimental test in this specific patient population was described by Nordling et al. [372] (LOE 3). In patients after radical hysterectomy, those with significant denervation of the bladder had a greater rise in maximum urethral pressure during noradrenaline infusion (>20 cm H2O) than normal subjects (1-15 cm H2O). They concluded that urethral supersensitivity to noradrenaline may signify damage of the sympathetic innervation of the LUT.

19.3. Radical Prostatectomy

In a study of the 875 patients 19% developed de novo OAB following RP [373]. After adjusting for age, BMI, smoking status, cancer stage and nerve-sparing status, radiation therapy was associated with an increased relative hazard of OAB. Among men classified with de novo OAB, only 41% received treatment. Post-radical prostatectomy urinary incontinence continues to be one of the most devastating complications, which affects 9-16% of patients. Sphincter injury and bladder dysfunction are the most common causes of developing urinary incontinence.

19.4. Prevention and treatment of bladder dysfunction

Reduction of risk requires detailed knowledge of pelvic neuroanatomy and meticulous preparation of the structures adjacent to nerves potentially at risk [374-377] (LOE 3). Nerve sparing surgery seems to have favourable effect on bladder functions and continence in patients after radical hysterectomy [359, 376, 378] (LOE3). Thus it seems that it is the nerve function, rather than the biomechanics of the urethrovaginal complex, which are responsible for incontinence. A method of intraoperative identification of the vesical branches of the pelvic nerves during radical hysterectomy was described by Kuwabara et al. [379] (LOE 3). Postoperative compliance of the detrusor in cases where this method was implemented demonstrated less decrement from pre-operative values than in cases with conventional approaches. These patients required significantly fewer days to achieve residual urine volumes less than 50 ml after surgery.

Nerve sparing technique and intra-operative identification of parasympathetic nerves seem also to play a role in rectal cancer surgery. Kneist and Junginger studied 62 patients undergoing mesorectal excision [380]. Pelvic autonomic nerve preservation was assessed macroscopically and with the aid of intra-operative electrical stimulation of pelvic autonomic nerves. In 46 patients, preservation of parasympathetic nerves was confirmed and these patients remained unchanged in early and long-term urinary function, contrasting with patients in whom preservation of the nerves was not confirmed [380] (LOE 3).

Should injury to the nerves innervating the bladder/urethra complex occur, the treatment should be based on standard principles and on the results of functional examination of the LUT. Zanolla et al. [381]
(LOE 2) suggested that early implementation of rehabilitative treatment (prompted voiding) allows satisfactory functional recovery of the bladder activity in 91% of the symptomatic patients after radical hysterectomy. Another interesting issue is the feasibility of the use of the artificial urinary sphincter to treat stress incontinence in patients with outlet denervation after colorectal surgery, hysterectomy and/or radiotherapy. Only one study on this subject was identified [382] (LOE 3), describing a series of patients after radical prostatectomy and amongst them a patient after abdominoperineal resection with adjuvant radiation. The authors concluded that this method of incontinence therapy should be the method of choice, however there is a significantly greater risk of revision (38% versus 22% in the literature for low risk groups). Bulking agents may be considered after radical hysterectomy, if no other treatment options are possible. If not resulting from sphincter damage, fecal incontinence after colorectal surgery might be considered for sacral neuromodulation [383] (LOE 3).

19.5. Future research

Future research priorities include good epidemiological research, particularly prospective studies of the true incidence of peripheral injury-related functional disorders of micturition. Descriptive studies of diagnostic testing and therapy are needed. A registry database of urinary and fecal incontinence after different types of pelvic surgery would be a considerable benefit for insight into prevalence and preparation of guidelines on treatment/prophylaxis.

Conclusions

• Injury to the bladder/sphincter innervation occurs in 30-50% of patients after extensive pelvic surgery (LOE 3)
• Pelvic irradiation could cause nerve damage affecting bladder and/or bowel functions (LOE 2).
• Fecal incontinence due to iatrogenic innervation damage could occur after complicated labour, anorectal surgery and pelvic irradiation (LOE 3)
• Focal injury results in impaired detrusor contractions and/or external urethral sphincter deficiency or detrusor sphincter dyssynergia (LOE 3-4)
• The key means to avoid these complications are nerve sparing techniques and intra-operative nerve identification (LOE 3)

Recommendations

• Patients after extensive pelvic surgery demonstrating functional disorders of micturition should be properly evaluated due to the varied potential underlying mechanisms (C)
• Early rehabilitation of the LUT and of the anal sphincter might improve function in a majority of patients (C)

20. MULTIPLE SCLEROSIS

20.1. Epidemiology

Multiple sclerosis (MS) is the commonest progressive neurological disorder in young people, with a mean age at onset of 30 years, and a prevalence of 40-220 cases per 100,000 people in Europe [384-386], with similar rates in North America [387, 388]. The impact on the quality of life for patients with lower urinary tract dysfunction (LUTD) due to MS is significant. In a cross-sectional study, Nortvedt et al. [389] demonstrated that patients with LUTD had distinctly lower quality of life scores on the SF36 scale in comparison with the population of MS patients that is asymptomatic. The tools for evaluating quality of life taking into account LUTD in MS have been validated, so that variations in it over the course of the illness can be measured [390-392].

LUTD is multifactorial, and typically appears within the first 6 to 10 years of the progression of the illness [393-398]. Once LUTD has started (for 10% of cases LUTD is a primary feature [384]), they will present an increased risk of developing severe urological problems [399]).

The prevalence of LUTD in patients with MS is in the order of 30 to 96% [6-8, 10, 11, 13, 14, 16-32]. The range signifies the differences linked to the type of MS, to the duration of the illness, and to the degree of handicap, as well as to a probable under-evaluation by certain practitioners of any urological problems that develop progressively and slowly.

20.2. Urinary tract dysfunction in MS

Symptoms of the storage phase are most frequently reported: urinary frequency (38 to 99%), urgency (26 to 82%), and urgency incontinence (27 to 66 %) [384, 395, 397, 398, 400-402]. Stress urinary incontinence (SUI) has a prevalence of about 56% and patients often report mixed urinary incontinence [384, 403]. Stress of the voiding phase are less frequent with a prevalence of 6 to 49% [384, 395, 398, 401] and symptoms of both the storage and voiding phase coexist in about 50% of patients [384, 398].

Considering the very high frequency of LUTS, it is important that the most appropriate tools are used to
evaluate the urological problems, especially also taking into account that LUTD is often ignored by the doctors who take care of these patients at least partially due to the fact that the patients under-report their symptoms. It is therefore crucial to identify the groups of patients that are at risk so that complex examinations that are seen as risky are not imposed upon the entire population of patients who are suffering from MS [384, 395]. Short evaluation of LUTD in MS patients by neurologists and appropriate referral to urologists could accelerate proper diagnosis and treatment [404]. Thus, the coordinating role of neurologists in LUTD management may considerably improve quality of life in MS patients [404].

In a systematic review by de Sèze et al. [398], the duration of the progression of MS was one of the principal factors that influenced the prevalence of LUTD. Another important factor associated with LUTD was the degree of the patient’s physical handicap as estimated by the Expanded Disability Status Scale (EDSS) [398]. This is also a common sense observation in daily clinical practice, i.e. a patient who can compensate for the urgency by going to the toilet beforehand may see the appearance of urgency incontinence following the appearance of a new motor or visual handicap. The appropriate management of this problem can allow the improvement of urinary disorders without any specific action on the bladder or the sphincter. Similar to patients with spinal cord injury, the clinical examination does not always allow the discovery of the specific neurological insults that are associated with LUTD. In addition, no correlation between radiological insults on the central nervous system (localization and intensity) and LUTD has actually been found [398].

Other factors have been controversially discussed as associated with LUTD, such as the type of MS progression (progressive or by crisis), the age at which MS started, sex, age and geographical location where the patient lives [398]. Importantly, older patients with MS will have the same problems as the general population (prostatic enlargement in men and stress urinary incontinence in women), and those problems will of course often be more difficult to treat than in the general population.

Lower urinary tract infections are reported in 13 to 80% (30% in average) [398, 405]. The occurrence of febrile urinary tract infection (pyelonephritis, orchitis, or prostatitis) is estimated at between 2 and 23% (9% on average). In addition to the risk of mortality, an aggravation of MS following an episode of urinary tract infection has been reported [389, 406, 407]. Neurogenic detrusor overactivity is probably a significant factor in the occurrence of upper urinary tract infections. Indeed, intradetrusor injections of onabotulinumtoxinA resulted in a relevant decrease of urinary tract infections [408].

A few studies suggest that the risk for bladder cancer is greater in patients with MS than in the general population, especially in patients under chronic catheterization and having been treated with immunosuppressants (for instance cyclophosphamide) [398, 409]. The overall incidence of bladder cancer in the MS population was 0.29% higher than in the general population (0.018 in men, 0.004 in women) and close to that of patients with SCI (from 0.27 to 9.6%) [398]. The risk for bladder cancer appeared higher in patients with indwelling (transurethral, suprapubic) catheters (incidence 0.7%) and in patients performing intermittent self-catheterisation (incidence 0.23%), with a maximum risk in the sub-population of patients under chronic catheterization having been treated with immunosuppressants (incidence 5.7%) [398, 409].

Complications of the upper urinary tract

Renal calculi were found in 2-10% of the cases, hydronephrosis in 1 to 16% and vesico-uretero-renal reflux in 2 to 15% of the cases [384, 398]. Contrary to patients with SCI and spina bifida, the risk of developing renal failure in patients with MS is generally low [410] and does not appear to be greater than within the general population [411]. However, in patients with MS progressed for more than 10 years, renal failure prevalence as high as 2 to 3% has been reported [384, 399, 412, 413].

Risk factors for urological complications

Although urological complications are less frequently reported in patients with MS compared to those with other neurological disorders such as SCI or spina bifida, they are not rare [384]. Risk factors for urological complications include the MS duration, post void residual, presence of an indwelling catheter, older age, male sex and urodynamic parameters (such as detrusor overactivity, detrusor sphincter dyssynergia, elevated intravesical pressure, low compliance bladder, vesico-uretero-renal reflux) [384, 398, 410, 414].

The role of urodynamics in MS

Urodynamic findings in patients with MS vary widely, and the following findings have been reported: detrusor overactivity in 34-91%, detrusor underactivity in ≤37%, low bladder compliance in 2-10%, detrusor sphincter dyssynergia in 5-60%, detrusor sphincter dyssynergia combined with either detrusor overactivity in 43-80% or with detrusor underactivity in 5-9% [384]. Importantly, urodynamic abnormalities can change during the course of disease, pathological findings may be identified in asymptomatic patients and symptomatic patients may have normal urodynamics.

The role of urodynamics in MS is a topic of ongoing debate [384, 410]. Guidelines published by the UK National Institute for Health and Care Excellence (NICE) [415], a UK consensus statement (Fowler et al., 2009) and a Turkish consensus statement [386] recommend not to offer urodynamics (i.e. cystometry and/or pressure-flow studies) routinely to MS patients, whereas the International Francophone Neuro-

1214 | COMMITTEE 10. NEUROLOGIC URINARY AND FAECAL INCONTINENCE
Urological Expert Study Group (GENULF) recommends using urodynamics in the initial diagnosis [398]. Thus, the inclusion of urodynamics in the routine assessment of patients with MS is determined by the available local guidance [384]. However, urodynamics are generally recommended in MS patients with risk factors predisposing to upper urinary tract damage, in those with concomitant stress urinary incontinence, in those whose symptoms have failed to respond to first-line treatment or if surgical treatment is being considered [384, 416].

Conclusions

- MS is the commonest progressive neurological disorder in young people (LOE 1)
- The most common LUTS in MS are storage symptoms, followed by voiding symptoms and in many patients both storage and voiding symptoms coexist (LOE 1)
- The risk of developing upper urinary tract damage and renal failure is much lower in patients with MS than in those with SCI or spina bifida (LOE 3)
- The role of urodynamics in MS is a topic of ongoing debate (LOE 2)

Recommendations

- Close collaboration between neurologist and urologist is mandatory and appropriate referral to the urologist is strongly recommended to improve quality of life in the MS patient (B)
- Urodynamics are generally recommended in MS patients with risk factors predisposing to upper urinary tract damage, in those with concomitant stress urinary incontinence, in those whose symptoms have failed to respond to first-line treatment or if surgical treatment is being considered (B)

20.3. Colorectal dysfunction in MS

Epidemiology

Digestive disorders are common in patients who have MS, and can have a significant impact on quality of life (LOE4) [389, 392, 417]. What is more, the patients tend to be ashamed of these problems and seldom report them. Clinicians have few tools at their disposal for evaluating this impairment. Consequently, digestive disorders are often undetected (LOE3-4) [413, 418].

Taking into account the great diversity of definitions in the several studies that are concerned with this problem, one is obliged to regroup the digestive symptoms into two large groups: those symptoms that can be defined as "retentive", including abdominal pain, flatulence, and constipation on the one hand, and those symptoms that can be defined as "irritant", including false urges to defecate, diarrhea, and/or incontinence of stool and/or gas. Digestive disorders of both types were found in 45 to 68% of the cases (LOE 4) [417-422]. The prevalence of the "retentive" symptoms is higher, ranging from 31% to 54%, compared with 6 to 20% for irritant symptoms [417]. The authors who had sought to flush out the more exceptional episodes of incontinence found a frequency of at least one episode of that type in the months that preceded the interview in 29 to 30% of the cases [418, 419]. The figures were clearly more significant than in the general population, where the "retentive" disorders are estimated to be around 2 to 20% and the "irritant" disorders 2% [423].

Risk factors for digestive disorders in MS have not been identified. The duration of the progress of MS does not appear to be a factor that influences the prevalence of digestive disorders. The factor that seems to be the most important is the estimated degree of disability (LOE 3) [422, 424]. Thus, Munteis et al. [424] found in a case control study (LOE 3) a frequency of digestive disorders that exceeded 21.2% if the patients had an EDSS between 0 and 1, compared with 78% if EDSS was greater than 4.5. Other risk factors were suggested (LOE4), such as female gender, the existence of related urinary disorders, age, and taking anticholinergic treatments, but they seemed to have an influence that was less clear [417-422] [424].

Pathophysiology of MS-related digestive disorders

Few studies have been carried out specifically in patients who have multiple sclerosis. One of the difficulties is the frequent existence of related treatments that can themselves bring about the specific symptoms. The colonic transit times can be extended or shortened in those patients who present with digestive disorders [425-427]. Several anorectal manometry anomalies were in evidence: reduced tone and compliance, a reduced sensation of filling and incoordination of the external anal sphincter during expulsion, with an onset of the phenomenon known as paradoxical anal sphincter contraction. In patients with faecal incontinence, a decrease in anal canal pressures and hyper-reactivity of the rectal wall have been shown manometrically. In the most recent of these studies, Munteis et al [424] has found that the anomalies that are found the most often are those of maximal sphincter pressure, of anal inhibitory reflex (which occurred later than in the control population), and the presence of paradoxical contraction of the puborectal musculature during straining. These anomalies might be able to allow the proposal of biofeedback re-education in affected patients. However, at present the benefit of this approach has not yet been proven.
21. SPINAL CORD LESIONS

Spinal cord injury (SCI) can be a devastating consequence of a variety of insults to the spinal column including road traffic accidents, gunshot wounds, surgical injuries, disc lesions or as a result of sports. It can be accompanied by vertebral fractures. Unlike other neurologic diseases, once established the neurologic status generally remains stable.

21.1. Epidemiology and prevalence

SCI epidemiology has evolved over the last three decades. The incidence in women has increased over time. The male/female ratio is now 4:1. The mean age at injury is 37.7 +/-17.5 years in 2000-2003 [428]. This comprises incomplete quadriplegics (28%), complete paraplegics (26%), complete quadriplegics (24%) and incomplete paraplegics (18%) [429].

There has been a steady improvement in life expectancy and quality of life after SCI. At present, the life expectancy of paraplegic patients is similar to the ripples (24%) and incomplete paraplegics (18%) and an improved and protocol driven follow-up plan.

The SCI is classified using the American Spinal Injury Association (ASIA) impairment (Table 16) scale of motor and sensory function [430].

Table 16: ASIA Impairment scale

<table>
<thead>
<tr>
<th>Scale</th>
<th>Description</th>

</tbody>
</table>

It separates into 5 clinical syndromes [4] as follows:

- **Central cord syndrome** is most commonly due to hyperextension injury and results in haemorrhagic necrosis of the central gray matter and some of the medial white matter. Arm function is less at risk than legs because more caudal fibers of the corticospinal and spinothalamic tract are localized in the spine more laterally so are better protected. Bladder dysfunction is also less common.

- **Brown–Séquard syndrome** is a unilateral cord condition. It presents as ipsilateral motor weakness and contralateral sensory impairment of pain and temperature. Bladder dysfunction in the pure condition is uncommon.

- **Anterior cord syndrome** is characterized by injury to the anterior aspects of the cord. The posterior columns and dorsal horns are preserved. There is a motor deficit and loss of pain and temperature sensation below the level of the injury.

- **Conus medullaris and cauda equina syndrome** result from damage to the conus and spinal nerve roots, leading to flaccid paraplegia and sensory loss. Sacral reflexes can be partially or totally lost.

It has been proposed to add an additional scale assessing the autonomic function [431] as it is generally impaired in SCI but not assessed in any classification. This scale involves an assessment of general autonomic function, lower urinary tract, bowel, sexual function and an urodynamic evaluation. The impact of SCI on the pelvic organ function constitutes a major part of this classification.

21.2. Bladder dysfunction after SCI

SCI can be divided into two phases; spinal shock and a chronic phase, and can be categorised according to the level of injury.

**Spinal shock**

Spinal shock is the period just after the injury. It lasts on average three months. It is characterised by loss of muscle tone and segmental spinal reflexes caudal to the SCI. There is detrusor areflexia and the bladder is acontractile but the bladder neck and proximal urethra remains closed. This areflexia cannot be reversed with bethanechol [432]. The only reflex activity that rapidly returns are the anal or bulbocavernous reflexes. Spinal shock is initially managed with an indwelling urinary catheter. The recovery of bladder function usually follows that of skeletal muscle reflexes. The removal of an indwelling urinary catheter and initiation of self catheterization should be instituted as soon as practical.

**Neurogenic Bladder Dysfunction in the chronic phase**

**Suprasacral lesions**

The spinal shock phase is followed by the appearance of a segmental spinal bladder reflex. This relates to emergence of unmyelinated C-fibers afferent function [433]. As a result, some stimuli can come to influence bladder and sphincter activity that were seemingly irrelevant prior to injury [434, 435]. The sacral micturition centre is disconnected from the control of higher centres and produces what is functionally an isolated spinal cord segment. This results in neurogenic detrusor overactivity (NDO) and detrusor sphincter dyssynergia (DSD). DSD is defined as in-
termittent or complete failure of relaxation of the urinary sphincter during a bladder contraction and voiding. It has been reported to occur in 96% of individuals with suprasacral lesions. In addition to DSD, internal sphincter dyssynergia also has been reported, often occurring at the same time as DSD. Patients present with both storage and voiding dysfunction [436]. DSD can manifest with both complete and incomplete lesions. However, complete injuries are significantly more often associated with DSD. This leads to high voiding pressure, dis-coordinated voiding, residual urine and incontinence. If left untreated, this can lead to recurrent urinary infections, hydroureter and renal failure. Ambulatory patients with incomplete spinal cord may have significantly less urinary tract dysfunction, but the urodynamic parameters may still be abnormal.

**Detrusor-(external) sphincter dyssynergia**

Schurich et al. [437] assessed types of DSD in 105 chronic SCI males and evaluated the change in the DSD pattern over time. Results showed that those with an incomplete sensory and motor SCI presented with DSD type 1 whereas those with complete sensory and motor SCI lesion had DSD type 2 to type 3. At medium to long-term follow-up, a significant change was found in the DSD type. Generally, presence of DSD was determined by increased wire needle EMG activity and/or by dilated bladder neck and proximal urethra during detrusor contraction, in the absence of valsalva or attempt to inhibit voiding. De et al. [438] did a comparative study to explore the diagnostic congruence for DSD between needle EMG and voiding cystourethrogram (VCUG) in the neurogenic population. They found 60% agreement and 40% disagreement between EMG and VCUG for diagnosis of DSD. Binomial testing demonstrated significant disagreement in observed proportions. By retrospectively analyzing clinical data consisting of bladder and EAS EMG from 41 SCI individuals with NDO, Wenzel et al. [439] found that the onset of bladder contractions was detected within 1 sec of the start of the EAS contraction for both synergic and dyssynergic human subjects. They concluded that this detection could be used as a control signal to deliver inhibitory electrical stimulation to arrest nascent bladder contractions.

**Autonomic dysreflexia**

Autonomic dysreflexia (AD) is a clinical emergency in patients who have a SCI, usually at level T6 or above. It is caused by a massive sympathetic discharge triggered by either a noxious or non-noxious stimulus originating below the level of the SCI. The mechanism might be changes occurring within the spinal and peripheral autonomic circuits. There is a loss of inhibitory and excitatory supraspinal input to the sympathetic preganglionic neurons [440] secondary to the destruction of the descending vasomotor pathways.

