## CONTENTS

Preface

6th ICI Group Photo

Faculty

Evidence – Based Medicine Overview of the Main Steps for Developing and Grading Guideline Recommendations

1. Epidemiology of Urinary Incontinence (UI) and Other Lower Urinary Tract Symptoms (LUTS), Pelvic Organ Prolapse (POP) and Anal Incontinence (AI)

2. Cell Biology

3. Neural Control

4. Pathophysiology of Urinary Incontinence, Faecal Incontinence and Pelvic Organ Prolapse

5A. Initial Assessment of Urinary Incontinence in Adult Male and Female Patients

5B. Patient-reported Outcome Assessment

6. Urodynamic Testing

7. Imaging, Neurophysiological Testing and Other Tests

8. Pharmacological Treatment of Urinary Incontinence

9. Diagnosis and management of urinary incontinence in childhood

10. Neurologic Urinary and Faecal Incontinence

11. Incontinence in Frail Older Persons

12. Adult Conservative Management

13. Surgical Treatment of Urinary Incontinence in Men

14. Surgery for Urinary Incontinence in Women

15. Pelvic Organ Prolapse Surgery

16. Assessment and Conservative Management of Faecal Incontinence and Quality of Life in Adults

17. Surgery for Faecal Incontinence

18. Fistula

19. Bladder Pain Syndrome

20. Management Using Continence Products

21. Primary Prevention, Continence Promotion, Models of Care and Education

22. Economics of Urinary & Faecal Incontinence, and Prolapse

23. Research

Recommendations of the International Scientific Committee: Evaluation and Treatment of Urinary Incontinence, Pelvic Organ Prolapse and Faecal Incontinence

The 6th International Consultation on Incontinence was held in Tokyo in September 2016, made possible by the generous support of the International Continence Society. The first four ICI Consultations were held as stand-alone meetings. The 5th ICI was held during the annual meeting of EAU, and this made possible the attendance of a wider range of participants than had previously occurred. Holding the 6th Consultation at the ICS meant that many more of those most closely associated with the care of sufferers with incontinence were able to contribute to the Consultation. They were able to participate in the open sessions where the chair of each committee presented to the audience the principle findings of their committee.

The 23 committees included more than 150 experts from every corner of the globe: all selected according to their pre-eminence in their topic area within the overall subject of incontinence. The committees prepared their chapters making full use of modern technology and in particular email discussions. Hence they arrived at the 6th ICI with their committees’ work in final draft. The principle of the Consultation is to present the final draft to a wider audience and then to finalise the chapter following the discussions at the Consultation. The Consultation again included the important conditions often associated with urinary incontinence, namely faecal incontinence, pelvic organ prolapse, bladder pain syndrome and obstetric fistula.

Whilst some conditions afflict either men or women, many conditions affect both sexes. The Consultation dealt with functional pelvic disorders, usually of a benign nature, although some patient’s problems emanate from treatment of malignancy, for example, stress incontinence after a radical prostatectomy for prostate cancer. However, the principles of management are similar in both men and women, in most conditions.

This book, produced by the huge efforts of the 23 committees has once again vigorously examined and summarised the latest scientific evidence, and remains a unique publication and reference source. The reference source is invaluable to all those who commit their professional lives to men and women suffering from these often miserable conditions. The conditions we deal with are not “glamorous” medicine and remain “Cinderella” subjects. However, we have seen the emphasis move towards measuring outcomes by assessing improved quality of life. As the population ages then maintaining or improving quality of life in the latest stages of all our lives will attract greater attention. Hence the work of the ICI remains vitally important to the many millions of women and men who suffer from these conditions.

On a personal note, it has been a great privilege to be involved with the ICI Consultations for 20 years. Now seems the right time to step down as chair, however it is the intention that there should be a 7th ICI in 2020. The first Consultation in 1998 resulted from my earlier involvement with the International Consultation on Urological Diseases (ICUD) in Consultations on benign prostate disease in 1993 and 1995. Professor Saad Khoury, a founder of ICUD, provided the encouragement and practical support that made the first and subsequent Consultations possible: we owe a great debt to him and the other founding fathers of the ICUD for their support. Alan Wein, Linda Cardozo and I shared the responsibilities for the first five ICIs, and we were joined by Adrian Wagg for this 6th ICI. It has been a tremendous honour to work with Alan and Linda, and latterly with Adrian. It has also been an honour to work with so many experts, who over the last 20 years, have willingly given their time to provide the scientific substance to these six publications that have been termed as “the” reference books on the subject. I am sure that this 6th book will be as valued as the previous five.