AD is characterized by severe hypertension and reflex bradycardia, though tachycardia also may occur. An increase in systolic blood pressure greater than 20 to 30mmHg is considered a dysreflexic episode. The other symptoms could be severe headache, feeling of anxiety, profuse sweating, flushing and piloerection above the injury level with dry and pale skin below. It might also cause blurred vision, nasal congestion, cardiac arrhythmias and atrial fibrillation. It can vary in intensity from mild discomfort to life-threatening. Untreated episodes may cause intracranial haemorrhage, retinal detachment, seizures, and death.

The severity of AD symptoms increases with completeness of injury and higher level of lesion (27% of patients with incomplete quadriplegia vs 91% of patients with complete tetraplegia) [441]. The commonest trigger for AD is bladder or bowel distention.

Immediate recognition and reversal of trigger factors is essential [442]. The treatment consists of non-pharmacologic interventions; removing the noxious stimulus, emptying the bladder, sitting the patient up, as recommended by the Consortium for Spinal Cord Medicine. If they fail, and systolic blood pressure continues to be at or above 150mmHg in an adult and 130mmHg in a child 6 to 12 years old, some type of pharmacologic agent should be used, usually Nifedipine 10 mgs sublingual.

**Infrasacral lesions**

In patients with injury to the sacral pathways there is decentralization of parasympathetic pathways to the detrusor with the loss of somatic innervation to the external sphincter. This results in loss of conscious awareness of bladder filling. There is partial preservation of pain sensation transmitted via hypogastric nerves in some people. Patients present with hesitancy, slow and interrupted stream, feeling of incomplete emptying, and are often in retention. The bladder has little or no contractile ability. Nevertheless, because of loss of compliance of the bladder wall, the bladder may still be subject to high intravesical pressure during filling, especially in individuals with conus medullaris lesions or with partial injuries. In the chronic state there is an increase in adrenergic innervation to the detrusor, resulting in change of functional role from beta-mediated adrenoceptor relaxation to alpha-mediated contraction [443, 444]. The sympathetic nervous system supplies the main innervation to the urethra. However, there may be a contribution of the somatic innervation to external sphincter [445, 446]. The perineal floor electromyography shows denervation of the perineal floor and an underactive urethral sphincter in infrasacral cord lesions.

21.3. **Natural History of Neurogenic bladder after SCI**

SCI usually causes impairments of urinary functions such as urinary incontinence (UI) and/or difficulty in urination. The studies on prevalence of bladder management in chronic SCI [447-449] (see Table 17) demonstrate about 8%-11% of patients had normal voiding, not different from the time after initial rehabilitation; and more normal voiding in tetraplegics then paraplegics [449].
According to the study from Denmark [449], at discharge from the initial rehabilitation period of 233 traumatic SCI patients, bladder-emptying methods were as follows: 12% normal voiding, 57% suprapubic tapping, 19% abdominal pressure, 5% Crédé manoeuvre, 11% CIC, 2% SIC, 8% urethral indwelling catheter (ICD), 0.4% suprapubic catheter (SPC), 0.4% sacral-anterior-root-stimulation (SARS), and 5% use of condom-catheter or diaper. When dividing the patients by timing of injury (before 1981 and after 1980), there was a decreasing trend of using suprapubic tapping (drop from over 60% to 45%), abdominal pressure (from over 20% to 15%) and Crédé manoeuvre (drop from over 12% to 1%) but there was an increasing trend of using CIC (rise from 0% to 26%). Over time, 37.5% to 46% of SCI persons changed their bladder-emptying management; 28% found their bladder-emptying methods to be a problem; of these 58% were tetraplegic and the biggest bother in bladder management to the subjects was in the compression or straining group (over 50% of the subjects).

There was a significant difference in the frequency of urinary tract infection (UTI) between the bladder management options [447]; the frequency of UTI was high (about 70%) in the mixed group (65% used CIC with other methods) and the CIC group and less (less than 50%) in the groups with catheter free management. According to the study financed by Medicon Valley Academy and Coloplast A/S and done in Denmark, of those using CIC, 92% reported using hydrophilic-coated catheters [449], but there was no report about frequency of UTI.

In a large prospective cohort study, Drake et al. [450] reported the changes in bladder management method with advancing time after SCI, finding that 29% of patients with SCI for at least 20 years changed method over the 6 year period. Podnar et al. [296] studied 55 patients with chronic cauda equina or conus medullaris injury; 76% of the patients reported LUT dysfunction, 70% had urinary incontinence (56% of men and 71% of women); and a post void residual (>100 ml) was found in 40% of men and 17% of women. Perianal sensation was abnormal in 96%, electromyography (EMG) of the external anal sphincter (EAS) muscle in 88%, and sacral reflex in 84% of patients; using multiple linear regression analysis, perianal sensory loss and female gender had a significant positive effect on urinary incontinence score.

21.4. **Disease-specific LUT mechanisms**

Pontari et al. [451] analysed 7 bladder specimens from 6 cervical SCI patients and 1 L1 congenital myelomeningocele (MMC) and compared them with bladder specimens obtained from 8 organ transplant donors to determine whether the muscarinic receptor subtype mediating contraction alters, and found that whereas normal detrusor contractions are mediated by the M3 receptor subtype, in patients with neurogenic bladder dysfunction, contractions can be mediated by the M2 muscarinic receptor subtype.

Drake et al. found a marked reduction in the range of transmitters expressed in bladder nerves in SCI [452]. Haferkamp et al. [453] evaluated the role of neuropeptide Y in 31 patients with NDO and 7 patients with stress urinary incontinence (SUI) and concluded that the reduction of neuropeptide Y-containing nerves, inhibiting the contractile response of the detrusor, may play a role in the development and persistence of NDO in SCI patients. Oner-Iyidoğan et al.
of the 10 patients. Schmid et al. [455], after electrical stimulation (ES) of the posterior urethral mucosa (single square pulses of 0.2 ms, 2 to 3-fold sensory threshold, 60 mA in complete SCI patients), evoked skin sympathetic responses (SSRs) of the hand could be recorded in 14 of 15 sensory incomplete SCI patients with disturbed urethral sensation but not in 13 sensory complete SCI patients with loss of any urethral sensation. Electrically evoked urethral sensations resembled the subjective desire to void at full bladder reported by controls and patients.

Schmid et al. [456] did a comparative study of motor evoked potentials (MEP) and evoked pressure curves (EPC) from the urethral compressive musculature (UCM) in 9 healthy persons and 33 patients with neurogenic UI (15 SCL, 14 cauda equina lesion, and 4 multiple sclerosis). In healthy subjects the central latency was 19.0 msec, the peripheral latency was 4.25 msec, and the ratio between central and peripheral latencies was 4.4. In patients with incomplete SCL, the central latency was significantly delayed (22.7 msec), whereas the peripheral responses were normal, and the ratio (5.5) was increased. Those with a complete SCL showed no UCM reaction after transcranial stimulation, whereas peripheral responses were normal. The increased ratio of 6.0 indicated a spinal cord lesion. Ten patients with incomplete cauda equina lesions and UI had normal central latencies but prolonged peripheral latencies of 6.7 msec; the ratio of 3.4 indicated a lesion of the sacral caudal roots.

According to Dai and Xiao [457], the thresholds of stimulation on ventral roots were 0.02 ms duration, 0.2-0.4 mA, (mean 0.3 mA+/−0.07 mA), compared with 0.2-0.4 ms duration, 1.5-3 mA (mean 2.3 mA+/−0.5 mA) for dorsal root (P<0.01) to cause evoked potentials and EMG. Continuous stimulation for about 3-5 seconds on S2 or S3 ventral root (0.02 ms, 20 Hz, and 0.4 mA) could result in bladder detrusor contraction, but the strongest bladder contraction was usually caused by stimulation on the S3 ventral root in 7 of the 10 patients.

21.5. Assessment/investigations

A complete assessment is required for evaluation of bladder dysfunction [458-460], to screen for upper urinary tract damage, evaluate the risk factors and to adapt the management to the patient’s disability.

The first detailed assessment is generally performed once the patient has recovered from spinal shock. It includes a complete clinical history, including prior surgery, medications, spinal cord injury date, spinal cord injury evolution, other past medical events, neuromologic symptoms, spasticity or autonomic dysreflexia, mental status and comprehension, mobility and hand function and socioeconomic situation. It has also to include a special focus on urinary symptoms, bowel and sexual functions and possible warning signs, such as pain, infection, haematuria, and fever. A 3-day bladder diary could be recorded. However, the spinal cord outcomes partnership endeavour considers that diary-based measures of continence and voiding are not well standardized and have limited sensitivity, accuracy and reliability [461]. Quality of life should also be assessed, using validated questionnaire such as qualiveen, which has been specifically developed for assessing quality of life in relation to bladder function after spinal cord injury [462].

The recommended investigations are kidneys and bladder ultrasonography, creatinine clearance, video-urodynamics (VCMG) or urodynamics and urothrocystogram. Other investigations could be performed, such as dimethylmercaptosuccinic acid (DMSA) renography or mercaptacetyl-triglycine (MAG3) renography, cystoscopy, abdominal CT scan, depending on the abnormalities detected on the initial investigations.

The renal ultrasound looks for upper urinary tract dilation, stone, pyelonephritic scars and atrophy, with bladder scan detecting stone, bladder wall thickness and any large mucosal lesions. A post-void residual volume assessment would be performed if the patient can pass urine spontaneously. In parallel, renal function should be assessed. Currently, creatinine clearance, rather than simply creatinine level, is recommended due to loss of muscle mass in these patients. In case of kidney ultrasound or of renal function abnormality, a renography (DMSA or MAG3), is indicated. Cystatine C has been proposed for assessing renal function in neurological patients [463].

In SCI patients, videocystometrogram (VCMG) is considered the gold standard for understanding bladder and urethral sphincter functioning and for assessing the upper urinary tract damage risks.

21.6. Urodynamic studies

Ockrim et al. [464] found that in men with SCI, cystometric variables and detrusor overactivity (DO) remained consistent over sequential studies while in those with LUT symptom of urgency, a significant decrease in the number and pressure of involuntary detrusor contractions (IDCs) in consecutive cystometries resulted in a reduction of observed DO from 72% to 63% and 48%, in the three studies. Chou et al. [465] did a retrospective study on urodynamic studies to provide reference ranges for “normal” variability in urodynamic parameters that can be considered as “no real change” from one study to the next. Fifty consecutive individuals with SCI had 2 trials (trial 1 and trial 2) of urodynamic studies done 5 minutes apart, and the following data were collected: maximum cystometric capacity, opening pressure, maximum detrusor pressure, volume voided, and postvoid residual (see Table 18).

Generao et al. [466] did a retrospective review of SCI cases with 1-year minimum follow up to determine the effect of SCI on the developing bladder and kidneys using video-urodynamics and sonograms. In 42 children (average age at injury of 5.3 years and mean follow up of 5.5 years), 40 used CIC and 37 took antispasmodics. No patient had reflux, hydronephrosis or renal scarring. Safe bladder capacity, the pressure specific volume at 40 cm water or less, was less than the expected capacity in 80%, 58% and 50% of cervical, thoracic and lumbar injured patients but 100%, 76% and 67% respectively of the groups undergoing multiple urodynamics had increasing capacity with time.

Ersoz and Akyuz [467] investigated bladder-filling sensation in 73 consecutive traumatic SCI patients to examine the quality of the preserved sensation and to determine the potential for sensation-dependent bladder emptying. Bladder-filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and 38.9% of the patients with complete lesions above T11. There were significant differences between three groups with respect to bladder sensation category. About 86% of the patients with incomplete lesions, 53% of the patients with complete lesions below T10 and 22% of those with lesions above T11 had bladder-filling sensation before $P_{\text{ves}}$ reached 25 cmH2O and simultaneous bladder capacity of more than 150 mL was present in 61.2, 41.2 and 22.2% of the patients in the groups, respectively. Bladder-filling sensation investigations were reliable in terms of bladder filling sensation category in 36 SCI patients who had a second cystometric examination.

To measure bladder mucosal sensory function quantitatively, Ukimura et al. [468] used neuroselective Current Perception Threshold (CPT) tests in 8 healthy volunteers and 38 patients with NBD. Standardized neuroselective CPT measures were obtained from the left index finger and the mucosa of the posterior bladder wall. The CPT values in the bladder could be determined using the neuroselective measures in all patients but three who had no sensory response (absence of sensation) caused by complete SCI. In the 8 patients with NDO due to incomplete suprasacral SCI, the bladder CPT value (4.0+/−1.9) at 5Hz was significantly lower than that in the controls (26.2+/−17.7). In the NBD determined to be underactive (n=11, including post pelvic surgery, post infrasacral level SCI and diabetes patients), the higher CPT values of bladder mucosal sensory functions were found at 5Hz (p<0.05), 250Hz (p=0.07), and 2000Hz compared to the controls. No fibre specificity has so far been found depending on frequency of current used or current type.

21.7. Urinary Tract Complications in SCI patients

Complications related to urethral indwelling catheterization (IDC)

During 2004-2006, at least three papers reported urinary complications related to prolonged urethral IDC; the catheter balloon of a Foley catheter inserted partially and a long-term IDC caused urethral erosion and a severe degree of hypospadias [469]; contracted bladder followed by autonomic dysreflexia (AD), gross haematuria and extravasation of contrast media due to improper technique of voiding cystourethrography [470]; and continuous incontinence despite a catheter and low bladder compliance leading to a urinary diversion to achieve continence [471]. In chronic SCI, IDC was associated with higher mean levels of C-reactive protein (CRP) while intermittent catheterization was associated with lower levels of CRP when compared with other methods of bladder management [472].

Vesicoureteral Reflux (VUR)

VUR seems common among SCI patients with upper motor neuron (UMN) neurogenic bladder. According to the study of Linsenmeyer et al. [473], there was an association of posterior position of ureteral orifices and reflux but no differences were found with regard
to bladder capacity, bladder wall compliance, or voiding pressures between the reflex group and non-reflux group.

**Stone formation**

Linsenmeyer and Linsenmeyer [474] found that the majority of bladder stones were calcium phosphate (46.8%) or struvite (26.7%). According to the retrospective study in 32 patients with NBD, Matlaga et al. [475] found renal stones were infectious in aetiology in 37.5% (12 struvite/carbonate apatite) and metabolic in 62.5%. All patients with struvite calculi were infected with urea-splitting bacteria.

Stone formation is usually related to IDC. Ke et al. [476] found bladder calculi with a nidus of hair that could have been introduced into the bladder accidentally during cystostomy catheter replacement. Over 17 years, 28% and 15% of 140 men were diagnosed with bladder and renal stones for a total of 59 and 25 episodes, respectively; bladder stone was more common in patients injured when aged > or = 24 years than in those injured when aged <24 years; patients with complete injury had a greater risk of renal stone formation than those with incomplete injury; renal stone was more common for patients with urethral catheterization than for those voiding spontaneously and for patients with bladder stone than for those without. According to the review by Ost and Lee [477], recurrent UTI, IDC, VUR, and immobilization hypercalciuria were major risk factors for the development of urolithiasis.

According to the retrospective study of Ozawa et al. [478], the incidence of bladder stone in urethral IDC was 1.11 times/100 months, cystostomy was 1.05, contemporary urethral IDC at night time only was 0.96, CIC-wet was 0.61, and CIC-dry was 0.21; and the urethral IDC group had significantly higher incidence of bladder stone than CIC-dry.

Linsenmeyer and Linsenmeyer [479] did a prospective cohort study by examination of IDC for encrustation at the time of removal for cystoscopy and found that 35% of 49 SCI individuals had bladder stones. Catheter encrustation was noted in 13 patients and 11 of them also had bladder stones i.e., a positive result for catheter encrustation had a positive result for bladder stones 85% of the time. Thirty-six individuals had no catheter encrustation; of these, 16% were found to have bladder stones.

**Bacteriuria**

In a retrospective study, Jayawardena and Midha [480] suggested that healthy asymptomatic SCI patients who came for annual evaluations should not have routine urine cultures if they are at low risk for UTIs; that is, <6 WBC/HPF in the urine and/or nitrite negative. Svensson et al. [481] studied the occurrence of bacteriuria in SCI patients with NBD who used CIC. Of 344 cultured samples, there were 285 isolates: coagulase-negative Staphylococci (27%), Enterococci (25%), Klebsiella spp. (19%), and Escherichia coli (12%); and bacteria grew at concentrations of 10^5-10^8 cfu/L, but only a few at 10^4 cfu/L. Levendorglu et al. [482] prospectively studied 27 SCI patients who applied CIC during the initial rehabilitation and 40 controls. E. coli was predominantly isolated from the urine and the urethral cultures of both female and male patients; there was concordance between urethra and urine cultures concerning the growth of E. coli; and Pseudomonas was colonized more in male patients. Waite et al. [483] found that among 77.1% of men with bacteriuria, uropathogens were shown in the perineum in 57.4% and in the urethra in 85.2%; differences in the occurrence of uropathogens in men with and without bacteriuria were statistically significant, and organisms were present in higher numbers in men with bacteriuria.

Fournier's gangrene is a recognised risk [484, 485]. Nambiar et al. [485] reported a C4 tetraplegia man presenting with a necrotic ulceration on the ventral aspect of the penis and scrotum of 2 days duration and diagnosed with fulminant Fournier gangrene. Vaidyanathan et al. [486] reported cases of a perineal haematoma due to warfarin and a tumour like of necrotic slough and debris in the bladder.

**Bladder cancer**

The reported prevalence is between 0.1 and 10%. The risk of bladder cancer is greater in SCI patients than in the general population [487, 488](58;59). The histological subtype is a squamous cell carcinoma in up to 80% of the cases. Symptoms are often nonspecific, such as recurrent tract urinary infections or incontinence, and diagnosis is often delayed. The risk factors are indwelling catheter, stones and recurrent urinary tract infections. It is recommended that patients with long term catheters should undergo surveillance cystoscopy and biopsies [489]. However, other groups have performed surveillance cystoscopies and have failed to detect any cancers [490, 491]. The cytology is often abnormal due to chronic inflammation.

**Quality of life (QoL)**

Oh et al. [492] conducted a prospective trial involving 132 SCI patients and 150 controls matched to age and sex to determine the psychological and social status of patients using CIC. According to health-related quality of life (HRQOL), the Medical Outcomes Study 36-Item Short-Form General Health Survey (SF-36) scores did not reveal any significant differences between the men and women in the patient group. When patients and controls were divided into two groups according to sex and age, the SF-36 scores of the patients were significantly lower than the controls across both sex and all age groups, other than the energy and vitality scale, the differences for which were not statistically significant in women and those younger than 50 years. Later Oh et al. [493] used the Beck Depression Inventory (BDI) with SCI patients on CIC and control group and found that the
average total BDI scores were 20.3+/ -1.0 in the patient group and 11.4+/ -0.5 in the control group, respectively; 69.6% of 102 the patients reported severe depression; female patients had a 3.8-fold higher risk of depression than male patients; and those who were unable to perform catheterization independently had a 4.6-fold higher risk of depression than those who were able to perform self-catheterization.

21.8. Treatment of NLUTD post SCI

The management is based on a multidisciplinary approach including urologists, rehabilitation physicians, physiotherapists, specialist nurses and often neurosurgeons and gastroenterologists. The goal of management of urinary tract in SCI patients is to preserve the upper urinary tract and renal function, to avoid urological complications and to improve patients’ quality of life. There are several guidelines for management of neuropathic bladder dysfunction after SCI related neurogenic bladder [458, 460].

The treatment of bladder dysfunction following a SCI can be divided according to the level of injury (Table 19).

21.9. Treatments to manage neurogenic detrusor overactivity

Medications

Antimuscarinics competitively inhibit acetylcholine at muscarinic receptors. This is associated with detrusor relaxation and lower intravesical pressures. Several antimuscarinics drugs are available, including oxybutynin, tolterodine, propiverine, trospium, solifenacin, darifenacin and fesoterodine. Only a few studies have assessed efficacy and safety of antimuscarinics in NDO [494]. They are broadly equally efficacious, with slightly different side effect profiles (dryness of the mouth, blurred vision for near objects, tachycardia, constipation and drowsiness).

Desmopressin, synthetic analogue of vasopressin, reduces the urine production and has been shown to be useful for the treatment of polyuria in spinal cord injury [495].

Vardenafil has been reported to decrease maximum detrusor pressure and improve maximum cystometric capacity [496].

Intermittent catheterisation (IC)

IC is recommended as the safest method of bladder emptying for SCI persons with NBD, especially for those who have sufficient hand skills or a willing carer to perform the catheterization. Mizuno et al. [497] reported a paraplegic woman using CIC for 27 years who had no complications and absence of UI due to underactive and normal capacity bladder. However SCI men on CIC, according to the retrospective comparative study of patients on CIC had a 7.0-fold higher risk of epididymo-orchitis.

Previously, recommended bladder training with CIC was time-dependent, however, some experienced bladder over-distention, especially in those with polyuria, that made an IC programme unmanageable [498]. Polliack et al. [499] compared volume-dependent IC (VDIC) following bladder volume measurement by a portable ultrasound device in SCI patients with time-dependent IC (TDIC). After 12-30 days follow-up, the number of IC per patient per day, the time required to perform volume measurements and IC, and
their total cost, were approximately 44, 49, and 46% lower in the VDIC group than in the TDIC group. UTI was found in three patients in the TDIC group and in none in the VDIC group.

In developed countries, there is a variety of urethral catheters available for SCI individuals. However, in reviewing all controlled trials comparing methods of using catheters in people with neurogenic bladder dysfunction, Jamison et al. [500] could not draw any conclusions regarding the use of different types of catheter. According to the multi-centre RCT of De Ridder et al. [501], 57 SCI male patients completed the 12-month study; 64% of those using the SpeediCath hydrophilic-coated catheter experienced 1 or more UTIs compared to 82% of those using the uncoated polyvinyl chloride (PVC) catheter. Twice as many patients in the SpeediCath group were free of UTI. According to another multi-centre study of Bjerklund Johansen et al. [502], of 378 patients (the mean duration of IC was 4.6 yr) who completed a 12-d trial of the novel hydrophilic catheter: LoFric Primo, 55.2% of the patients were happy to continue with the novel device, which was 74% of patients using standard PVC catheters and 36% of those using prelubricated PVC.

Ozawa et al. [478] applied a contemporary (reusable) balloon catheter at night time only. After a mean follow up of 41 months, the incidence of febrile episode was as follows: CIC-wet 3.36 times/100 months, IDC 2.96, cystostomy 1.26, the contemporary catheter 0.57, and CIC-dry 0.42. The incidence of febrile episode in CIC-wet and IDC were significantly higher than in CIC-dry. The incidence of bladder stone was as follows: IDC 1.11 times/100 months, cystostomy 1.05, the contemporary catheter 0.96, CIC-wet 0.61, and CIC-dry 0.21.

Botulinum toxin type A

This has revolutionised the treatment of NDO since being popularised by Schurch and colleagues [503]. Botulinum toxin is a potent neurotoxin produced by the gram-positive anaerobic bacterium Clostridium botulinum. In the bladder, botulinum toxin has a direct effect on the presynaptic vesicular release of acetylcholine but also on sensory pathways [504]. It is associated with a significant improvement in urinary continence (40–80% of patients became completely dry), a decrease in mean maximum detrusor pressure (which became less than 40 cmH2O in most studies), an increase in maximum bladder capacity and an improvement of patients’ quality of life. Injections are performed under local or general anaesthesia using flexible or rigid cystoscopy. Median duration of effect ranges from 7 to 9 months. This treatment has to be considered for individuals with SCI suffering from NDO with urinary incontinence refractory to oral antimuscarinics. The majority of patients have to perform CIC before and after botulinum injections. As a result of pivotal studies [505] a dose of 200U is licensed. A long term study has shown consistent results with repeated injections [506, 507].

Neuromodulation

Electrical stimulation has been used to manage bladder dysfunction in SCI since 1950s. Sacral neuromodulation (SNM) can be used as a second line treatment to control NDO in incomplete spinal cord injury. Sievert and colleagues [508] have demonstrated that use of SNM early in the injury recovery can prevent detrusor overactivity and maintain continence, in addition to preserving bladder capacity, reduced urinary infections and an improved bowel function. This was sustained for more than 2 years.

Sacral Anterior Root Stimulation

Sacral anterior root stimulation (SARS) with sacral deafferentation was first reported by Brindley in the 1970s [509], and results of small case series have been published [510, 511]. Detrusor overactivity is abolished by deafferentation. The electrodes are placed on the sacral anterior roots (S2, S3 and S4) to stimulate detrusor contraction, leading to bladder emptying. This can be used only in patients with complete lesions. The success rate is reported to be around 70%. In addition, this can be used to manage bowel dysfunction and achieve erections with separate programs. Importantly, men have to be informed that posterior rhizotomy will interrupt reflex erections.

Augmentation Cystoplasty

A number of procedures have been proposed to decrease detrusor overactivity and increase bladder capacity including detrusorotomy to subtrigonal cystectomy and ileal bladder substitution [512]. The one that has stood the test of time is clam cystoplasty, this technique involves bivalving the bladder and inserting a 20-30 centimetres of intestine segment in the defect.

The long term results indicate good control of overactivity and incontinence [513]. Generally, this is offered to patients who have failed to respond to botulinum toxin A injections or those with very low compliance bladder and in patients at risk for upper tract damage. If the patient has difficulty performing CIC via the urethra, a cutaneous diversion can be fashioned as well. Bladder augmentation is contraindicated in severe inflammatory bowel disease, significant pelvic irradiation related bowel damage and in patients who refuse CIC. These patients require life-long follow up. They can get a variety of problems including mucus production, persistent asymptomatic or symptomatic bacteriuria, stones, hypercholestermic metabolic acidosis, deterioration of renal function, bowel disturbances and cancer [514].

Cutaneous continent diversion

This is reserved for patients who cannot perform CIC via the native urethra because of congenital abnormalities, obesity, strictures and poor hand mobility. The principles are similar to bladder augmentation but a drainage channel is created between bladder and umbilicus or lower abdominal wall using either appendix (Mitrofanoff procedure) or ileum (Yang-
Monti procedure). Usually, the bladder outlet is left accessible as a safety mechanism. If the native bladder cannot be preserved, a substitution cystoplasty using ileum or colon can be performed. The complications are the same as described above for cystoplasty, with the additional risk of perforation, which can prove fatal if not diagnosed early.

Ileal conduit

This is generally reserved as a fall back option. It is a non-continent procedure, undertaken when there is severe motor and/or cognitive disability or in case of severe complications, alteration of renal function, or urethrocystaneous fistula. A cystectomy is often performed simultaneously as there is a risk of bladder cancer, pyocystis and spasticity. It can be performed laparoscopically [515]. The complications are mainly related to the uretero-ileal anastomosis, stomal hernia and pyelonephritis.

21.10. Treatments to overcome external sphincter dyssynergia

Medications

A number of medications have been proposed to overcome sphincter dyssynergia but the level of evidence is low. Baclofen can be used orally and intrathecally. High dosages are required with a significant risk of side-effects [516], including effects on erection and ejaculation [517]. The α-blockers that have been evaluated include indoramine, urapidil and tamsulosin. Alpha blockers have been reported to improve flow rate, increase voided volume and improve quality of life with a decrease in maximum urethral pressure. Abrams and colleagues reported that with tamsulosin treatment (0.4 and 0.8 mg once daily), 71% of patients reported an improvement of symptoms with good tolerance and decrease in dysreflexic symptoms [518]. Oral nitric oxide donors have been proposed to decrease urethral resistance in SCI patients [519].

Botulinum toxin A for sphincter

Botulinum toxin type A was first used to control DSD in the 1980s. It can be injected directly in the urethral striated sphincter. It is associated with an improvement in flow, with a decrease in postvoid residual volume and maximal urethral closure pressure. The benefits are variable, between 53 and 100 %, and lasting for 1 - 9 months [520]. These results have not been universally reproducible.

Sphincterotomy

This is a destructive procedure. The aim is to relieve the bladder outlet obstruction by cutting into the external urethral sphincter. It can be performed only in men because patients become incontinent and a condom has to be placed to collect urine. Endoscopic sphincterotomy was developed for the treatment of DSD in the 1950s. It has been demonstrated to be effective for both treatment of DSD and the prevention of genitourinary complications. However, this technique is associated with a failure rate of 15–50%, erectile dysfunction in 4–40%, perioperative complications such as septicaemia and haemorrhage in 5% of cases, and is irreversible [521]. Balloon dilatation has also been explored but is not advocated due to high failure rate.
Urethral Stents

These were popularized in the 1990s. There are 2 varieties available: permanent and temporary stents. The temporary stents could be used as a test to ensure the acceptability of the voiding method, verify the efficacy on bladder emptying and give the patient time to think regarding a definite management strategy. It can also be used as a reversible treatment in patients with a transient problem whilst awaiting for recovery or rehabilitation of the upper limbs. Following temporary urethral sphincter stenting, 70% of the patients choose a permanent one [522].

The long-term complications with permanent stents (Urolume) are stent encrustation, migration, bladder neck obstruction and if required, difficult stent removal [523]. The complications with temporary stents (Memokath) include a higher rate of stent migration, stent blockage with stone or calcification and recurrent urinary tract infections [524].

21.11. Bladder emptying in sacral injuries

Pharmacotherapy

There are no established medications to facilitate bladder emptying. Bethanechol chloride has been used with only limited success, and bothersome side effects including flushing, headaches and diarrhoea.

Clean intermittent self-catheterization

This is the mainstay to facilitate effective bladder emptying in an underactive detrusor. It is not a difficult technique to master but requires support from healthcare professionals. Generally, a size 14F catheter is used in males and a 12F in females. A variety of catheters are available and it is not uncommon for patients to try 2 or more types of catheter before finding the most convenient one.

Valsalva or crede maneuver

This entails emptying the bladder by increasing the intra-abdominal pressure. This can be performed by either valsalva technique or bending forward and compressing the lower abdomen. This is not an ideal method but for some SCI patients works quite well, if there is no outflow obstruction. In the absence of recurrent UTI this can be an acceptable technique for bladder emptying in some patients.

21.12. Treatments to improve sphincter function

Pharmacotherapy

These are no longer used as there has been a very limited benefit with their use. The drugs used include pseudoephedrine and phenylpropanolamine. Duloxetine has been shown to increase urethral resistance. Although some studies have shown improvement in continence rates this is generally limited to mild type with quite bothersome gastrointestinal side effects. It has not been specifically tried in neuropathic sphincter incontinence.

Bulking agent injection

This is a minimally invasive technique. It is performed endoscopically. Initially collagen based beads were implanted but they degraded over time. Currently, hydropolymers or silicone based substances (Macroplastique-polydimethylsiloxane) are used. They are effective in 60%-80% of cases but the effects are short lasting and quite often multiple injections are required [526]. The main advantage of this therapy is

Figure 5: Quadriplegia patients with a temporary urethral sphincter stent (A) and a permanent urethral sphincter stent (B) Adapted from (525)
being minimally invasive and it does not prevent further treatment.

**Slings**

These are used in females. They can be either autologous or synthetic. They are placed vaginally in the mid urethra. At present the synthetic slings are gaining popularity [527]. The reported efficacy is about 70%. The complications include difficulty in self catheterisation and development of de novo detrusor overactivity. Further research is needed to understand outcomes and risks.

**Artificial urinary sphincter**

This is the most effective method of achieving continence both in males and females, although the success rate is lower and complications higher than in non SCI patients. The complications include mechanical failure, erosion of the cuff or infection requiring removal of the implant.

**Bladder neck closure**

This is generally the last resort when other methods have failed. Bladder neck closure is usually performed when the urethra is almost destroyed- generally as a result of long-term catheterization. It is mainly employed in females, as sheath collection of urine cannot be employed, and can be performed either vaginally or abdominally. The initial success rate is about 50%, as the tissues are scarred secondary to infections and trauma and another 25% can be salvaged after a second procedure.

**21.13. Prevention of UTI**

According to 2 double blinded, placebo controlled RCTs [528, 529] studying the effectiveness of cranberry supplement (400-mg cranberry 3 times a day for 4 weeks and 2 g per day for 6 months, at preventing UTI in SCI individuals with NBD, bacterial count, white blood cell (WBC) count, bacterial counts in urine, urinary pH or episodes of symptomatic UTI did not differ between the placebo and cranberry groups. According to another RCT to determine the effectiveness of methenamine hippurate (MH) (1 g twice-daily) and of cranberry (800 mg twice-daily), MH as well as cranberry did not have a significantly longer UTI-free period compared to placebo [530]. In addition, when taking phosphorus supplementation, there was no significant change in urine pH during the 2-week period compared to when the patient was off supplementation [531].

**Antibiotic prophylaxis**

Some centres advocate antibiotic prophylaxis for recurrent UTI [532]. Salomon determined the safety and efficacy of a weekly oral cyclic antibiotic (WOCA) regimen consisting of the alternate administration of an antibiotic once per week over a period of at least 2 years to prevent UTI in SCI adult patients; symptomatic UTI dropped from 9.4 to 1.8 per patient-year, no severe adverse events and no new cases of colonization with multiple drug resistant bacteria were reported [533].

**Bladder irrigation**

Waites and colleagues [534] conducted a randomized, double-blind comparison of twice daily bladder irrigation using 1 of 3 different solutions for 8 weeks with 30 mL of (a) sterile saline, (b) acetic acid, or (c) neomycin-polymyxin solution in community-residing persons with NBD who used IDC. Results showed that the 3 irrigants had no detectable effect on the degree of bacteriuria or pyuria. There was no significant development of resistance to oral antimicrobials beyond what was observed at baseline, but all groups had a significant increase in urinary pH.

**Treatment of UTI**

Bycroft and colleagues [532] found few centres routinely treating asymptomatic UTI in SCI individuals using catheters; and the range of recommended duration of treatment for symptomatic UTI was 3-14 days (mean 6.3).

**Guidance for further research**

Most of the papers relating to epidemiology and pathology of urinary incontinence in spinal cord lesion patients were case series; few papers were clinical trials or RCTs relating to pharmacological treatments. As UTI is a common complication among SCI individuals, further RCT should be done to prove whether a weekly oral cyclic antibiotic for UTI prophylaxis is effective, as well as optimal dosage, effectiveness and safety of bladder relaxants. Regarding types of catheter, RCT should be conducted to prove whether to re-use of catheters is safe. In addition, to make an automatic, event-driven electrical stimulation for the treatment of NDO suitable in a clinical setting further investigations are needed.

According to cohort studies [304, 450, 535] there was evolution of bladder management by time, outcomes and complications in both paediatric onset and adult onset SCI; treatment was modified in a substantial proportion of patients over the observation periods. Regular urodynamic follow-up is warranted for protection of the upper urinary tract (UUT) and maintenance of continence, however, urological follow-up practice varied: in Bochum, Germany, follow-up included urodynamic evaluation, sonography of the UUT and LUT, urine examination, and evaluation of renal function and treatment modifications were based on the urodynamic findings [536]; in the Spinal Injuries Units of U.K., all units performed routine upper tract screening, ranging from annually to every 3 years [532].

According to the retrospective chart review of Sepahpanah et al. [537], the 24-hour creatinine clearance (CCr) was highly variable from one evaluation to the next and the within-subject standard deviation (SD)
for Ccr was 25.9mL/min; for all comparisons of repeatability, variability, and reliability, serum creatinine was superior to Ccr, and renal ultrasound results and post-void residuals were the major factors in changing medical management with regard to renal function preservation. To determine the accuracy of bladder stone detection by abdominal x-rays of individuals with SCI, 13/62 (21%) of stones found during cystoscopy were detected by the x-ray; the detection by x-ray was 33% for stones 1.0 cm to 1.49 cm, 33% for stones 1.5 cm to 1.9 cm, and 54% for stones > or = 2.0 cm; and 57% for volumes > or = 1.0 cm³ [474]. In addition, long-term SCI individual with aged 50 to 60 or more should be screened for prostate and bladder cancer [538, 539]; however, PSA cannot be used in patients with IDC and diagnosis should be based on prostatic biopsies [539].

Although SCI patients need lifelong follow-up, no studies have been done on the optimum frequency of follow-up to determine the frequency and the investigations required to achieve this goal. There is an urgent need to undertake prospective evaluation of SCI patients to draw evidence based conclusions for optimal follow-up protocols.

Conclusions

- The profile of muscarinic receptors in the bladder may be altered in patients with neurological disease (LOE 3)
- Skin sympathetic responses and motor evoked potentials may help assess autonomic and somatomotor pathways of the lower urinary tract. (LOE 3)
- In patients with neurological disease, individuals often change their method of bladder management, influenced by a range of factors including renal function. (LOE 2)
- Long-term urethral indwelling catheterization leads to bladder and urethral complications (LOE 3)
- Encrustation of a catheter is predictive of bladder stones; abdominal x-ray is not an adequate method to detect bladder stones (LOE 3)
- Volume-dependent intermittent catheterization may offer advantages compared with time-dependent intermittent catheterization. (LOE 3)
- Combined clean intermittent catheterization during the day time with indwelling contemporary balloon catheter at night time showed less urinary infection than clean intermittent catheterization with incontinence and permanent urethral indwelling catheterization. (LOE 3)
- Increased dosage of Tolterodine or Trospium gave a better effect to control neurogenic detrusor overactivity with incontinence. (LOE 2)
- Urethral flora may be a bacterial source for the development of urinary infection. (LOE 3)
- Low bacterial concentrations in the urine (<10⁶cfu/L) of patients on intermittent catheterization might be due to contamination. (LOE 3)
- Cranberry extract, methenamine hippurate or phosphorus supplements were not found to be effective in acidifying urine or preventing urinary tract infection. (LOE 2)
- A weekly oral cyclic antibiotic seemed efficacious in preventing UTI. (LOE 3)
- Bladder irrigation was not effective in reducing bacteriuria in persons with neurogenic bladder using indwelling catheterization. (LOE 2)

Recommendations

- Regular urological monitoring, at least annually, is appropriate to early detect complications and to adjust bladder management in patients with neurogenic bladder dysfunction. (A/B)
- Recommend urine culture only if there is high risk of current urinary tract infection. (C)
- Routinely inspect catheters for encrustation, as an early indicator of risk of bladder stone formation. (C)
- Cystoscopy is necessary if bladder stones are suspected. (C)
- Adjust urinary tract management according to results of urological evaluation and emergence of complications. (B)
- Clear diagnosis of DSD requires VCUG facilitated by EMG. (C)
- Clear instructions on catheter management can help to reduce risk of complications. (B)
- Dosages of bladder relaxant drugs in excess of the licensed doses have been used in attempting to control neurogenic detrusor overactivity and incontinence; if side-effects cannot be tolerated, intravesical botulinum toxin injection are effective. (B)

21.15. Faecal incontinence in SCI

Epidemiology and prevalence

According to Dvorak and colleagues [540], in patients with central cord syndrome, bowel and bladder continence was reported by 81% in those with American Spinal Injury Association (ASIA) motor score improvement from a mean of 58.7 at injury to a mean of 92.3 at follow-up. However, neurogenic bowel dysfunction (NBoD) is common among spinal cord injured (SCI) patients. From 2004 to 2007, there were multiple studies reporting epidemiology of NBoD in chronic spinal cord injured (SCI), from various countries (see section below for details). Apart from SCI, there were
other spinal cord lesions (SCL) that cause NBoD, such as tumours (e.g. a conus medullaris ependymoma and filum terminale lipoma [541]; a clear cell menigioma along the thoracic and lumbar levels [542], neuroblastoma [543]; venous congestive myeloopathy, mostly at thoracolumbar and/or conus medullaris levels [544]; and iatrogenic [545]. Tanaka reported 77% of 22 transverse myelitis (average age at onset 8.8 years, mean follow-up 7.1 years) had NBoD [546].

21.16. Pathology and disease specific lower gastrointestinal (LGIT) problems

According to electromyography (EMG) of external anal sphincter (EAS), 18 and 22 of 64 patients with cauda equina or conus medullaris lesions had bilateral and unilateral EMG abnormalities [552]. Using anorectal manometry, the maximum anal resting pressure of a 26-lumbosacral SCI patients group with mixed symptoms of constipation and/or FI was slightly lower than that of a 13-normal volunteers control group [553]. During defection, 88.5% of the patients but 7.7% of the control group significantly showed pelvic floor dysfunction (PFD). Rectoanal inhibitory reflex (RAIR) was identified in both groups. The rectal volume for sustained relaxation of the anal sphincter tone in the lumbosacral SCI patient group was significantly higher than the control group. The mean rectal volume to generate the first sensation was significantly higher in SCI patients in the control group. Regarding constipation, its association with level of injury was supported by many studies, i.e. upper motor neuron vs lower motor neuron NBoD. Decreased colonic pressure activity was found during sleep in SCI individuals and may contribute to delayed colon transit time after SCI [554].

Furlan and Fehlings [555] examined the characteristics of the top 100 most frequently cited articles (so-called “citation classics”) on traumatic SCI that were published between 1986 and 2003, and compared this selected professional literature with the consumers’ perspective on the key issues in SCI research. From the SCI consumers’ perspective, the areas of greatest interest included motor function, bowel and bladder control, sexual function, and pain. Motor function was the leading topic in the matching list between professional literature and consumers’ perspective. According to Anderson’s quality of life (QOL) survey of the SCI population [556], regaining arm and hand function was most important to quadriplegics, whereas regaining sexual function was the highest priority for paraplegics; and improving bladder and bowel function was of shared importance to both injury groups. Later, according to a web-based survey of 286 SCI patients aged 18 years or older, bladder and bowel concerns during sexual activity were not strong enough to deter the majority of the population from engaging in sexual activity; however, bladder and/or bowel incontinence during sexual activity was a highly significant concern in women with SCI. In addition, the occurrence of autonomic dysreflexia (AD) during typical bladder or bowel care was a
significant variable predicting the occurrence and distress of AD during sexual activity [557].

FI had 10 times more impact on QOL than those with no FI and NBoD had significant impact on their QOL [558]. They had significantly lower Gastrointestinal QOL score as compared with the normal persons. There were no statistically significant differences in satisfaction or QOL between those with colostomies and those with traditional bowel care programs; however, 55.7% of those with colostomies and 41.7% of those without colostomies were very unsatisfied with their bowel care program [559].

**Conservative bowel management**

According to the "Neurogenic Bowel Management in Adults with Spinal Cord Injury" Clinical Practice Guideline published by the Consortium for Spinal Cord Medicine, rectal stimulations help assist elimination of the stool: mechanical stimulations – digital rectal stimulation (DRS) and manual evacuation; and chemical stimulations – suppository and mini-enema (liquid suppository). Korsten et al. [560] used a manometric catheter to assess colonic motility at baseline, during DRS, and after DRS and evacuation of barium oatmeal paste in six subjects with SCI. Their results showed that manometric changes in response to DRS were accompanied by expulsion of barium oatmeal paste in every subject by the fifth DRS. In patients with cervical SCI, a significant increase in systolic blood pressure (BP) was induced by insertion of rectal medications and persisted during additional DRS, and AD induced by the manual removal of stool has been reported [561, 562]; however, systolic BP recovered to pre-program values within 5 min after defecation [561].