Paul Abrams, Chair of the 6th International Consultation on Incontinence.

INTRODUCTION

The International Consultation on Urological Diseases (ICUD) is a non-governmental organization registered with the World Health Organisation (WHO). In the last ten years Consultations have been organised on BPH, Prostate Cancer, Urinary Stone Disease, Nosocomial Infections, Erectile Dysfunction and Urinary Incontinence. These consultations have looked at published evidence and produced recommendations at four levels; highly recommended, recommended, optional and not recommended. This method has been useful but the ICUD believes that there should be more explicit statements of the levels of evidence that generate the subsequent grades of recommendations.

The Agency for Health Care Policy and Research (AHCPR) have used specified evidence levels to justify recommendations for the investigation and treatment of a variety of conditions. The Oxford Centre for Evidence Based Medicine have produced a widely accepted adaptation of the work of AHCPR. (June 5th 2001 http://minerva.minervation.com/cebmg/docs/levels.html).

The ICUD has examined the Oxford guidelines and discussed with the Oxford group their applicability to the Consultations organised by ICUD. It is highly desirable that the recommendations made by the Consultations follow an accepted grading system supported by explicit levels of evidence. The ICUD proposes that future consultations should use a modified version of the Oxford system which can be directly ‘mapped’ onto the Oxford system.

1. 1st Step: Define the specific questions or statements that the recommendations are supposed to address.

2. 2nd Step: Analyse and rate (level of evidence) the relevant papers published in the literature.

The analysis of the literature is an important step in preparing recommendations and their guarantee of quality.

2.1. What papers should be included in the analysis?

- Papers published, or accepted for publication in the peer reviewed issues of journals.
- The committee should do its best to search for papers accepted for publication by the peer reviewed journals in the relevant field but not yet published.
- Abstracts published in peer review journals should be identified. If of sufficient interest the author(s) should be asked for full details of methodology and results. The relevant committee members can then ‘peer review’ the data, and if the data confirms the details in the abstract, then that abstract may be included, with an explanatory footnote. This is a complex issue – it may actually increase publication bias as “uninteresting” abstracts commonly do not progress to full publication.
- Papers published in non peer reviewed supplements will not be included.

An exhaustive list should be obtained through:

I. the major databases covering the last ten years (e.g. Medline, Embase, Cochrane Library, Biois, Science Citation Index)

II. the table of contents of the major journals of urology and other relevant journals, for the last three months, to take into account the possible delay in the indexation of the published papers in the databases.

It is expected that the highly experienced and expert committee members provide additional assurance that no important study would be missed using this review process.

2.2. How papers are analysed?

Papers published in peer reviewed journals have differing quality and level of evidence.

Each committee will rate the included papers according to levels of evidence (see below).
The level (strength) of evidence provided by an individual study depends on the ability of the study design to minimise the possibility of bias and to maximise attribution.

is influenced by:

- **the type of study**
  - Systematic reviews and meta-analysis of randomised controlled trials
  - Randomised controlled trials
  - Non-randomised cohort studies
  - Case control studies
  - Case series
  - Expert opinion

- **how well the study was designed and carried out**

Failure to give due attention to key aspects of study methodology increase the risk of bias or confounding factors, and thus reduces the study’s reliability.

The use of **standard check lists** is recommended to insure that all relevant aspects are considered and that a consistent approach is used in the methodological assessment of the evidence.

The objective of the check list is to give a quality rating for individual studies.

- **how well the study was reported**

The ICUD has adopted the CONSORT statement and its widely accepted check list. The CONSORT statement and the checklist are available at http://www.consort-statement.org

### 2.3. How papers are rated?

Papers are rated following a «Level of Evidence scale».

ICUD has modified the Oxford Center for Evidence-Based Medicine levels of evidence.

The levels of evidence scales vary between types of studies (ie therapy, diagnosis, differential diagnosis/symptom prevalence study).