Uchikawa and colleagues [563] reported a successful bowel movement in 75% of 20 SCI patients by using a modified washing toilet seat equipped with a camera monitor and an electronic bidet to facilitate precise hitting of the anal area with water streams to stimulate bowel movement for a maximum of 30 minutes. Regarding transanal irrigation, a randomised study showed improvement in constipation, FI and symptom-related QOL in SCI individuals [564].

Push up, abdominal massage and a forward-leaning position may aid evacuation by increasing abdominal pressure. Ayaş et al. [565] studied patients with SCI and showed that abdominal massage gave positive effects – increase in frequency of defecation per week, decrease in total colonic transit time and lesser FI.

Oral medications to enhance bowel movement have been used, but evidence of efficacy is lacking. Cisapride does not seem to have clinically useful effects in people with SCI [566]. Korsten et al. [567] did a randomized, blinded design, to test the efficacy of neostigmine in SCI persons with defecation difficulty by infusing one of three intravenous infusates (normal saline, 2 mg neostigmine, or 2 mg neostigmine + 0.4 mg glycopyrrolate – to prevent neostigmine's muscarinic effects) on separate days and determining bowel evacuation of the barium paste, heart rate and airway resistance. Their results indicated that both neostigmine and neostigmine + glycopyrrolate resulted in prompt bowel evacuation. Potentially, neostigmine may be administered by other routes [568].

**21.17. Guidance for further research**

Most of the studies reported were case series and used different definitions of faecal incontinence and constipation. Therefore further research should be based on internationally acceptable definitions so that they can be compared. In addition, RCTs on rectal or anal stimulations, both mechanical and chemical, as well as medications promoting bowel movement are needed.

**Conclusions**

- Constipation is more common than faecal incontinence among people with established SCI (LOE 3)
- Constipation is more common in those with preserved sacral reflexes, whereas faecal incontinence is more common in those without sacral reflexes. (LOE 3)
- Faecal incontinence has impact on the QOL of SCI individual and is a substantial concern for women with SCI during sexual activity (LOE 3)
- Digital rectal stimulations aid bowel evacuation in individuals with SCI, in part by increasing left-side colonic motility (LOE 3)
- Transanal irrigation with water improves constipation and quality of life in individuals with SCI (LOE 2)
- Abdominal massage may be effective in enhancing bowel movement and defecation (LOE 3)
- Anal stimulation by water stream may be effective in stimulating bowel movement and shortening bowel care time (LOE)

**Recommendations**

- Encourage adherence to the clinical practice guidelines on neurogenic bowel management in adults with spinal cord injury (A)
- Apply mechanical stimulation e.g. digital rectal stimulation, to aid bowel evacuation especially in those with preserved sacral reflexes (B)
- Use chemical stimulants when mechanical stimulation fails (C)
- Beware of autonomic dysreflexia during bowel care, especially in those with a high SCI lesion (C)
21.18. Sexuality

The majority of SCI patients (> 60 %) have alterations in sexual functioning. The degree of sexual dysfunction depends on the level and completeness of injury.

Male Sexual dysfunction

There is a significant impact of SCI on male sexual function. Erectile dysfunction occurs in up to 50 % of the patients. Less than 10% can ejaculate spontaneously. The patients with complete lesions above L2 level generally can have reflex and psychogenic erections. Patients with a complete lesion below S2 can generally have psychogenic erections. They have no reflex erections and ejaculation is rare.

As for non-SCI population, first-line treatment of erectile dysfunction is based on phosphodiesterase type-5 (PDE5) inhibitors. The three PDE5 inhibitors currently available are quite effective in treating erectile dysfunction in this patient group. Most of studies reporting the impact of PDE5 inhibitors in spinal cord injury used sildenafil. The reported erectile function improvement with sildenafil is more than 90% [569]. These treatments are also well-tolerated, with mild to moderate side effects including headache and facial flushing.

In case of failure of PDE5 inhibitors, the majority of patients are dissatisfied with a vacuum erection device, as they find it difficult to use- especially in patients with low hand dexterity. Intracavernous injections of vasoactive substances are effective, with a reported intercourse rate of up to 50 %. Priapism is not an uncommon occurrence, though the duration is variable. The injection can be performed by the partner in case of limited manual dexterity. When all conservative treatments fail, a penile prosthesis can be implanted. Like other implants the success rate is lower and complications higher in this patient group.

The majority of SCI patients cannot ejaculate. The most commonly employed technique to obtain semen is vibro-ejaculation. This is performed by a specially designed vibrator. The vibrator’s plate is placed underneath glans penis and the vibrations are performed for 1-3 minutes. This is only effective in lesions above T10, as an intact spinal arc is required. The success rate is 60%-80% of cases. It can cause retrograde ejaculation. The complications include bruising and autonomic dysreflexia. In unsuccessful cases and for all patients with a lower motor neuron lesion, the ejaculate can be obtained by electroejaculation. This is performed with a probe in the rectum and stimulating the seminal vesicles with electric current. The success rate is around 98%. This is an invasive method and there is a risk of rectal injury. As it can be quite painful, it is generally performed under general anaesthesia or sedation for patients with an incomplete lesion.

Fertility in men is impaired after SCI due to erectile dysfunction, ejaculatory failure and abnormal semen characteristics. Alteration of sperm is promoted by urinary tract and genital infections, hormonal and hypothalamic-pituitary testicular axis abnormality, local temperature change and sympathetic nerve alteration [570]. Sperm retrieval is performed with vibro or electroejaculation. In the majority of cases, assisted conception techniques are required to achieve conception.

Conclusions

- There is a significant impact of SCI on male sexual function
- Erectile dysfunction occurs in up to 50 % of the patients
- Less than 10% can ejaculate spontaneously
- Patients with complete lesions above L2 can have reflex & psychogenic erections
- Patients with a complete lesion below S2 have psychogenic erections.

Recommendations

- Oral PDE5Is are the recommended first-line medical treatment (GR A)
- Intracavernous injections of vasoactive drugs (alone or in combination) are the recommended second-line medical treatment (GR A)
- Mechanical devices such as vacuum devices and rings can be effective and may be offered to patients (GR B)
- Vibrostimulation and transrectal electroejaculation are effective methods of sperm retrieval (GR B)

Female sexual dysfunction in SCI

There are only a few reports on female sexual dysfunction after SCI. The level and completeness of spinal-cord injury determines the preservation of psychogenic and reflex lubrication. Women with complete lesion above L2 have reflex lubrication. Those with a complete lesion between L2 and S2 have psychogenic and reflex lubrication and those with a complete lesion below S2 have psychogenic lubrication. Clitoral stimulation can lead to orgasm in patients with S2-S5 lesions.

It has been shown that all the domains of sexual function are altered in SCI women. Only 50% are able to achieve orgasm, with time to orgasm significantly increased. Female sexual function can also be altered by bladder and bowel incontinence and spasticity. Sildenafil has been reported to have a positive effect...
on sexual dysfunction in a pilot study, with no associated adverse events [571].

**Recommendation**
- There is currently no effective medical therapy for the treatment of neurogenic sexual dysfunction in women (GR A)

The fertility in SCI women is not altered as compared to healthy individuals. The first months after injury are associated with amenorrhea but menstruations usually resume relatively soon. All contraceptive methods can be used.

Pregnancy in SCI women can be challenging. There can be issues with premature cervical dilatation and premature labour. The management of urinary tract infections and detrusor overactivity can be difficult as Botulimum toxin A injections are contraindicated in pregnancy. There are no guidelines on the use of antimuscarinics during pregnancy and the impact of these medications on the foetus has not been studied. Clean intermittent catheterization is maintained and often an increased number of catheters are required per day.

The management of labour is another problem. In women with an injury at level T6 and above there is an increased risk of developing autonomic dysreflexia. These women require frequent check-ups and early hospitalization if necessary. However, most women will have successful vaginal deliveries. SCI in itself does not constitute an indication for caesarean section. Probably the most important aspect of the management is involvement of a specialized multidisciplinary team.

**Recommendation**
- Management of fertility, pregnancy and delivery requires a multidisciplinary approach tailored to individual patient needs and preferences (GR A)

### 22. SPINA BIFIDA

#### 22.1. Urinary incontinence

Spina bifida is one of the most common birth defects with an annual incidence of about 0.35 per 1000 live births in the US [572], potentially involving all levels of the spinal column but most commonly the lumbo-sacral area. Associated (Arnold-)Chiari malformation is seen in more than 80% of children, often requiring ventriculo-peritoneal shunting of cerebrospinal fluid. Ingestion of folic acid prior to conception and during the first trimester of pregnancy has significantly reduced the incidence of this problem and other associated neural tube defects. The neurologic defect produced is quite variable and cannot be totally predicted by the vertebral level of the lesion. Additionally the fibrosis associated with spine closure may tether the cord. Subsequent growth of the infant or child may produce further neurologic problems, manifesting as changes in bladder, bowel and lower extremity function.

The incidence of urinary tract dysfunction in spina bifida is not absolutely known, but most studies suggest it is very high (>90%). Similarly, anorectal dysfunction is very common, but its exact incidence has not been reported.

The two major neuro-urological consequences in patients with spina bifida are urinary incontinence and hydrourteronephrosis leading to renal failure, which can occur early or later in life. There are many studies documenting a variety of urodynamic findings of spina bifida patients such as detrusor overactivity, detrusor underactivity, low compliance, detrusor sphincter dyssynergia or static/ fixed external urethral sphincter [410, 414, 572, 573]

In the past, much attention has been directed at the significance of dyssynergia between the external sphincter and the detrusor, and the associated deterioration of the upper renal tracts in these patients. With the increasing use of IC, more emphasis has been placed on the pressure the bladder is able to generate prior to leaking as a prognostic factor in predicting upper tract deterioration.

Urodynamics is the cornerstone in the diagnosis of urinary tract dysfunction in patients with spina bifida. Urodynamic findings may predict the patients at risk of upper tract deterioration. Controversy continues regarding when to initiate these studies: as soon as possible after back closure; at the first sign of upper tract changes; or before considering management of incontinence. The preponderence of opinion suggests earlier diagnosis of potentially unfavourable factors is advisable.

As hydronephrosis and vesico-ureteric reflux are a consequence of detrusor dysfunction, synchronous fluoroscopic evaluation of the urinary tract is advisable at the time of urodynamics, i.e. video-urodynamics. Similarly, renal ultrasound has become an invaluable routine serial evaluation in these patients, assessing renal growth, development of scarring and, most importantly, hydrourteronephrosis. Repeat urodynamics and ultrasound have a relevant role in this patient population, however, recommendations for timing and frequency of these studies still need to be elucidated. Although renal scans are routinely used, especially in the spina bifida patient with hydronephrosis, the exact role of this study in these patients is not clear.

Urologic treatment depends on the age of the patient and the nature of the urinary tract dysfunction as characterized by urodynamics. Targeting the primary urological abnormality (the dysfunctional and usually poorly compliant bladder) allows implementation of effective treatments, including regular IC, in order to
preserve upper renal tract function and to achieve urinary continence. Associated postural abnormalities may complicate both conservative and interventional therapies.

The mainstay of treatment is IC and antimuscarinic medication. As continence is not at issue in the neonate and infant, treatment may be postponed, unless upper tract changes are present. Some evidence exists pointing to the fact that early initiation of treatment may prevent subsequent deleterious bladder changes. Although intradetrusor onabotulinumtoxinA injections have become an established treatment for refractory neurogenic detrusor overactivity incontinence [410, 414], the value in patients with spina bifida is unclear and there is a lack of high evidence level studies [574]. Surgical treatments should be reserved for patients refractory to conservative treatments, depending on the type of urinary tract dysfunction, and do not differ from the procedures for the general neuro-urological patients [410, 414].

In adult patients who in childhood underwent bladder augmentation surgery, it is thought that there is an increased risk of a development of bladder malignancies. However, this assumption is not supported by high level evidence and screening for bladder malignancies in spina bifida patients with an augmented bladder seems not to be cost-effective (LOE2) [572].

Lumbar-to-sacral nerve re-routing was suggested as an approach to restore voiding and bowel movement in spina bifida patients [575] (LOE3). Another interesting treatment option is fetal surgery, but in utero closure of spina bifida seems not to improve lower urinary tract function [576, 577] (LOE3).

Management of incontinence and/or upper tract deterioration mirrors the treatment of neurogenic lower urinary tract dysfunction. Variations in this algorithm include the use of vesicostomy in the younger child who has failed conservative measures and has evidence of deteriorating upper tracts. External sphincterotomy has no routine place in the management of these patients and the use of the appendico-vesicostomy in continent LUT reconstruction (Mitrofanoff) has increased. Most studies on surgical management of neurogenic lower urinary tract dysfunction are descriptive (LOE 4) at best.

Data from adult and paediatric surveys show renal damage to be the single most prevalent cause of morbidity and mortality; even in children, 30-40% exhibit evidence of renal damage. Additional factors such as chronic infection and stone formation will then render the kidney more vulnerable to progressive loss of renal mass and subsequent chronic renal failure. Renal transplantation is now considered the optimal treatment for end-stage renal disease in all age groups. Although more prone to complications, recent data on patients with spina bifida or severely abnormal LUTs demonstrate good patient and graft outcomes [578] (LOE 3).

Guidance for further research

Further clarification of the role of fetal surgery to repair the neural tube defect is required, especially in terms of prevention of damage to the lower urinary tract. Similarly the role of early intervention, conservative or surgical, needs to be understood better. The timing of surgical intervention needs further study, as well as better quality of life assessments and risk/benefit analyses of LUT reconstructive procedures. The development of a tissue-engineered substitute for cystoplasty and nerve re-routing is being studied. Finally, the fate of the adult spina bifida patients, especially those who have undergone reconstruction, needs to be documented.

Conclusions

- Spina bifida is one of the most common birth defects (LOE 1)
- Incidence is decreased by appropriately-timed folate ingestion during pregnancy (LOE 2)
- Most patients have lower urinary tract dysfunction which can lead to incontinence and/or upper tract deterioration (LOE 3)
- The majority will derive significant benefit from conservative measures (LOE 3)

Recommendations

- Regular surveillance with urodynamics and renal ultrasound is mandatory from infancy. However the exact timing is not defined. One must observe the general rules for neurogenic lower urinary tract dysfunction (B)
- Early initiation of conservative measures (clean intermittent catheterization, antimuscarinic medication) generally provides protection of the upper urinary tract (B)
- The role of new treatment options, for example, biotechnology and nerve surgery, needs to be evaluated (C)
- Extensive surgery is reserved for failed conservative treatment (B)

Bowel problems

Voluntary control of defecation requires rectal sensation, peristalsis and adequate anorectal sphincter function. Neurological defects in patients with spinal lesions may affect one or more of these components, resulting in different types of defecation disorders: fecal incontinence, chronic constipation or both. Incontinence is one of the major stigmas affecting patients born with myelomeningocele [579]. Bowel dysfunction occurs in most children with spinal cord impairment from disease or injury.

Although many different regimens have been used to manage this problem, none has had universal success. Behavioural modification and laxatives failed to
achieve an acceptable result because of the persistence of soiling. A small dose of laxatives alone accomplished nothing while administering a large dose to an incontinent patient only resulted in profound embarrassment [580]. Biofeedback was introduced for use in children with intact rectal sensation, but recent trials have reported less encouraging results. “Digital disimpaction” is unpleasant to perform and only succeeds in emptying the distal rectal ampulla.

Bearing in mind that few of these patients can resist the push of peristalsis, the most effective therapy is complete emptying of the colon, since it takes at least 24–48 h to refill again. This can be achieved nowadays by two ways: retrograde colonic enema (RCE) using a special balloon catheter, or an operative procedure which allows an antegrade continence enema (ACE). In neurological fecal incontinence, standard enemas are difficult, if not impossible, to administer, because there is inability to retain the enema which flows out involuntarily through the weak anus during its instillation. Therefore a catheter-based RCE system has been developed by industry, the application of which can be applied either by the parents or even by children over the age of 7–8 years. Not all children tolerate this procedure, as colonic peristalsis creates pains in some of them. However the reported results are good according to Eire et al. [581]. Shandling et al. [582] reported 100% success in using the enema continent catheter in the management of patients with spina bifida. These authors regard the RCE as one of the best conservative methods of treatment for relieving fecal incontinence originating from myelomeningocele and other neurological problems.

The impact of ACE surgery in the management of patients with myelomeningocele was analysed by Lemelle et al. [579]. 47 patients were treated with ACE, of whom 41 still used the method at a mean time of 4.1 ± 1.9 years after the ACE operation. With ACE, faecal incontinence was significantly improved compared with conventional management, and neither retrograde rectal enema nor digital extraction were required. In most cases, ACE was performed using the appendix or the caecum. Six patients (12.8%) stopped using the ACE for various reasons, from conduit problems due to stomal stenosis or catheterization difficulties, lack of motivation or “too long time to empty the enema”. ACE stoma surgery was applied before, concomitantly or after urinary incontinence surgery in 5, 27 and 10 cases respectively. Enemas were performed at most three times a week, and tap water was used in the majority of patients. Mean volume for ACE was 1.2 L (range 0.25–3.0 L). Mean enema time for colonic washout with ACE was 50 ± 19 min (range 15–90 min), however mean washout duration for ACE tended to be shorter with implantation of the conduit on the left-segment of the colon.

Casale et al. [583] were unable to find any differences in the continence rate or stomal complications between total reconstruction (concurrent ACE and continent urine stoma) or staged reconstruction. However, because of shared pathology, the authors believe that most patients benefit from intervention in both the gastrointestinal and the genitourinary tract. Therefore, a major advantage of total continence reconstruction is avoidance of the morbidity of a second major surgical procedure (LOE 3). Nevertheless, conventional treatment should be tested first, and the efficacy of RCE may be a predictor of the efficacy of ACE on bowel management. Moreover, percutaneous endoscopic insertion is fully reversible and does not present drawbacks potentially encountered with the catheterizable conduit [579]. Nevertheless, experience with the Malone procedure has proved that a suitable continent and catheterizable conduit can be obtained with an appropriate technique. In selected and motivated patients, and with the help of a specialist nurse providing close support in the postoperative period, surgical ACE procedure might be preferred according to the surgeon’s experience.

As no absolute indication has been defined for ACE, other criteria should be used to evaluate clinical outcome of bowel management, including health – related quality of life (HRQoL). The development of a disease-specific HRQoL measure for use with myelomeningocele has been proposed by Parkin et al. [584]. HRQoL assessment should be performed prospectively when ACE produce is planned and performed during pre and post-operative periods. According to Eire et al. [581] ACE procedure and RCE can be the best options for achieving the best social integration. For wheelchair users and other selected patients, the ACE (being faster and easier) is better than the RCE, which needs some help in its use [581, 585].

Sacral neuromodulation has been described also in the therapy of these patients, but the persistence of continence control and tolerance of the patient need to be evaluated for a prolonged period of time. Sacral neuromodulation may only be successful in a small selected number of patients, in whom preserved anatomy of the sacral nerves permits placement of the electrodes on the sacral nerves [586].

Conclusions

- Neurologic bowel dysfunction and bowel problems, including fecal incontinence and constipation, are prevalent among myelomeningocele patients (LOE 3).
- Fecal incontinence and methods of bowel care affect the QoL and social activities of myelomeningocele patients (LOE 3).
- The main goal is to empty the colon as much as possible, to achieve continence during the subsequent 24–48 hours. This can be achieved by retrograde colonic enema using a special balloon catheter, or by an operative procedure which allows an antegrade continence enema (ACE) (LOE 3).
23. DIABETES MELLITUS

23.1. Epidemiology

Diabetes mellitus (DM) has a prevalence of 1-6% in the United States, depending on the specific criteria utilized to identify the disease. The prevalence is significantly higher amongst the elderly: 21.8% of residents of nursing homes suffered from DM in a multinational eight countries study (the Services and Health for Elderly in Long TERm care (SHELTER) project) [587].

Overall, up to 59% of diabetic patients will report urinary symptoms, while 75-100% of those with evidence of peripheral neuropathy will develop NLUTD [588] [589]. The classic "diabetic cystopathy" (impaired bladder sensation, increased capacity, increased post void residual) has been estimated to occur in 43% to 87% of insulin-dependent diabetics, with no sex or age differences [590]. Typically, severely impaired bladder emptying is thought to occur in patients with more long-standing poorly controlled diabetes. It is also described in about 25% of diabetic patients on oral hypoglycemic treatment [591]. A Scandinavian study showed that in patients who have had diabetes for 10 years, the prevalence of diabetic cystopathy in those who were insulin-dependent was 2 to 4 per 1000 and in those on oral hypoglycemic agents was 1 to 3 per 1000. The correlation between diabetic cystopathy and peripheral neuropathy ranged from 75% to 100%. Nephropathy was seen in 30% to 40% of cases [589] (LOE 3). Urodynamic studies have noted a spectrum of findings in DM; those presenting relatively late with severe LUTS have a higher likelihood of impaired bladder sensation, detrusor underactivity and impaired emptying, while those investigated earlier are more likely to have detrusor overactivity and urgency incontinence [592].

23.2. Diabetes and Urinary incontinence

Large prospective studies are now available (the Diabetes Control and Complications Trial (DCCT; 1983-1993) and its observational follow-up study, the Epidemiology of Diabetes Interventions and Complications (EDIC; 1994- present, the Diabetes and Aging Study, NHANES, the Services and Health for Elderly in Long TERm care (SHELTER) project). These confirm the association between DM and incontinence. In gynaecological consultations, DM is a risk factor for incontinence, together with prolapse and gynaecological surgery [593] [587, 594]. In a controlled study, after adjusting for age, body mass index, parity and history of urinary tract infections, diabetes was significantly associated with any incontinence (OR: 1.99; 95% CI: 1.44-2.74) urgency incontinence (OR: 2.23; 95% CI: 1.38-3.61) and stress incontinence (OR: 1.54; CI: 1.07-2.22) [595] (LOE 1). Gestational DM is an independent risk factor for all types of UI. Compared with women without gestational DM, women with it tended to exhibit more severe symptoms of stress incontinence for up to 2 years postpartum, whereas for urgency or mixed incontinence, more severe symptoms were found only for 6 months postpartum [596].

Among women with type 2 diabetes white race, higher body mass index, higher parity, lower physical activity, current postmenopausal hormone use and diuretic use were risk factors for prevalent and incident UI, whereas hysterectomy, vascular disease and longer duration of diabetes were associated with increased odds of prevalent UI only (Nurses’ Health Study I and II) [597]. Diabetes duration, treatment type, peripheral neuropathy, and retinopathy were significantly associated with severe incontinence in multiple regression models adjusted for age, education, and history of UTI [598] (LOE 3). Lewis et al. in a cross-sectional study of 50-90 year old women found that insulin dependent diabetes was strongly associated with UI, while non insulin dependent diabetes was not [599] (LOE 2). In other studies, both the use of insulin (OR 2.62, 95% CI: 1.67-4.13) and of oral glucose-lowering agents (OR 1.81, 95% CI: 1.33-2.45) were predictors of UI in community-dwelling frail older adults with DM [600]. Most, but not all, studies suggest that diabetic measures, such as glycemic control, may be associated with UI. In women with Type 1 diabetes, incident UI was associated with higher HbA1c levels, independent of other risk factors [601]. Among women with relatively controlled diabetics, each one-unit increase in HbA1c was associated with a 13% increase for any UI and a 34% increase in risk for only stress incontinence but was not significantly associated with urgency or mixed incontinence [602]. In a controlled study, after adjusting for all variables, high HbA1c levels were associated with OAB (odds ratio 1.24, 95% confidence interval 1.06-1.45), urge UI (odds ratio 1.20, 95% confidence interval 1.00-1.45) and nocturia [603]. Compared to women with normal HbA1c participants with DM type II had an increased prevalence of stress and urge UI (38.6% vs 52.5% and 21.7% vs 40.3%, respectively). Diabetes measures (glycemic control and insulin resistance) were each significantly associated with UI in univariable but not in multivariate models when adjusted for patient body mass index [604]. Also, in community-dwelling frail older adults with DM, UI was not associated with HbA1c level, but with geriatric factors such as the inability to ambulate or transfer independently [600]. In the Diabetes and Aging Study, HbA1c levels were again not associated with the presence or absence of incontinence, alt-
hough poor glycemic control (HbA1c ≥9%) was associated with more limitations in daily activities due to incontinence [605]. Also, there is level 2 evidence that poor glycemic control increases the frequency of UTI in women with type 1 diabetes. For every unit increase (1%) in recent HbA1c level, there was a 21% increase in UTI frequency after adjusting for race, hysterectomy status, urinary incontinence), sexual activity, peripheral and autonomic neuropathy and nephropathy [606].

Consequently, the question is whether improved glycemic control can lead to modification of the risk of UI. Available studies to date have demonstrated a variable, positive effect. In the Diabetes Prevention Program Outcomes Study which included 1778 female participants who had been randomly assigned to intensive lifestyle intervention, metformin or placebo, intensive lifestyle intervention had a modest positive but enduring impact on UI (prevalence 46.7%, 53.1%, 49.9% urinary incontinence/week) [607]. In the Look AHEAD trial in a cohort of overweight/obese men with type 2 DM, intensive lifestyle intervention reduced the odds of prevalent UI by 38% at 1 year compared to diabetes support and education. The prevalence of UI decreased from 11.3% to 9.0% in the intensive lifestyle intervention group and increased from 9.7% to 11.6% in the diabetes support and education group. The intensive lifestyle intervention group also had almost twice the odds of UI resolving compared to the diabetes support and education group [608].

Van Poppel et al. [609] reported neuropathological examination of bladder biopsies from 14 patients with severe insulin-dependent adult-onset diabetes, compared with acetylcholinesterase and S100 staining of 38 control specimens. A decrease in acetylcholinesterase activity, due to axonal degeneration, was found in all cases. An increase in S100 positivity was found in the majority and is due to Schwann cell proliferation as a regeneration attempt after demyelination or axonal degeneration. When acetylcholinesterase activity decreases and an S100 density increase is found in a patient with diabetes, this combination is highly suggestive of diabetic cystopathy amenable to early symptomatic treatment (LOE 2). Because of the uncontrolled hyperglycaemia, patients with DM develop altered NGF activity, which may be a mechanistic factor in the development of diabetic bladder dysfunction [610] [611]. In this respect, electrophysiological studies offer support to associations between diabetic cystopathy and peripheral neuropathy. Hyposensitivity of unmyelinated C-fiber afferents at the distal extremities was found to be an indicator of early-stage diabetic bladder dysfunction in type 2 diabetic women. C-fiber dysfunction at the distal extremities appeared to be concordant with vesical C-fiber neuropathy [612].

Since the peripheral nerves are involved, the clinical manifestations of diabetic cystopathy might be very varied. Usually there is reduced sensation of bladder fullness, and decreased frequency of voiding. This is followed by slowing of the urinary stream and difficulty in voiding due to impaired detrusor contraction. Post-voiding dribbling may also occur. The impaired bladder emptying and urinary retention predispose to urinary tract infections. A prospective study investigated the temporal effect of DM on the functional disturbances of the LUT in diabetic patients. In a cohort of 181 women with type 2 DM, there appeared to be a time-dependent progression trend in the development of bladder dysfunction, advancing from urodynamic stress incontinence to DO and/or increased bladder sensation and eventually to impaired voiding function. The duration of DM was longer in women with voiding dysfunction (6.8 ± 2.8 years in women with stress incontinence, 7.3 ± 6.5 years in DO and/or increased bladder sensation, and 10.4 ± 8.3 years in women with voiding dysfunction) [613]. Earlier studies had suggested that urine output does not contribute significantly to diabetic cystopathy [614]. Retrospective studies support however an unfavourable effect of DM on detrusor contractile force. Mean maximal flow rate and P_det Qmax and bladder contractility index were lower in the DM group, in whom mean DM duration was 9.24 ± 7.63 years and mean HbA1c level 7.27 ± 1.43%. DM duration was significantly correlated with Q_max, P_det Q_max, and BCI. Moreover, the HbA1c level was negatively associated with Q_max, P_det Q_max, and BCI [615]. In diabetic women, poorer glycemic control was associated with an increased likelihood of PVR ≥ 100 mL (OR 1.30, CI 1.06-1.59 for each-one unit increase in HbA1c) [616].

Yamaguchi et al. studied 84 diabetic cystopathy patients [617]. In addition to large post-void residual and decreased sensation, urinary urgency, DO, and increased bladder sensation were seen in 55%, 42% and 14%, respectively. The prevalence of DO in patients with increased bladder sensation was 58%. DO increased with age, but not with the duration of diabetes. Urodynamic characteristics of DO are different between diabetic women and age-matched controls; amplitude of first overactive contraction, volume at first overactive contraction and maximal detrusor pressure were greater in diabetics compared with the non-diabetic group (16.00 cm H2O vs. 9.00 cm H2O, 309.00 mL vs. 167.00 mL and 76.48 cm H2O vs. 55.41 cm H2O respectively) [618]. In a brain MRI study of 32 cases, the prevalence of multiple cerebral infarctions in patients with DO was 76.5%. The authors concluded that urinary urgency is not uncommon in diabetic cystopathy. Both central and peripheral mechanisms are involved [619] (LOE 3).

Ishigooka et al. [620] (LOE 3) described the results of the ice-water test in diabetic patients with and without cystopathy. 12.5% of patients without cystopathy and 25% of patients with cystopathy did not feel the ice water sensation. Ueda et al. [621] (LOE 2) performed studies evaluating sympathetic skin response in correlation with cystometry. They found that patients without sympathetic skin responses had increased residual urine and decreased detrusor contraction pressure, while patients with lower amplitude of sympathetic skin response and more prolonged latency
than controls had a significant decrease in detrusor contraction pressure. The changes within the bladder function were observed as early as within one year from the diagnosis of diabetes.

Beylot et al. [622] (LOE 2) found that the presence of residual urine in diabetic patients, after exclusion of co-morbidities, was strongly associated with peripheral neuropathy. Ho et al. showed increased bladder sensation, followed by DO in 94 female diabetic patients undergoing urodynamic studies [623]. Those patients with OAB are more likely to have impaired voiding function. In a questionnaire based survey, OAB was twice as prevalent (24.2%) in diabetics compared to the general population, while the presence of symptomatic diabetic polyneuropathy significantly increased the risk for development of OAB [624]. Similarly, in a cross-sectional hospital-based survey of women with type 2 DM, peripheral neuropathy, nephropathy, and presence of metabolic syndrome were significantly associated with moderate to severe LUTS and OAB [625]. In a controlled, questionnaire-based survey, diabetic patients had higher OAB-q scores compared to the control group, with disease duration showing significant correlations with OAB-q scores (LOE1) [626]. In another controlled study DM patients had a significantly higher proportion of OAB symptoms compared with the controls (28.0% vs 16.3%), as well as nocturia (48.0% vs 39.1%) (LOE1) [603].

No specific treatment has been described in regards to the population of patients with diabetic cystopathy. Therefore general rules as for the other bladder conditions with impaired (absent) detrusor contractions should be followed. Sacral Neuromodulation has been used to treat LUTD in DM, with similar long term results as in non DM patients [627]. By contrast, in women undergoing mid-urethral sling procedures for UI lower cure rates were seen in diabetics (0.50; CI 0.35-0.74) [628]. Similarly, in a controlled study, the presence of DM was associated with a significantly smaller reduction of OAB symptoms when treated with antimuscarinics, but the effect attributable to diabetes was small relative to the overall treatment response (LOE1) [629].

Future research should endeavour to give epidemiological information on the incidence of both type I and II diabetes-related functional disorders of micturition, and specific results of therapeutic interventions on each type of incontinence as well as on urinary tract infections. Gender effects should also be investigated.

Conclusions

- Diabetic cystopathy occurs in up to 80% of insulin dependent diabetes mellitus (LOE3)
- Urinary incontinence is strongly associated with diabetes. The current evidence is stronger for insulin dependent diabetes compared with insulin independent diabetes (LOE 2)
- The frequency and severity of Overactive bladder is increased in diabetes, presumably reflecting both central and peripheral mechanisms (LOE 1,2)
- Patients with diabetic cystopathy generally can have OAB and/ or impaired detrusor contractions with increased post-void residual (LOE 3,4)
- The urodynamic characteristics of detrusor overactivity are different in diabetics compared to controls (LOE 3)
- There is an unfavourable effect of diabetes and poor glycemic control on the urodynamic contractile characteristics of the detrusor (LOE 3, 4)
- Poor glycemic control is associated with higher risk of increased post-void residual (LOE 3, 4)
- In type 1 diabetes, poor glycemic control is associated with higher risk of urinary tract infections (LOE2)
- Recurrent urinary tract infections might be a long term problem (LOE 3, 4)
- Intensive lifestyle intervention in diabetics has a positive impact on the prevention and resolution of urinary incontinence (LOE1)
- There is a lack of specific treatment for diabetic cystopathy
- However, the presence of diabetes may negatively affect the outcomes of surgical treatment for stress UI and pharmacotherapy for OAB (LOE 1, 2)

Recommendations

- Post void residual measurement and urine dipstick (optional culture) for patients with diabetes mellitus should be performed yearly (C)
- In case of increased post-void residual, prompted voiding might be useful (C/D)
- Treatment of choice for acontractile bladder in this group remains intermittent catheterization (B/C)
- Patients with diabetes and incontinence should receive consultation about the positive effect and consequent need for (intensive) lifestyle intervention and good glycemic control (A)
- Patients should be warned about the negative effect of diabetes on the improvement of stress incontinence and OAB symptoms following appropriate therapeutic interventions (C)

23.3. Faecal Incontinence

Caruana et al. [630] (LOE 3) found that diabetic patients with faecal incontinence showed increased thresholds of phasic external sphincter contraction and had reduced resting/ maximal voluntary anal
sphincter pressures compared with controls. Increased thresholds of conscious rectal sensation in some incontinent patients with diabetes may contribute to faecal incontinence by impairing the recognition of impending defecation. Nakayama et al. [631] (LOE 3) found that age and diabetes have an independent negative influence on faecal incontinence after stroke. Abnormal internal-anal-sphincter function could be contributory in diabetic patients with faecal incontinence [632] (LOE 3). Russo found that acute hyperglycaemia inhibits external anal sphincter function and decreases rectal compliance, which could explain the pathogenesis of faecal incontinence [633] (LOE 3).

Talley and colleagues [634] (LOE 3) studied gastrointestinal symptoms, frequent abdominal pain, bowel-related abdominal pain, reflux, dyspepsia, constipation, diarrhoea and faecal incontinence in diabetic patients. There was a clinically significant decrease in QoL scores in diabetics compared with population norms across all subscales. The impact on QoL in diabetes was predominantly observed in type 2 diabetics. For all the Short Form-36 subscales, GI symptom groups were significantly associated with poorer QoL in diabetes, independent of age, gender, smoking, alcohol use, and type of diabetes.

Cross-sectional analyses of data from the Nurses' Health Study revealed that obesity was associated only with urinary incontinence while type 2 DM was a stronger risk factor for fecal than urinary incontinence [635].

Conclusions
- Faecal incontinence in diabetes patients may be due to impaired anorectal sensation and/or decreased anal closing pressure after hyperglycaemic episodes (LOE 3)
- Gastro-intestinal symptoms impact negatively on health-related QoL in diabetes mellitus (LOE 3)

Recommendations
- Patients with diabetes and fecal incontinence should have anorectal manometry performed before introducing therapy for fecal incontinence (C/D)
- More studies on neurologic bowel dysfunction and management in diabetes are needed (B).

24. SYSTEMIC AND OTHER CONDITIONS

24.1. Systemic Lupus Erythematosus

Nervous system involvement occurs in about half of patients with systemic lupus erythematosus (SLE) [636]. Neurological manifestations of SLE are subacute encephalo-myelopathy, subacute myelopathy (rarely) and chronic encephalomylopathy. Seizures and psychiatric disorders are the most common manifestations, while spinal cord lesions are uncommon. Symptoms of LUT dysfunction can occur, however, data on prevalence are lacking. Several pathological urodynamic findings are reported [636-638]: slow urinary stream, high post-void residual, high maximum urethral closure pressure, detrusor overactivity, low compliance bladder, low maximum cystometric capacity, or loss of bladder sensation. LUTS in patients with SLE may also be caused by lupus cystitis, a rare entity often associated with lupus mesenteric vasculitis [639].

Conclusions
- About half of the patients with SLE show nervous system involvement. Subacute and chronic encephalomylopathy may cause LUT dysfunction with varying patterns (LOE 4).

Recommendations
- Urodynamic investigations are necessary to define the underlying pathophysiology of the urinary symptoms, and are relevant to guide treatment (B).

24.2. Herpes Zoster

Herpes zoster (shingles) results from reactivation of the dormant varicella-zoster virus (VZV) resulting in vesicular eruptions of the skin or mucous membranes. Two distinct syndromes due to genital varicella zoster infection, cystitis and urinary retention, have been described. Cystitis classically presents with dysuria, frequency and hematuria and cystoscopic verification of local inflammatory changes on the bladder mucosa should be performed for the diagnosis of herpetic cystitis [640, 641] (LOE 3). Urinary retention may precede the emergence of the characteristic dermatomal skin rash [642], or it may follow initiation of zoster therapy [643].

The overall incidence of LUT dysfunction is 4% [644], however involvement is reported as high as 28% if cases of lumbosacral involvement are considered. According to Chen et al., voiding dysfunction following herpes zoster can be; 1. Cystitis-associated, whereby direct involvement of the bladder wall results in herpetic cystitis, 2. Neuritis-associated, due to retrogade spread of infection by the VZV from the dorsal root ganglia of the sacral segments, or 3. Myelitis-associated, caused by herpetic myelitis. Occasionally, patients with skin rash in the lumbar or even lower thoracic dermatomes may develop bladder dysfunction and this is thought to be due to spread of VZV to the sacral segments.

Two case reports describe urodynamics findings in herpes-zoster patients. Usually patients develop complete urinary retention, with or without overflow incontinence due to detrusor acontractility and lack of
bladder sensation. Repeat urodynamic studies at week 10 after the onset of the disease demonstrated a return of the detrusor contraction, normalising after 14 weeks [645, 646] (LOE 4).

Herpes zoster-associated voiding dysfunction is a transient phenomenon and is not uncommon in patients with lumbosacral dermatome involvement. Treatment with IC or indwelling catheter placement is recommended in order to avoid secondary damage to the LUT due to chronic urinary retention or UTIs. The disease usually is of a benign clinical course, with recovery of bladder functions.

Conclusions
- 28% of patients with Herpes zoster in the lumbosacral dermatomes show LUT dysfunction, with impaired voiding as the most common symptom (LOE 4).
- The most common symptom is overflow incontinence due to detrusor acontractility and lack of bladder sensation (LOE 4).
- Voiding dysfunction has a transient course and almost every patient will regain normal voiding within 3-4 months, or at the least achieve balanced bladder function (LOE 3).

Recommendation
- Till functional recovery takes place, urinary tract management with intermittent catheterisation or indwelling catheter is recommended (GOR B).

24.3. HIV
Urinary incontinence
HIV virus belongs to the family of retroviruses. This family of viruses is known for latency, persistent viremia, infection of the nervous system, and weak host immune responses. HIV has high affinity for CD4 T-lymphocytes and monocytes. HIV binds to CD4 cells and becomes internalised. The virus replicates itself by generating a DNA copy by reverse transcriptase. Viral DNA becomes incorporated into the host DNA, enabling further replication. HIV enters the nervous system early, at the time of initial infection, and may immediately cause symptoms, or it may cause delayed-onset symptoms, potentially at any time during the person's lifetime. All parts of the nervous system may be involved. Neurological disorders could be HIV-related, or due to secondary infections, malignancies, metabolic or nutritional problems and to therapy.

It is estimated that up to 80% of patients are symptomatic in terms of nervous system and for 30%, neurological symptoms are the initial clinical problem, in the absence of anti-retroviral treatment. Neurological syndromes may be the sole clinical problem or cause of death. The following brain symptoms have been described: meningitis, dementia, stroke, seizures, and degenerative disorders. For the spinal cord, transverse myelitis and progressive myelopathy have been observed.

Due to nervous system involvement in HIV infection, consequent effects on LUT function can be anticipated [647]. Shin et al. (LOE3) described a higher prevalence of incontinence in HIV-positive patients as compared to HIV-negative in nursing homes [648]. Whether this represents a true trend, or an observation related to the terminal stage of the disease and associated comorbidities, remains to be elucidated. Gytrup et al. (LOE 3) found voiding problems in 12% of HIV-infected patients, mostly in advanced stages of the disease [649].

Virtually all parts of the body could be involved in AIDS patients, either as the primary location of HIV infection or secondary to HIV-related complications. Among the different manifestations, particular attention should be paid to the primary locations as they develop early in the stage of the disease. HIV can affect all areas of the central and peripheral nervous system- for example, HIV-associated dementia, vascular myelopathy, distal sensory peripheral neuropathy and myopathy. Pelvic organ dysfunction has, however, been little studied. Patients may develop voiding dysfunction and chronic retention due to lumbosacral polyradiculopathy. Prior to the introduction of the newer anti-retroviral therapies in the 1990s, infection with cytomegalovirus was the most common cause [650] and other causes include lymphomatous infiltration, syphilis or a herpetic radiculopathy due to herpes varicella zoster or simplex. Mahieux et al. (LOE 3) described a case of acute myeloradiculitis due to cytomegalovirus as the initial manifestation of terminal stage HIV [651]. Matsumoto et al. (LOE 3) [652] reported a case of lumbosacral polyradiculopathy where voiding difficulties and lower limb paresis were the primary manifestation of HIV infection. Another pattern of LUT dysfunction is urgency incontinence and DSD [649] in the context of vascular myelopathy.

Bladder cancer is a recognised occurrence in these patients [653]. Though rare, they can occur in relatively young HIV-infected patients with a low CD4 nadir, presenting with haematuria. Most of them are smokers, and have aggressive pathological features [654-656].

Begara et al. (LOE 3) performed urodynamic studies in 10 patients with AIDS and voiding disorders and found that the most common symptom was urgency incontinence and the most common urodynamic finding was DSD [657]. In 3 patients they found demonstrable functional disorders of the LUT (2 patients had DO: one of them had a history of encephalopathy from HIV and the other patient had polyneuritis; the third patient had myelitis and a urodynamically-diagnosed sympathetic decentralization. Detrusor areflexia was described in 2 HIV-positive patients by Menendez et al. [658] (LOE 3). One of them had an ascending myelitis of probable herpetic origin, the
other had a cerebral abscess caused by Toxoplasma gondii.

Since during the course of the disease all parts of the nervous system can be involved, either as the primary location or secondary to AIDS-related complications, no disease specific diagnosis or treatment can be proposed. It is important to observe that sometimes functional disorders of the LUT can be the first manifestation of the HIV infection. When managing the patient with HIV infection one must bear in mind that both storage and voiding problems can occur and that both should be treated, potentially according to the results of urodynamic studies.

Future research needs to be supported by a stronger evidence base. All reports of HIV and voiding problems are rather anecdotal and no good prospective studies exist. The need for such studies is particularly important, when realizing that it takes up to 20-30 years from HIV infection to AIDS full manifestation, and that new antiviral treatment modalities could prolong the life of a patient with HIV significantly. Particular attention should be paid to primary nervous system involvement by HIV and the voiding dysfunctions that could be the side effects of HIV drug therapy.

Faecal incontinence

As diarrhoea is common in HIV infected patients, faecal incontinence can also occur, mostly due to anal sphincter weakness. The true incidence of HIV neuropathy-related faecal incontinence is not known and further studies are needed [659] (LOE 4). Many of the limitations of knowledge seen with urinary incontinence apply to faecal incontinence.

Conclusions

- HIV can influence the nervous system and LUT function in two ways: as a result of primary infection, or secondary to AIDS-related complications (LOE2/3).
- Nervous system manifestation of HIV infection can by the only sign of infection, and it is therefore important to take the possibility of HIV infection into consideration when facing unusual signs and symptoms from the LUT without any other obvious cause (LOE 3).
- HIV/AIDS is a progressive disease and dynamic changes to the LUT functions can occur during the evolution of the disease (LOE 2).
- Faecal incontinence in HIV/AIDS patients is usually associated with diarrhoea, however the true incidence is not known (LOE 4).
- Bladder cancer should be considered in any HIV patient with haematuria (LOE 4)

Recommendations

- Patients with HIV and nervous system pathological signs and symptoms should be evaluated for functional LUT problems (B).
- Due to the variety of LUT functional damage in HIV patients, dynamic evaluation of LUT function is essential for tailoring of therapy (C).
- No HIV-specific therapy of LUT problems and faecal incontinence is currently available. Due to the variety of functional damage, therapy should be individually tailored, according to the results of functional/ imaging studies (C).
- All HIV patients with haematuria should be screened for bladder cancer (B)

24.4. Neurosyphilis

Neurosyphilis results from longstanding infection with Treponema pallidum. Bladder dysfunction is common, though most classically in tabes dorsalis. The predominant neurological manifestations are sensory ataxia and spontaneous lancinating pains. Voiding dysfunction occurs due to involvement of sacral posterior roots and the dorsal column of the spinal cord, resulting in loss of bladder sensation and significantly elevated post-void residual urine. The bladder is atonic, though there may be some myogenic damage from chronic overdistention. Some patients may demonstrate detrusor overactivity and DSD [660, 661]. The condition is rare and there is no contemporaneous epidemiological data.

REFERENCES 1397
INTRODUCTION

Older people have the highest known prevalence of urinary incontinence (UI) of any group, other than those with specific neurological disease (e.g., spinal cord injury). As the proportion of older people in the populations of the developed world increases, so will the absolute numbers of those with either urinary (UI) or faecal incontinence (FI) or lower urinary tract symptoms [1]. Even if improvement in physical functioning among older people continues, and research in the field is able to demonstrate continuing benefit whilst containing costs, the impact on future health care and long-term care costs will still be profound [2]. Early signals suggest however that the decrease in disability for older people observed in the last two decades of the twentieth century has not been seen in those aged 40 – 64 years [3].

No matter how those in later life, conventionally defined as those of 65 years and older, are described this population is characterized by its variety, ranging from active, community-dwelling, working, healthy nonagenarians to bed-bound, chronically ill, functionally and cognitively-impaired persons in their late 60’s. Because the healthier group is closer in phenotype and physiology to middle aged than to frailer older people, information relating to the management of urinary and faecal incontinence in this group is integrated into the other ICI chapters. This chapter focuses on frail older people, emphasizing not only the different aetiologies and treatment of UI and FI, but the additional issues of disease burden, disability, altered responses to drug therapy and the role of caregivers. Those sections in the previous (5th) Consultation, dealing with catheters and the organization of care have been moved to the more relevant chapters. This Consultation sees for the first time a dedicated section dealing with continence at the end of life and examines the effect of both cognitive and physical frailty as the presence of each or both may need different considerations when offering treatments for incontinence.

The committee took the view that where there is a paucity of data reflecting the effectiveness or utility of approaches to the treatment of UI or FI in frail older adults, interventions aimed at community dwelling older adults should be employed with due regard to the likely benefits, harms, feasibility, expectations and outcomes of treatment, rather than not be attempted at all. The committee recognized that frail older people may be “victims” of therapeutic nihilism and may receive standards of care below those received by younger persons [4, 5].

The pathophysiology of UI in the frail elderly requires a broader conception of “disease,” centring on patient-level factors rather than just the bladder or bowel and its neurological control. UI and FI in frail older people is normally a result of multiple interacting risk factors including age-related physiological changes, comorbidity, polypharmacy, functional and cognitive impairments and common pathways between them (Figure 1). Furthermore, the impact of UI or FI in frail older persons extends beyond the affected individual to their caregivers, leading to caregiver stress and an increased likelihood of institutionalisation [6]. Therefore, assessment in frail older persons requires a broader scope than that employed in the care of younger individuals. Failure to address the multifactorial nature of disease and treatment limits not only clinical care and research, but also important opportunities to improve function and quality of life [7]. Management of incontinence in frail older persons is necessarily multicomponent, and must address the many associated factors and shared underlying impairments with other geriatric syndromes (for example, by combining physical exercise with prompted voiding) [8]. Drug therapy must be placed in the context of altered pharmacology, pre-existing polypharmacy and an increased susceptibility to adverse events. The continuing challenge in providing a review of incontinence in frail older people is the relative dearth of Level 1 evidence for interventions. Thus the frail older person presents multiple challenges for research (not the least of which is substantial difficulty in recruiting to clinical trials due to either overt or covert exclusion.
and the additional challenge of intervening illness and death) [9]. Despite the oldest-old (those of 80 years of age and above) forming the fastest growing group of affected individuals, intervention studies continue to be rare. Moreover, trial outcomes need to be more broadly based, incorporating caregivers, a range of care settings, alternative models of care, and goals of care unique to this population [10].

### 1. SEARCH STRATEGIES

Given the broad range of this report, we used multiple searches using the following MESH terms (in caps) and phrases, alone and in combination, using the PubMed and Ovid search engines: AGED, AGED OVER 80, ACTIVITIES OF DAILY LIVING, DEPRESSION, elderly, FALLS, frail, FRAIL ELDERLY, FRAILTY, function, geriatrics, LONG TERM CARE, MEDICATIONS, NURSING HOME, older, QUALITY OF LIFE, RANDOMIZED CONTROLLED TRIAL; and BLADDER, GYNAECOLOGICAL SURGICAL PROCEDURES, PELVIC FLOOR, PROSTATE, STRESS INCONTINENCE, SURGERY, URE- THRA, URINARY INCONTINENCE, URINATION DISORDERS, UROGyneCOLOGY, UROLOGY, VAGINA, VOIDING DYSFUNCTION , nocturia OR nocturia OR “night-time voiding” OR “night-time voiding” OR “night-time voiding” OR “night-time voids” OR “night-time voids” OR “nocturnal voids” OR “night-time frequency” OR “night-time frequency” OR “nocturnal frequency” OR “night-time urination” OR “nocturnal urination” OR “nocturnal micturition” OR “night-time micturition” OR “nocturnal micturition” OR “night-time polyuria” OR “night-time polyuria” OR “nocturnal polyuria” OR nocturia) OR (noctur* OR night*) AND (void* OR urination OR micturition OR polyuria OR pollakuria OR “LUTS” OR “lower urinary tract symptoms” OR “BPH” OR “benign prostatic hyperplasia”)) AND (“aged, 80 or over” OR aging OR elderly OR older OR “very old” OR senior OR “all aged” OR geriatric OR frail OR aged) AND (“double blind method” OR “double blind” OR placebos OR placebo OR “controlled clinical trial” OR “randomized controlled trial” OR “random allocation” OR “single blind method” OR “research design” OR “exp clinical trials” OR “clinical trial” OR “single blind” OR “double blind” OR “triple blind” OR “single mask” OR “double mask” OR “triple mask”) (longitudinal OR “natural history” OR cohort OR incidence OR remission OR progression OR prospective OR “community-based” OR “population-based” OR epidemiol* OR “follow-up”): TOLTERODINE; OXYBUTYNIN; SOLIFENACIN; PROPIVERINE; TROSPUIM, IMIDAFENACIN; DARIFENACIN; FESOTERODINE; fecal incontinence OR, constipation, R anal incontinence. Ovid Expert Search Filter; Publication years 2010-15. We included, where possible, information from non-English language articles where an English language abstract with sufficient information was available. References in retrieved articles were reviewed for additional relevant articles. We also searched the Cochrane Database and National Guideline Clearinghouse for relevant systematic reviews, meta-analyses, and evidence-based recommendations. A research librarian aided this process.

### 2. FRAILTY

The proportion of older persons in the population is increasing in almost every country around the world. By 2050, approximately 2000 million people will be aged 60 years or over, and 400 million will be over the age of 80. Frailty is essentially a state of vulnerability to insult, which may be in the form of a relatively minor stressor, from which the individual does not
fully recover. The Consultation has defined “frail older persons” as those over the age of 65 with a clinical presentation or phenotype combining impaired physical activity, mobility, balance, muscle strength, motor processing, cognition, nutrition, and endurance (including feelings of fatigue and exhaustion). This is consistent with the Fried phenotypic approach to frailty in which there is a clear distinction between frailty and disability, and from the accumulation of diseases (deficits) model of Mitnitski and Rockwood [11]. Among persons meeting strict phenotypic criteria for fragility, only 22% also had both comorbidity and disability, 46% had comorbidity without disability, 6% disability with- out comorbidity, and 27% had neither comor- bidity nor disability [12, 13]. Frail people do however usually have multiple chronic medical conditions, take multiple medications, require care from others and assistance to perform some or all of the personal activities of daily living (PADLs) (e.g., bathing, dressing, toileting, and mobility), are often homebound or institutionalized. They have a high risk of intercurrent disease, increased disability, hospitalisation, and death [1]. In the United Kingdom, an examination of 5,450 people aged 60 and over from the English Longitudinal Study of Ageing using Fried criteria found the overall weighted prevalence of frailty to be 14%. Prevalence rose with increasing age, from 6.5% in those aged 60–69 years to 65% in those aged 90 or over. Frailty was more common in women than in men (16% versus 12%). 93% of frail individuals had difficulties with mobility compared to 58% of non-frail individuals [14]. In the United States, using the Fried model of frailty applied to 7,439 participants in the 2011 baseline of the National Health and Aging Trends Study of persons aged 65 and older, 15% (95% CI: 14%, 16%) of the older non-nursing home population was frail, and 45% prefrail (95% CI: 44%, 47%). Frailty was more prevalent at older ages, amongst women, racial and ethnic minorities, those in supportive residential set- tings, and persons of lower income. Chronic disease and disability prevalence increased steeply with frailty [15]. In Latin America and the Caribbean, a meta- analysis of 29 studies including 43,083 people, of mean age of approximately 60 years, using a variety of frailty assessment scores, identified a prevalence of frailty of 19.6% (95% CI: 15.4-24.3%) with a range of 7.7% to 42.6% [16]. Likewise there have been an increasing number of epidemiological studies as- sessing the point prevalence of frailty, using a variety of definitions, across a number of countries such as Russia [17], China [18], South Korea [19] and Brazil [20] amongst others [21].

2.1. Frailty and incontinence

Several studies suggest that the relationship between urinary incontinence, faecal incontinence and frailty is not unidirectional. Incident UI in those over age 65 has been associated with a two-fold increased risk of impairment in ADLs, instrumental activities of daily living (IADLs – e.g., transportation, finances, shopping, laundry, housekeeping), and poor performance on three physical measures, suggesting that incident UI may be an early marker of the onset of frailty [6]. In a Taiwanese study of UI and its association with frailty among 440 men aged 80 years and older using the clinical frailty scale, the prevalence of UI was 19.1%. Frailty was more common among subjects with UI than those without (60.7% vs 32.3%). Men with UI also had more comorbidity, poorer physical function, were more likely to have depressive symp- toms, impaired cognitive function, poorer nutritional status, more polypharmacy and a higher likelihood of fecal incontinence than those men who were not frail [22]. In a population-based study of older Mexican Americans, incident but not prevalent UI was inde- pendently associated with functional decline in ADLs, IADLs, and physical performance [23]. Another popu- lation-based study found an association between UI and IADL decline, but not ADL decline, nursing home admission, or death, after adjustment for age and comorbidity [2]. A Portuguese study showed that older people who presented with either “slowness” or “exhaustion” had a risk of UI almost five times greater than those without [24]. Although one early study sug- gested that older persons with UI had a higher mor- tality risk subsequent studies that more fully adjusted for comorbidity and functional status have not found any association [2, 25-27].

2.2. Frailty, continence and consequence

Several multivariate studies suggest that patients with new onset UI at the time of stroke have higher rates of death or disability at 2 years (OR 4.43; 95% CI 1.76 to 11.2) to 5 years (OR 3.21 [95% CI 1.04–9.91]), especially if UI persists (OR 7.47 [95% CI 2.29–24.42]) [28, 29]. Given its association with frailty, it is not surprising that UI remains a risk factor for nursing home admission, particularly in associa- tion with a dementia diagnosis. Studies showing a significant association between UI and institutionalisation have been done in Finland (in men, but not women, with urgency UI); [30] Germany; [31] New Zealand (persons > age 65) [32]; US (men more than women) [33], after hip fracture [34], among Hispanic elderly [23], and patients attending a dementia clinic in rural Japan [35]; and Hong Kong [36]. Two studies failed to find a significant association after controlling for comorbidity, using US [2] and Canadian data- bases [37]. It was estimated that the proportion of US NH admissions attributable to UI in men is 0.10 (95% CI 0.08–0.13) and in women 0.06 (95% CI 0.05– 0.09) [38]. The prevalence of UI at NH admission in the U.S. shows variation of almost 50% and differs by race [39] suggesting that patient and caregiver factors and local resources affect the role UI plays in in- stitutionalisation. An issue, particularly in studies of institutionalisation in people with a dementia diagno- sis, is the failure to include UI as a risk factor or de- fining it only by a composite function score [40, 41]. The significant association of faecal incontinence and institutionalisation (odds ratio 1.79, 95% CI: 1.00– 3.20), in one Canadian study was lost when adjusted for cognition, ADL dependence, and self-reported health, although a survey of US geriatricians found
that the presence of faecal incontinence was more likely to result in a referral to a nursing home than not [42, 43].

2.3. Cognitive Frailty

Whilst age associated cognitive impairment has received extensive research and clinical interest, cognition has not been conceptualised in a similar fashion to physical frailty. Frailty per se includes both physical and cognitive domains. The term cognitive frailty has been operationalised as an heterogeneous clinical manifestation characterised by the simultaneous presence of both physical frailty and cognitive impairment. The key factors defining such a condition include the presence of physical frailty and mild cognitive impairment and excluding concurrent dementia, reflecting reduced cognitive reserve [44]. The exclusion of the dementias may not be useful in that the two features are often intimately intertwined but conceptually the definition may have clinical utility in terms of continence management, where the application of treatment options may vary depending upon the predominant factor influencing frailty. To be able to distinguish those with a vulnerability to cognitive decline amongst persons either with or without physical frailty may be of use, but again, the pathophysiological mechanisms leading to both entities are common and probably shared.

2.4. Dementia

The proportion of people living with dementia, a group of conditions also associated with an impairment in quality of life and physical function increases; prevalence estimates suggest that globally in 2010 35.6 million people lived with dementia with numbers expected to almost double every 20 years, to 65.7 million in 2030 [45],[46]. In addition to the morbidty associated with urinary incontinence in older people, its presence with co-existent dementia increases the likelihood of institutionalisation [47]. Unfortunately, once there, there is evidence of institutional practices, such as en masse toileting, making incontinence more likely [48]. Likewise, caregivers identify looking after an older person with dementia and incontinence as being burdensome [49, 50]. Management guidelines for urinary incontinence and lower urinary tract symptoms seldom consider the implications for management in those patients with co-existing medical conditions [51-53]; few discuss management in those with a dementia diagnosis [54]. The likelihood of incontinence increases in association with the severity of dementia but until recently longitudinal studies did not identify an association with incident cases [55, 56]. One longitudinal study of 6,349 community dwelling women found that a decrease in mental functioning as measured by a modified mini mental status exam (MMSE) was not associated with increased frequency of urinary incontinence over 6 years, but did predict a greater impact [57]. Despite strong associations with baseline incontinence in the Canadian Study of Health and Aging, moderate or severe cognitive impairment, measured by the same modified MMSE, was not associated with incident UI over 10 years [58]. However, in a longitudinal study of 12,432 women aged between 70-75 years with a 3 year follow up there was a strong association with a dementia diagnosis (OR 2.34) [59]. Similarly, over 9 years follow up of 1,453 women aged 65, dementia was strongly associated with incident urinary incontinence (RR 3.0) [6]. Likewise, in a Scottish study, the prevalence of urinary incontinence increased with decreasing mini-mental state scores and was notably more common in those with impairments of attention and orientation, verbal fluency, agitation and disinhibition [60]. In a United Kingdom General Practitioner database, when compared with those without a dementia diagnosis, dementia was associated with approximately three times the rate of diagnosis of urinary incontinence. The incidence rates of first diagnosis per 1,000 person-years at risk (95% confidence interval) for urinary incontinence in the dementia cohort, among men and women respectively, were 42.3 (40.9-43.8) and 33.5 (32.6-34.5) [61]. When assessed urodynamically, most incontinence associated with dementia appears to be related to detrusor overactivity, resulting in urgency incontinence [62, 63].

Incontinence in dementia adds to caregiver burden [64], and influences decisions to relocate people to care homes [6]. Whether successful management of incontinence reduces either this associated burden or alters decisions to institutionalise these people is unknown, evidence is limited to case reports and anecdotal evidence. Family physicians identify dealing with incontinence in dementia as a significant challenge [65]. Likewise there is the concern regarding the influence of antimuscarinic medications on cognition, where there is increasing evidence of cognitive impairment and higher rates of incident dementia diagnosis associated with high antimuscarinic load and long exposure in older persons in epidemiological studies [66, 67], although data in persons with pre-existing dementia are less consistent [68]. Once institutionalised, urinary incontinence becomes a major factor in those with dementia. In a study in Austrian nursing homes, urinary incontinence was present in 84.2% of residents with dementia versus 53.2 % of those without and was highly prevalent even in those with early dementia, affecting 64% of the 277 residents studied [69]. Once admitted to a nursing home, the presence of a dementia diagnosis is associated with a hastening of loss of continence, compared to those residents without. Incontinence is associated with a reduced quality of life and impaired nutrition and mobility in older people with dementia [70, 71], but is sadly neglected in terms of the amount of attention paid to it despite the acknowledged adverse effect on quality of life and the associated costs of management [72].

2.5. Managing incontinence in dementia

Most people with a dementia diagnosis living in the community can potentially be managed in a similar way to any other community dwelling adult, in line
with current guidelines. As noted in the 5th International Consultation on Incontinence, the expectations of both patient and caregiver, the nature of the proposed treatments and likelihood of benefits and harms should be taken into account [73]. Successful and safe management of incontinence in people with more advanced dementia presents additional challenges. For the most part, successful delivery of conservative or behavioural therapies in late life requires the ability for the individual to learn or change behaviour; the active engagement of a caregiver is also required [73]. A dementia diagnosis should not preclude an attempt to manage incontinence with behavioural methods, but for those with a compromised ability to retain behavioural change this is clearly inappropriate. A stepwise approach to initiating interventions and assessing the results seems like a reasonable first step in management, recognising that older people do appear to be more likely to need drug therapy for urgency incontinence than younger persons [74]. For prompted voiding to be successful, a three day trial should result in either a 20% reduction in wet episodes or an increase in spontaneous requests to use the toilet [75]. If this is not successful then the mainstay of management is a strategy of check and change of appropriately assessed containment products [54, 76]. The remaining option is to introduce a fixed voiding schedule, which requires no behavioural change, but this too may be impractical in circumstances where there is limited caregiver support or availability. Even in adequately staffed institutions, evidence suggests that for those who need toileting, the average number of toilet assists per resident is around two per day, sadly short of that which might be needed [77, 78]. A recent systematic review examining the evidence for conservative management approaches for those with dementia living at home concluded, unsurprisingly that there was insufficient evidence to make any recommendation; little, if any, specific guidance for practice in the community exists [79, 80]. The England and Wales National Institute for Health and Care Excellence guideline on incontinence in those with neurological disease recommends that treatment be tried on an individual basis [81].

Evidence on pharmacological treatment for UI in those with dementia is lacking; that which does exist is discussed in the pharmacological treatment section.

II. URINARY INCONTINENCE

1. AETIOLOGY & ASSESSMENT

1.1. Background

The aetiology of UI in frail older adults is grounded in the concept of a classical geriatric syndrome, involving multiple interacting risk factors, including age-related changes, comorbidity, and potentially common pathways between them. This section addresses these components.

1.2. Quality of the data

The data on aetiology of UI in frail older persons remain limited, and observational studies of varying quality constitute much of this literature. Additionally, longitudinal studies of large numbers of frail individuals are difficult to carry out because of paucity in recruitment and the high rate of natural attrition. Despite the lack of such studies, many relatively large, careful descriptive studies and case series, as well as expert consensus processes, have made important contributions to our understanding of the aetiology of UI in this population.

1.3. UI as a geriatric syndrome

In older adults, especially those who are frail, UI forms a classical geriatric syndrome, many of its risk factors are not directly related to the genitourinary tract [82, 83]. Geriatric syndromes have been defined as ‘multifactorial health conditions that occur when the accumulated effects of impairments in multiple systems render an older person vulnerable to situational challenges’ [82]. Thus, large numbers of different baseline as well as precipitating risk factors may interact with each other in influencing the ability of an older individual to remain continent in the face of common daily challenges. This multifactorial complexity, combined with the fact that most individual risk factors typically account for only a small proportion of the overall risk, have greatly complicated the development of a pathophysiological framework for the study of common geriatric syndromes [82]. Figure 2

Nevertheless, because common risk factors (e.g. arm and leg weakness, sensory and affective impairment) may be shared by different geriatric syndromes (such as UI, falls, and functional dependence) [84], they may represent particularly attractive sites for the development of interventions [82]. For example, the presence of brain white matter hyperintensities within critical periventricular and subcortical regions could represent key risk factors for the development of different geriatric syndromes such as falls, impairment in executive cognitive function, depressive symptoms, and UI [85]. Functional magnetic resonance imaging (fMRI) studies have identified central nervous system areas that are particularly relevant to urinary storage symptoms and urgency [86, 87]. Therefore, failure of activation within orbitofrontal regions may contribute to an older individuals’ decreased ability to suppress urgency [88]. Connectivity pathways within the right insula and anterior cingulate gyrus may also play a role in maintaining continence supporting the concept that decline in connectivity [88] and coordination between different brain regions represent early critical events in aging. These findings suggest the possibility that interventions to prevent the development of white matter hyperintensities, such as
control of vascular risk factors, could also prevent UI.

![Figure 2. The mechanistic geriatric syndrome](image)

**2. AGE RELATED CHANGES RELEVANT TO UI IN FRAIL OLDER PERSONS**

Age-related changes in the lower urinary tract (LUT) can function as risk factors for the development, continuation, and worsening of UI in frail elderly persons (Table 1). At the same time, they rarely are alone sufficient to cause UI, and in some persons have no effect on lower urinary tract symptoms (LUTS) or UI. Furthermore, the literature on “normal” LUT ageing has many potentially confounding methodological limitations. Normal ageing changes are difficult to study, because longitudinal data including large numbers of individuals spanning many years are necessary to definitively separate “normal LUT ageing” from confounding factors and comorbidity. Cross sectional studies are subject to confounding by comorbidity and time-dependent cohort effects, such as change in labour and delivery practices. Thus, to date many studies actually describe “age-related” associations, as opposed to normal ageing. Other limitations include: derivation of much of the cellular and neurochemical data from animal studies; morphologic studies based on cadavers with unknown parity, comorbidity, and LUT symptoms; “age-effects” derived from studies of symptomatic persons; and use of surgical patients at tertiary centres as “normal” controls. Even the definition of “normal” can be difficult: is it continence, absence of LUTS, lack of comorbid disease, or normal physiological testing [89]? The following sections focus on findings from more robust and, where possible, confirmatory studies.

--- | ---
Increased incidence of benign prostatic obstruction | Increased likelihood of urinary symptoms and UI
Increased incidence of prostate cancer | 
Decreased oestrogen (women) | Increased incidence of androgenital atrophy related symptoms
Increased incidence of recurrent urinary tract infections
Increased night-time urine production | Increased likelihood of nocturia and night-time UI
Altered central and peripheral neurotransmitter concentrations and actions | Increased likelihood of lower urinary tract dysfunction
Altered immune function | Increased likelihood of recurrent urinary tract infections
Increased prevalence of white matter hyperintensities in brain | Increased prevalence of severe urge / urgency, link to cognitive impairment and impaired mobility

### 2.1. Bladder

Understanding age-related changes in the bladder is complicated by a paucity of longitudinal data, variable definitions of “normal,” and use of potentially biased (and symptomatic) referral populations. It is difficult to isolate such factors as the role of decreased blood flow, poor voiding habits, comorbidity, central and peripheral nervous system innervation, and reflex patterns as determinants of bladder function in older persons. The research focus has been urodynamic function, neurohumoural responsiveness of detrusor smooth muscle, and ultrastructure. While the key role of the urothelium and afferent systems on micturition are increasingly appreciated (See Committee 2, Cell Biology; Committee 3, Neural Control; and Committee 4, Pathophysiology), there are only limited human data on urothelial changes with age. Urodynamic changes associated with age have typically included smaller voided volume, increased residual volume, smaller bladder capacity, and increased involuntary detrusor contractions (detrusor overactivity (DO)). Correlations with age are often small, suggesting that other factors are at least as important [90]. Urodynamic findings may not relate to symptoms: in a urodynamic study of community-based healthy persons over age 55, DO was found in 42% of continent women, one-third of whom were totally free of LUTS [89]. In another study, charts of 53 consecutive females over age 80 undergoing multichannel urodynamics according to ICS standards were retrospectively analysed. These elderly patients presented with LUTS, yet in 11% urodynamic studies were reported as being normal, with considerable other discordance between symptoms and urodynamic findings [91]. Nevertheless, in a cross-sectional study involving ambulatory, cognitively intact, community-dwelling older female volunteers, maximum urethral closure pressure, detrusor contraction strength, and urine flow rate all declined significantly with age, regardless of whether DO was present or not [92].

The ability of the bladder to empty efficiently also declines in healthy older men and women who have no evidence of bladder outlet obstruction (BOO) or significant confounding disease [89, 93]. A variety of different risk factors associated both with ageing and common comorbid conditions may contribute to age-related declines in detrusor contractile function, which may ultimately lead to detrusor underactivity [94, 95]. Decreased contractile function during voiding in older persons is associated with lower urine flow rates and a small increase in post voiding residual volume (PVR) (generally to < 50 ml) [94]. Even in men with BOO, an elevated PVR may reflect decreased bladder contractile function rather than obstructed voiding [95]. While some studies suggest a myogenic origin of impaired contractility, others suggest that impaired blood supply, with concomitant ischaemic-reperfusion injury causing patchy denervation, leads to decreased contractility (see Committee 3, Neural Control). More recently, Smith highlighted the potential contribution of age- and disease-related declines in bladder afferent sensory activity in contributing to impaired voiding performance seen with detrusor underactivity [96]. Incomplete bladder emptying from all such causes can reduce functional bladder capacity, and thereby contribute to the urinary frequency and nocturia common in frail older persons [94]. The recent development of a model allowing continuous uroflow in mice has led to studies evaluating the impact of normal aging on overall LUT performance [97, 98]. While aging did not influence measures of detrusor expulsive strength, pre-contraction pressures, intervoid intervals, per-void volumes and voiding flow rates all increased with aging [97]. Moreover, aged animals demonstrated a decreased homeostatic ca-
pacity to respond to the challenge of continuous blad-
ner filling, with indirect measures suggesting a role for
decreased bladder volume sensitivity [97, 99].

In human studies, the observation that bladder vol-
ume at the initial desire to void declines with age may
be confounded by comorbid conditions and concu-
rent medications [100]. Furthermore, unlike the posi-
tive association between detrusor contraction strength and DO found in younger subjects, older
adults demonstrate a decline in DO-associated detru-
sor contractile function [92] and detrusor contractility
[101]. Moreover, many frail older persons with UI pre-
sent with a combination of DO on filling and poor con-
tractility during voiding, an association termed detru-
sor hyperactivity with impaired contractile function
(DHIC) [62, 94, 102]. In such cases, the bladder con-
traction does not empty the bladder fully, leaving a
large PVR otherwise not explained by BOO. Because
DHIC symptoms can include urgency UI, stress and
mixed UI, dribbling, frequency, and nocturia, they
may be mistaken for other conditions. At the same
time, DHIC may be mistaken for DO with normal con-
tractility because significant detrusor underactivity
may be present in the absence of any relevant symp-
toms. Thus, while it is not possible to speak of precise
cutoffs when differentiating between “normal” and
“abnormal” PVR values, PVR assessments do pro-
vide crucial information into age- and disease-related
alterations in overall LUT performance [103].

Ultrastructural studies demonstrate cellular changes
associated with age-related changes in detrusor func-
tion. One series of such studies involved symptomatic
and asymptomatic persons aged 65 - 96, using uro-
dynamic testing and electron microscopy of bladder
biopsy specimens, which were read in a blinded fash-
on using explicit protocols [104-107]. A consistent,
one-to-one correlation between specific urodynamic
findings and bladder ultrastructure was observed, al-
though there has been considerable debate about the
veracity of these findings and they have not been re-
produced and have been disputed by the findings of
a later study which found the ultrastructural changes
described evenly distributed between normal women
(n = 15) and women with detrusor overactivity (n = 22)
[108]. The small number of asymptomatic patients
with no DO, normal contractility, and no obstruction,
detrusor muscle fascicles were largely intact, with two
distinctive ultrastructural findings that may be related
to ageing alone: muscle cell membranes character-
ized by numerous “dense bands” and markedly de-
pleted caveolae, and slightly widened spaces be-
tween muscle cells with limited content of collagen
and elastin. Depletion of caveolae may be related to
de-differentiation of muscle cells, which could eventu-
ally result in the reversion of actively contractile
cells to inactive, synthetically immature cells. A simi-
lar phenomenon has been reported in atherosclerotic
blood vessels and postmenopausal myometrium, and
may be related to reports of increased collagen in
bladders from older women [104, 109]. Moreover,
lack of oestrogen contributes to, and oestrogen re-
placement reverses, both caveolar depletion and de-
trusor fibrosis [110, 111]. Thus, both ageing and post-
menopausal decline in oestrogen levels may contrib-
ute to bladder muscle cell differentiation and contrac-
tile function [94].

The natural history of these ultrastructural changes
remains largely unknown. From the ultrastructural
studies described above, a subset of 23 patients was
followed longitudinally [112]. The previously observed
one-to-one correlation between ultrastructure and
function was maintained, but it was unclear whether
urodynamic or ultrastructural changes occurred first
in subjects who developed or had a change in LUTS.
The pattern of dense-bands and non-disruptive mus-
cle cell degeneration varied over time: the DO with
dysjunction pattern developed in some subjects, and
impaired detrusor contractility and the corresponding
degeneration pattern was observed to progress in se-
verity or develop. Other investigators have found sim-
ilar results but without the one-to-one correlation
(e.g., see Brierly et al [113, 114]). Clearly, further
work is needed understand the associations between
changes in ultrastructure, urodynamic features and
clinical syndromes.

In addition to such alterations in ultrastructure, a vari-
ety of changes involving relevant nerve fibres, recep-
tors and signalling pathways have also been de-
scribed in bladder tissues from aged animals, and to
lesser extent human biopsies. For example, with ag-
ing overall, sympathetic nerve fibre density may de-
crease [115, 116]. Bladder biopsies from older sub-
jects with normal urodynamic profiles typically show
little or no evidence of axonal degeneration and the
density of some CGRP-positive sensory nerves is
maintained in old age, yet the impact of aging on
other categories of sensory fibres or on motor fibres
remains unknown [104, 115]. Examples of other
changes include decreased contractility and calcium
fluxes in response to cholinergic agonists or depolar-
ization [117]; increased responsiveness to adrenergic
agonists with increased expression of the alpha 1D-
adrenergic receptor [116]; declines in phos-
phodiesterase 5 (PDE5) levels and possibly signaling
[118]; as well as decreased P2X1 purinergic receptor
expression [119]. Unfortunately, the interpretation
and generalisability of these findings is often limited
by a failure to include intermediate age-points which
would allow investigators to distinguish changes at-
tributable to aging as opposed to maturational pro-
cesses [120, 121].

More recent studies have suggested a role for de-
creased A2B receptor expression in lower ability of
adrenosine to relax the detrusor [122]. Also, use of
permeabilised bladder muscle strips suggested that
IP3-induced calcium release is primarily responsible
for the contractions in older rats, thus aging-related
decline in carbachol contractions may result from de-
creased calcium-induced calcium release rather than
carbachol-induced calcium sensitisation [123]. The
use oxidative stressors has shown that mechanisms
possible related to the TRPM8 (cold sensing TRP melastatin 8) ion channel may compromise urethelial function in aged bladders [124]. Studies conducted with human bladder muscle strips suggested an age-related increase in carbachol-mediated contraction via Rho Kinase pathways [125], associated with lower MLCK expression [126]. Finally, studies conducted in aged mice from a systems-based perspective demonstrated that an increase in neurogenic power during filling accompanied augmented centrally mediated compliance enhancement with aging, thus suggesting the existence of a bladder control model in which brain processes related to micturition may compensate for age-associated changes [127].

2.2. Urethra

Due to their common embryological origin, the urethra undergoes age-related mucosal and stromal changes like the vagina, and urethral changes in older women can be partially inferred from examination of vaginal tissue. Because of the difficulty of obtaining non-cadaveric urethral tissue, data on urethral smooth and striated muscle changes with age are complicated by confounding factors and definitions of controls. Urethral closure pressure decreases with age [128, 129]. Based on a sample of 82 women aged 20-70, urethral closure pressure was found to decrease by 15 cmH2O per decade [130]. A number of anatomical and physiological changes may account for this decline. Mucosal thinning and lack of proteoglycans reduce urethral wall apposition; this also may contribute to retrograde movement of perineal bacteria into the bladder causing urinary tract infections [131]. These mucosal changes may extend up to the bladder trigone, causing irritation of sensory afferent nerves, and possibly triggering DO [132]. The submucosal venous plexus in the proximal urethra loses its corkscrew shape, the number and volume of arterial vessels decrease, and vascular pulsations lessen [133]. Several studies, using different measurement techniques, have shown that urethral vascular density and blood flow decrease with age, but not vascular flow velocity [134-136]. However, age explained only 9% of the variability in vascular density in one study [134], and none of the studies controlled for vascular risk factors such as hypertension and diabetes. The relative importance of decreased vascular volume versus hypoxia on urethral functional integrity is unclear. Other alterations in the urethral stroma are increased volume of connective tissue, decreased ratio of proteoglycans to collagen, and decrease in nerve density [137, 138].

Cadaver studies suggest that the number and density of urethral striated muscle fibres decrease with age, especially in the ventral wall of the proximal urethra [139, 140]. These authors estimated that striated fibres decrease by 1% per year. Large inter-individual variations were observed, with age and parity accounting for only a small part of the variability, suggesting that other yet to be defined factors are important. These studies also found that cross-sectional striated muscle fibre area decreased while fibre diameter was preserved. Another cadaver study by the same group found that circular smooth muscle width was 25%-50% higher in younger women (aged 20-39 years) than older (aged 70-89), and that younger women had higher fibre counts [141]. Smooth muscle loss in the older women correlated with loss of striated muscle in the anterior urethra. Moreover, a recent study raised the possibility that TNF-alpha may contribute to age-related rhabdosphincter satellite cell death and muscle loss with aging [142]. Urethral sensation, measured as current perception thresholds, was significantly higher in older women in two studies (by the same authors), one comparing 48 asymptomatic women and 13 with urgency UI [143], and another in asymptomatic women [132]. The authors concluded that age-related LUT sensory neuropathy could contribute to the higher prevalence of overactive bladder (OAB) symptoms with age; however, urethral sensation thresholds were higher in women with urgency UI when controlled for age and parity [143], and the “asymptomatic” older women may have had urodynamic DO [132].

With age, the urethral meatus generally moves toward the vaginal introitus, and may be difficult to see if there is considerable introital stenosis. Caruncles - benign violaceous soft swellings-often appear at the meatus, and are not problematic unless they cause discomfort or obstruction. Urethral diverticula can be a diagnostic challenge, especially in older women, because the symptoms (dysuria, pain, UI, frequency, urgency, dyspareunia) may be attributed to postmenopausal changes, age, OAB, or urgency UI [144]. Diverticula should be considered in women who have repeatedly failed “conventional” UI treatment. Diagnosis requires imaging by voiding cystourethrography, ultrasound, or magnetic resonance scans. Urethral obstruction is relatively uncommon in older women, and is nearly always secondary to other LUT dysfunction (e.g., pelvic organ prolapse) or iatrogenic (from LUT/pelvic surgery or radiation. In men, age-related decrease in striated sphincter muscle cell density occurs as well, [145, 146] and has been associated with increased muscle cell apoptosis [145]. While some investigations describe an increase in resting prostatic urethral pressure with age, [147] others note the increase occurs only to the sixth decade then subsequently decreases, along with a shortening of sphincteric urethral length [148]. These discrepancies may reflect differences in prostate volume and morphology.

2.3. Pelvic floor

Pelvic floor changes in normal older men have not been well studied. In women, the effect of age on pelvic floor structure and function is difficult to differentiate from the effects of hormonal status and parity [149]. A number of studies are cross sectional rather than longitudinal, and focus on symptomatic women. For example, a questionnaire study of over 4,000 community women aged 25-84 found no association between age and stress UI (SUI), OAB, or anal UI,
after adjustment for obesity, birth history, menopause, and hormone use [150]. Similarly, in a random sample of 343 Austrian women aged 18-79 years, impaired pelvic muscle contraction (graded by the Modified Oxford Scale) was weakly associated with parity and body mass index but not age [151]. In contrast, a study combining an interview, physical exam and transperineal ultrasound identified age as a weak (r = -0.25) but statistically significant predictor of pelvic muscle weakness and levator ani morphology even after controlling for obvious confounders [152]. A recent MRI study was able to distinguish distinct patterns of change in pelvic support in women with stress as opposed to mixed urinary incontinence [153]. Evidence of denervation and changes in pelvic striated muscle fibre number, type, and diameter have been found in asymptomatic and nulliparous women (see Committee 2, Cell Biology). For example, in a sample of 82 nulliparous women, neither levator function (measured by resting vaginal closure force and augmentation of vaginal closure force) nor pelvic organ support (on pelvic exam) showed an association with age [154]. A histomorphometric study, using levator ani muscle from 94 female cadavers (aged 15-58), 10 male cadavers (aged 23-35), and 24 women undergoing pelvic surgery, found that myogenic cell damage was associated with both parity and age (</> age 35), but there was no difference between nulliparous women, men, and women with pelvic organ prolapse and/or UI [155]. Total collagen content in pelvic muscle and fascia declines with age, with increased cross-linking and decreased elasticity, [156] but this association does not imply a direct causative effect of “ageing.” Constipation may independently contribute to pelvic floor dysfunction in older women [157, 158].

2.4. Vagina

The prevalence of age-related changes in the vagina varies with hormonal status, coexistent vascular disease, and the continuation or lack of sexual activity [159]. The postmenopausal decrease in oestrogen plays a part in many age-associated vaginal changes. Oestrogen is trophic for much of the LUT in women, with oestrogen receptors found in the vagina, vestibule, distal urethra, bladder trigone, pelvic muscles, and ligamentum rotundum [160]. Yet, as the Women’s Health Initiative trial has shown, one cannot assume that the association between low oestrogen levels and physiological changes implies that hormone replacement will reverse these changes, restore function, or reduce symptoms [161, 162]. Moreover, the data are equivocal whether and how LUT oestrogen receptors change in number, density, or function with age [133].

Following menopause, the vaginal epithelium loses the majority of its superficial and intermediate layers. Mucosal thinning may be associated with inflammation, evident as erythema, telangiectasia, petechiae, friability, and erosions. This may be responsible for urgency and frequency in some frail elderly women. In addition, there is loss of epithelial glycogen and lubrication, and mucosal pH increases from 4.5-5.5 to 7.0-7.4 [163]. These changes can lead to loss of normal adherent flora (lactobacillus), colonisation with pathogenic organisms such as E. coli and enterococci, and the observed increase in bacteriuria and recurrent symptomatic urinary tract infections (UTIs) in older women [164].

Vaginal blood flow, which is important for mucosal integrity and submucosal fullness, decreases with age. Whether this is oestrogen-related, and/or due to concomitant vascular disease is not known. Collagen and lipofuscin deposition in the stroma increases, and may be accompanied by invasion by lymphocytes and plasma cells [164]. The combined epithelial and stromal changes are associated with vaginal wall thinning and flattening of rugae [160]. The vaginal vault may shorten and narrow, and the introital opening decrease (and in severe cases become stenotic), which may make vaginal examination, intercourse, and use of pessaries difficult. However, it is not clear that vaginal shortening is clinically relevant: in one case series of over 3,000 women attending a general clinic, total vaginal length decreased by only 0.08 cm every 10 years [165]. Vaginal shape also may be altered by POP. Because of the multiple potential confounding factors discussed above, a causal relationship between urogenital atrophy and urogenital symptoms/LUTS should not be automatically assumed. Very few randomised trials of oestrogen (oral or topical) for urogenital symptoms include women over age 75, use patient-defined outcomes in addition to physiological measures, or evaluate quality of life outcomes [166]. There are insufficient data to provide an evidence-based approach to symptomatic urogenital atrophy in older women. Oral oestrogen should not be used, but expert opinion supports topical oestrogen treatment (cream, intravaginal tablets, or oestrogen-impregnated pessary-like ring). The validation of vaginal self-swab collection specimen collection offers new opportunities for extending relevant questions to epidemiological studies of older women living in the community [167]. Nevertheless, despite all reported biological changes, aging did not interfere with the ability of fibroblasts obtained from older women with prolapse to be successfully reprogrammed [168].

2.5. Prostate

Histological benign prostatic hyperplasia (BPH) is strongly age-related [169], and may lead to prostate enlargement (BPE) and outlet obstruction (BOO). While many LUT changes in women are associated with lower oestrogen levels, BPH results from the development of an oestrogen-predominant hormonal milieu in the prostate. The trophic prostatic androgen, dihydrotestosterone, is formed by the 5-a reduction of testosterone. Dihydrotestosterone levels decrease with age, while oestradiol concentrations increase in the prostate stroma and remain constant in epithelial tissues, leading to an increase in the oestradiol/dihydrotestosterone ratio and promoting stromal proliferation [170, 171]. Epithelial hyperplasia in turn is mediated by an array of stromal factors [172].
Histological BPH occurs in nearly 80% of men by age eighty [169]. Mean prostate volume increases with age but is very variable; its strongest predictor is prostate specific antigen level of >1.4-2 ng/mL [173]. LUTS in men increase linearly over time, with the fastest increase during the seventh decade, such that by age 80 approximately one-third of men have received treatment for moderate to severe LUTS [174]. Natural history studies and randomized intervention trials, however, consistently demonstrate that symptomatic progression of benign prostate disease is not inevitable. LUTS remit in about one-third of symptomatic men without treatment [175]. Approximately one-third to one-half of affected men develop DO. Thus, even in the presence of demonstrable BPE and/or BOO, the aetiology of LUTS is multifactorial, making prostate-related LUTS in older men a diagnosis of exclusion. Nevertheless, age-stratified normative values for prostate volume, PSA level, as well as indicators of clinical symptoms, quality of life measures and urodynamic parameters may help in such decisions [176].

Although most patients are asymptomatic at the time of prostate cancer diagnosis, this is another possible cause of LUTS, including urgency UI, in older men. However, evaluation for prostate cancer in frail elderly men is rarely if ever indicated, given the high likelihood of limited remaining life expectancy.

The evidence as to whether prostatic inflammation, either acute or chronic, contributes to urinary retention and LUTS in frail older men is contradictory. In a single institution case series of 374 men undergoing TURP for acute urinary retention (AUR) or LUTS, pathological evidence of acute inflammation was significantly more common men presenting with AUR than LUTS (70% vs. 45%) [177]. However, in a much smaller case series of 70 men presenting with AUR, there was no association between inflammation from prostate infarction and AUR [178]. Nevertheless, a recent study demonstrated phenotypic changes and an increased differential expression of a variety of genes involved in inflammation and oxidative stress within glandular adjacent stroma microdissected from young and aged mouse prostates [179]. Such changes may play a role in promoting the development of BPH, BPE and cancer in aged prostates [180]. However, recent studies conducted using both human tissues and animal models support the hypothesis that senescence-associated inflammatory pathways contribute to the pathogenesis of BPH [181].

2.6. Other changes

The role of various neurotransmitters in the central and peripheral nervous system in UI is under active investigation (see Committee 2, Cell Biology). Nevertheless, age-related changes in the actions of these neurotransmitters, their receptors, or the cellular events they stimulate may contribute to the development of UI in frail older persons.

Conversely, a number of aging changes involving the nervous system may reflect a common mechanism for both aging and each other; and therefore strategies designed to target such pathways would have the potential to delay the onset of such chronic diseases, thus enhancing function, independence and health span in older adults [187-189]. Although there is growing evidence that atherosclerosis and other forms of aging-related cardiovascular dysfunction [191, 192], contribute to declines in LUT function and
symptoms in old age, from the perspective of mechanisms this hypothesis remains to be explored in the context of genitourinary aging.

3. FACTORS OUTSIDE THE LOWER URINARY TRACT CAUSING OR CONTRIBUTING TO URINARY INCONTINENCE

A hallmark of UI in the frail elderly population is the wide variety of factors and conditions outside the lower urinary tract that can cause or contribute to leakage (Table 2).

3.1. Medications

The risk of difficulty controlling urination in community dwelling older women taking medications with LUT effects was about 30% higher compared to those who did not take such medications (OR 1.31 CI 1.05-1.21). This did not occur in men [193]. Overall 20.5% of these women reported incident incontinence at Year 4 (3 years from baseline). Several studies have implicated alpha blockers as causing urinary incontinence in women with an adjusted OR of 4.98 [194, 195] and increasing to OR 8.81 in conjunction with loop diuretics [196]. Oestrogens have been shown to increase risk of incontinence in women OR 1.6 to 2.0. [195, 197] A wide range of medications have been implicated in causing urinary incontinence with varying degrees of evidence [198]. There has even been a case report of hydroxychloroquine causing urinary incontinence [199]. A retrospective analysis of drug dispensing data in a Japanese cohort found that polypharmacy was associated with the use of medications known to contribute to urgency [200]. Similarly, a Canadian cross-sectional study identified a strong association (OR 4.9, 95%CI 3.1-7.9) between polypharmacy, defined as 5 or more medications, and the prescription of a medication known to cause LUTS [201]. However, there is little evidence that polypharmacy in the absence of drugs that cause incontinence has an impact on the lower urinary tract, and it is likely that the association between polypharmacy and urgency relates to the fact that the more drugs an individual is prescribed, the higher the odds that one of them will be a drug known to induce urgency. Elderly patients commenced on new treatments should be monitored for changes in urinary symptoms. Many classes of medications commonly prescribed for the frail elderly can cause or contribute to the development of UI (Table 3).

Increased mobility and decreased levels of physical activity, the elderly, is associated with cognitive impairment, decreased urinary incontinence including arthritis of the hip or knee (Relative Risk Ratio (RRR) = 1.21, P \leq 0.001), arthritis of the hand or wrist (RRR = 1.15, P = 0.001), stroke (RRR = 1.18, P = 0.078), other heart conditions (RRR = 1.19, P = 0.001), and having any cancer (RRR = 1.13, P = 0.0020). Obesity and being overweight increased the likelihood of having UI (RRR = 1.32, P = 0.001 and RRR = 1.14, P = 0.0013, respectively), compared with being at normal weight. Incontinence remained a significant predictor of lower quality of life [202].

The prevalence of urinary incontinence (UI) is increased in the presence of frailty. The elderly are prone to frailty and commonly have co-morbid medical illnesses. In a large population-based observation study UI (defined as use of pads) was independently associated with one or more other geriatric conditions (cognitive impairment, injurious falls, dizziness, vision impairment, hearing impairment) in 60%, two or more conditions in 29% and three or more in 13% [203]. Elderly subjects with urinary incontinence had a 2.9 fold greater chance of becoming more frail over a 12 month period than those without incontinence (p=0.007) [204].

In a sample of 572 older Latinos participating in a programme to increase walking, medical comorbidity was independently associated with higher rates of UI (OR 1.66). More physical activity was independently associated with lower UI (Odds Ratio (OR) 0.77). Hypertension, congestive heart failure, arthritis, depression and anxiety were associated with a higher prevalence of UI. A linear correlation was found between prevalence of UI and the number of comorbid conditions. (correlation coefficient =0.81) [205].

In an observational study of 6,361 community dwelling women, aged 65 and older, participating in the study of Osteoporotic Fractures, after adjusting for confounders, women with recent physical function decline (a worsening of 1 standard deviation from baseline) were more likely to report weekly incontinence (OR 1.3) for decline in walking speed over 6 meters and (OR 1.4) for decline to stand from sitting [206]. The Nurses’ Health Study found that moderate-intensity low impact physical activity including walking resulted in a 20-25% reduction in the risk of developing UI in older women particularly stress rather urge incontinence [207]. Factors associated with persistent UI were similar to those associated with increasing incidence including lower physical activity levels. The strongest factors for

</table>
persistent UI were older age, white race and obesity [208]. Likewise, impaired cognition is associated with an increased likelihood of UI. For example in a UK cross-sectional survey of over 15,051 subjects, persons with cognitive impairment (Mini Mental State Exam score <= 23, prevalence 18%) were significantly more likely to have UI (adjusted OR 1.3), impaired hearing (OR 1.7), poor vision (OR 1.7) have had at least two falls in the previous six months (OR 1.4), and report poorer health (OR 1.9) [209].

The Jerusalem Cohort Longitudinal study assessed the same community dwelling subjects at age 70, 78 and age 85. Urinary incontinence increased from 14.1% to 31.3% and to 42.5% at age 85. This was associated with an increase in comorbidity and Charlson’s disability index of 7.3, 11.7 and 21.7 respectively and increase in geriatric syndromes [210].

A study of 6903 participants (mean age 82.2) in Europe and Ontario receiving home care services identified an increase in Geriatric syndromes (GS) in the presence of associated diseases. Participants presented with an average of 2.6 diseases and 2 GS. Urinary incontinence was present in 47% [211]. A study of 270 subjects aged 65 to 89 reported 26.3% moderate or severe urinary incontinence in the preceding 12 months in 3 groups: frailty (7.4%), pre-frail (45.9%) and non-frail (46.7%). In a second sample of 300 frail subjects aged 90 to 107, 37.4% reported moderate or severe incontinence. Incontinent subjects were 6.5 times more likely to be in the frail group and 2.3 times in the pre-frail with respect to continent subjects. The authors concluded that UI was a marker of frailty [212]. In a cross sectional study of 521 community Brazilian elderly > 60 years were assessed for the association between frailty and geriatric syndromes. Subjects were classified as frail, (>2 criteria) pre-frail (1 or 2 criteria) or robust elderly. Urinary/faecal incontinence occurred in 23.7%, 12.8% and 9.2% respectively. The commonest Geriatric syndrome was cognitive impairment. In this study there was no association between incontinence and frailty [213]. A study of 447 community dwelling nursing home eligible elderly with diabetes found a prevalence of urinary incontinence of 44%. Older age, dependence on others for ambulation or transferring and cognitive impairment were associated with UI [214].

Comorbid conditions can affect incontinence through multiple mechanisms e.g. diabetes mellitus, present in approximately 15-20% of frail elderly may cause UI by diabetes associated LUT dysfunction (DO, OAB, cystopathy and incomplete bladder emptying) or by poor diabetic control (hyperglycaemia causing osmotic diuresis and polyuria). The Nurses Health Studies, NHS and NHS II [215] showed an increase in weekly urgency incontinence (OR 1.4) in women with type 2 diabetes compared to those without. Findings from the NHANES 2001-2002 Survey showed that prevalence of UI was significantly higher in women with impaired fasting glucose and diabetes mellitus compared to those with normal fasting glucose. Two microvascular complications caused by diabetes, peripheral neuropathic pain and macroalbuminuria, were positively but not statistically significantly associated with weekly UI [216]. In diabetic women, peripheral neuropathy have been significantly associated with LUTS and metabolic syndrome has been associated with OAB [217]. In a younger population of mean age 59 years, the Diabetes and Aging Study found the prevalence of occasional urinary incontinence to be over 65%. HbA1C level was not associated with the presence or absence of urinary incontinence. Women with HbA1C >= 9% had more limitations in daily activity due to incontinence, defined as self-reported “quite a bit” or “extremely” in the preceding 12 months compared to women with HBA1C < 6% [218]. Higher glycated haemoglobin levels have been associated with increased symptoms of OAB [219].

Incontinence impairs quality of life (QOL) in the elderly [220]. In a cross sectional study of 1124 subjects over 70, (mean age 79.5 years) urinary incontinence prevalence was 18% and the severity of UI increased with age. UI was more common in women, and was associated with worse self-reported health. Incontinent subjects were more likely to require assistance with ADLs, had more depressive symptoms and worse physical performance. Increasing severity of incontinence was negatively associated with QOL as measured by the Short Form-36 [221].

3.3. Neurological & psychiatric disorders

3.3.1 Neurological disorders

A more detailed summary of neurological disorders and their impact on UI is covered in the Chapter on Specific Neurological Diseases. Neurological and psychiatric disorders are highly prevalent in frail older people. Neurological conditions in the elderly commonly associated with urinary incontinence include stroke, Alzheimer’s dementia (AD), multi-infarct dementia or mixed AD and vascular dementia, Diffuse Lewy Body (DLB) disease and Parkinson’s disease. Less common conditions include Normal Pressure Hydrocephalus (NPH), Progressive Supranuclear Palsy (PSP) and Multiple System Atrophy (MSA). Each of these conditions are associated with the development of brain lesions that can interfere with the micturition pathway and interfere with the normal ability to inhibit voiding as well as affecting cognition. These conditions are associated with impaired mobility and can interfere with the ability to toilet independently.

In Alzheimer’s disease, UI is often associated with severe cognitive decline whereas in DLB it usually precedes severe cognitive impairment. Occurrence of UI was significantly earlier 3.2y in DLB compared with 5.9y in AD [222]. NPH should be a diagnostic consideration in any frail older patient who presents with new onset of UI in association with gait disturbance and cognitive impairment. A subset of these patients benefits from surgical implantation of a cerebrospinal fluid shunt [223].
LUTS, UI and urodynamic DO are common in older persons with Parkinson’s disease. A logistic regression analysis of 3414 Parkinson’s disease patients found a significant correlation of orthostatic hypotension and urinary incontinence with age and duration of the disease. The presence of UI in persons with Parkinson’s may in turn increase their risk for disability: in one series of patients with Parkinson’s UI increased the risk of falling by nearly six-fold. Urinary symptoms often non-responsive to L Dopa therapy [224]. MSA presents with a combination of impaired autonomic function, parkinsonism (MSA-P) or cerebellar ataxia (MSA-C) or both [225]. It frequently begins with bladder dysfunction and erectile dysfunction in males and is associated with bladder symptoms of DO, often progressing to incomplete emptying. High PVR may help in pointing to a diagnosis of MSA-P rather than Parkinson’s disease [226].

With the introduction of magnetic resonance brain imaging into routine clinical practice, radiology reports in older patients have increasingly emphasised the presence of structural abnormalities involving the white matter [227]. Terminology has also undergone a great change, moving away from subcortical atherosclerotic encephalopathy (Binswanger’s disease, a specific and relatively rare form of dementia), towards leukoaraiosis [228] and, most recently, to the concept of white matter signal abnormalities (WMSA) [227, 229]. Brain MRI identified subjects with leukoaraiosis as more likely to have urinary dysfunction which may precede cognitive impairment particularly in grade 1 disease [230]. White matter hyperintensities (WMH) have been linked to severity of incontinence rather than to its presence [231]. The disorder of bladder control resulting from white matter disease (WMD) has been termed vascular incontinence [232]. WMH load appears to progress in association with ageing and the amount of frontal WMH are predictive of urinary incontinence in amnestic mild cognitive impairment and AD [233].

White matter lesions were found to be a more significant contributor to OAB and incontinence than AD in the elderly [234].

3.3.2 Depression

As in younger persons, frail older persons with UI have a higher risk of depression, a finding that has been replicated across cultures. Depression in older persons with UI may be under-diagnosed and under-treated: in one study of homebound adults with UI and severe depression, only 35% carried a previous diagnosis of depression and only 34% had been prescribed an antidepressant [235]. UI may add to the burden of depression by decreasing life satisfaction [236] and self-rated health, [237] and by its association in frail elders with comorbidity [238].

Studies of the association of depression and UI in older persons are consistent across several depression measures. The validated Center for Epidemiologic Studies-Depression was used in two U.S. studies: a cross-sectional analysis of nearly 10,000 community-based persons found an adjusted risk ratio for depression with UI 1.39 [95% CI 1.24, 1.55]), [239]. A large community-based study of older Mexican Americans reported adjusted OR for depression 1.94 [95% CI 1.46-2.59]) [240]. The emotional disturbances and social isolation subscales of the Nottingham Health Profile Questionnaire was associated with urgency but not stress incontinence [241] and have included studies in Asia [242]. Although no association between UI and depression was found in a Korean study of 135 community living elderly aged greater than 85 years, it used a higher cut-off (>7) on the Geriatric Depression Scale and, unlike many other studies, found no association between UI and mobility [243]. Self-report of depression or sadness has [244],[245] and has not been associated with UI [246].

3.3.3 Psychological distress and quality of life

Psychological distress, assessed by the General Health Questionnaire, was associated with UI in African Americans (adjusted OR 5.60 [95% CI 1.88–16.67]), but not in whites, in a cross-sectional study of community based older persons with mean age 67y. However, a longitudinal analysis of the same population over 13 years found that persons with UI and psychological distress were more likely to report UI-specific functional impairment (e.g., avoidance of social activities, shopping, and physical activities) (adjusted OR 6.55 [95% CI 1.94–22.12]). Additionally, persons with UI and condition-specific functional loss were more likely to develop psychological distress (OR 3.66 [95% CI 1.61–8.33]) [247, 248].

The EpilUTS a large cross-sectional internet study showed significant impairments in mental health and HRQOL when different urinary symptoms were combined [249, 250]. The US sample of the EpilUTS study involving 2485 men and 2877 women aged 65 and older found OAB was associated with significant impairment in HRQOL. Rates of Anxiety of >7 on HADS-A were 16.4% for men and 23.6% for women with OAB compared to 3.3% and 8.6% with minimal or no symptoms. Similarly rates for depression on the HADS-D were 17.3% and 15.7% for OAB compared to 4% and 6.4% in those with no or minimal symptoms [251].

A case controlled study of 100 elderly men attending a Urology outpatient matched with 100 age matched controls from the community and Geriatric outpatient clinics found those with moderate to severe LUTS had worse HRQOL. This was evident in a number of ageing male symptoms including depression, decline in feelings of general well-being, decreased sexual performance, decreased muscle strength [252].

The direction of the causal relationship between UI and depression in frail persons is unclear, as nearly all studies were cross-sectional. The results of the one longitudinal study suggested that it is not UI itself but UI-specific functional loss (e.g., avoidance of social activities, attending church, etc.) that is most
closely associated with psychological distress, even after controlling for important covariates [235].

3.3.4 Falls

Urinary urgency and urinary incontinence, urinary frequency, and nocturia have been identified repeatedly as risk factors for falls among community-dwelling older adults [253-259]. Mixed incontinence (a combination of urgency and stress incontinence) has also been associated with falls risk in women 70 years and older [260]. Brown and colleagues [259] performed a secondary analysis of data from an osteoporosis cohort study, examining a group of 6049 community-dwelling older women using regular self-completed questionnaires sent to all participants every four months. In this cohort, followed for an average of three years, those with at least one weekly UUI episode were more likely to fall (OR 1.26, 95%CI 1.14-1.40) than those without. Weekly UUI was also associated with higher odds of sustaining a non-spinal fracture (hazard ratio 1.34 95%CI 1.06-1.69). In this study, stress incontinence was not associated with higher odds of falling (Odds ratio (OR) 1.06, CI 0.95-1.19) or sustaining a fracture (relative hazard 0.98, CI 0.75-1.28).

Analysis of the Concord Health and Ageing in Men Project, a longitudinal study of community-dwelling men in Australia followed 1090 men over a period of 2 years. Here, the presence of urgency incontinence, defined as weekly episodes of UUI, was associated with a higher incidence of falls (OR 2.57 95%CI 1.51 – 4.3) and men with a higher International Prostate Symptom Score storage sub-score, defined as a score of 19 and above, had a higher incident rate of falls (incident rate ratio 1.72 (95%CI 1.24-2.38) [261]. A Japanese study of patients with Parkinson’s disease found that increased micturition frequency either by day or night was not associated with falls, but that the presence of urinary urgency was strongly associated with a large increase in the odds of falling (OR 5.14 95%CI 1.51-17.48). Only 14% of the falls reported in this study occurred on the way to or from the toilet [262].

A recent systematic review of the association between falls and LUTS in community-dwelling men aged 60 years and over identified six cross-sectional studies and three prospective cohort studies. The identified data were only suitable for qualitative synthesis but urinary incontinence and storage LUTS were consistently shown to have a weak to moderate association with an increased likelihood of falls. None of the identified studies examined potential causes for these associations; the categorisation of continence or not and degree of accounting for confounding variables was inconsistent across the included studies [263]. A small cross-sectional analysis of community dwelling women aged 65 and over in the US examined the association between nocturia, nocturnal enuresis and falls. Neither severity of UI nor severity of nocturia was associated with an increased risk of falls, but there was a statistically significant association between nocturnal enuresis and impairment of physical function and the presence of frailty. However, in the multivariable regression model, which included age, physical function, and the frequency of nocturnal enuresis episodes, only physical function remained as significant risk factor for falls [264]. One study, a prospective cohort study of older men in the USA, identified a statistically significant association between straining to void and falls, with a 60% increase in falls risk for those reporting the need to push or strain to initiate urination at least half the time [265]. In hospital, urinary incontinence is associated with an increased propensity to fall in older inpatients [266, 267]. Urinary incontinence is also associated with falls in institutionalised older persons [268, 269]. The underlying reason for the association is not yet clear, although several and multiple mechanisms are most likely. A UK case control study in older community dwelling women presenting to an urban Emergency Department found that only 6% of those with a fall attributed this to their LUTS[270]