- the Oxford Center for Evidence-Based Medicine Website:
  - http://minerva.minervation.com-cebm/docs/levels.html

#### 3. 3rd Step: Synthesis of the evidence

After the selection of the papers and the rating of the level of evidence of each study, the next step is to compile a summary of the individual studies and the overall direction of the evidence in an **Evidence Table**.

#### 4. 4th Step: Considered judgment (integration of individual clinical expertise)

Having completed a rigorous and objective synthesis of the evidence base, the committee must then make a judgement as to the grade of the recommendation on the basis of this evidence. This requires the exercise of judgement based on clinical experience as well as knowledge of the evidence and the methods used to generate it. Evidence based medicine requires the integration of individual clinical expertise with best available external clinical evidence from systematic research. Without the former, practice quickly becomes tyrannised by evidence, for even excellent external evidence may be inappropriate to, or inapplicable for, an individual patient: without current best evidence, practice quickly becomes out of date. Although it is not practical to lay our rules for exercising judgement, guideline development groups are asked to consider the evidence in terms of quantity, quality, and consistency; applicability; generalisability; and clinical impact.

#### 5. 5th Step: Final Grading

The grading of the recommendation is intended to strike an appropriate balance between incorporating the complexity of type and quality of the evidence and maintaining clarity for guideline users.

The recommendations for grading follow the Oxford Centre for Evidence-Based Medicine.

The levels of evidence shown below have again been modified in the light of previous consultations. There are now 4 levels of evidence instead of 5.

The grades of recommendation have not been reduced and a “no recommendation possible” grade has been added.

#### 6. Levels of Evidence and Grades of Recommendation Therapeutic Interventions

All interventions should be judged by the body of evidence for their efficacy, tolerability, safety, clinical effectiveness and cost effectiveness. It is accepted that at present little data exists on cost effectiveness for most interventions.

##### 6.1. Levels of Evidence

Firstly, it should be stated that any level of evidence may be positive (the therapy works) or negative (the therapy doesn’t work). A level of evidence is given to each individual study.

- **Level 1** evidence (incorporates Oxford 1a, 1b) usually involves meta-analysis of trials (RCTs) or a good quality randomised controlled trial, or “all or none” studies in which no treatment is not an option, for example in vesicovaginal fistula.

- **Level 2** evidence (incorporates Oxford 2a, 2b and 2c) includes “low” quality RCT (e.g. < 80% follow up) or metaanalysis (with homogeneity) of
good quality prospective ‘cohort studies’. These may include a single group when individuals who develop the condition are compared with others from within the original cohort group. There can be parallel cohorts, where those with the condition in the first group are compared with those in the second group.

- **Level 3** evidence (incorporates Oxford 3a, 3b and 4) includes:

  - **good quality** retrospective ‘case-control studies’ where a group of patients who have a condition are matched appropriately (e.g. for age, sex etc) with control individuals who do not have the condition.

  - **good quality** ‘case series’ where a complete group of patients all, with the same condition/disease/therapeutic intervention, are described, without a comparison control group.

- **Level 4** evidence (incorporates Oxford 4) includes expert opinion where the opinion is based not on evidence but on ‘first principles’ (e.g. physiological or anatomical) or bench research. The Delphi process can be used to give ‘expert opinion’ greater authority. In the Delphi process a series of questions are posed to a panel; the answers are collected into a series of ‘options’; the options are serially ranked; if a 75% agreement is reached then a Delphi consensus statement can be made.

- **Grade A** recommendation usually depends on consistent level 1 evidence and often means that the recommendation is effectively mandatory and placed within a clinical care pathway. However, there will be occasions where excellent evidence (level 1) does not lead to a Grade A recommendation, for example, if the therapy is prohibitively expensive, dangerous or unethical. Grade A recommendation can follow from Level 2 evidence. However, a Grade A recommendation needs a greater body of evidence if based on anything except Level 1 evidence

- **Grade B** recommendation usually depends on consistent level 2 and or 3 studies, or ‘majority evidence’ from RCT’s.

- **Grade C** recommendation usually depends on level 4 studies or ‘majority evidence’ from level 2/3 studies or Dephi processed expert opinion.

- **Grade D** “No recommendation possible” would be used where the evidence is inadequate or conflicting and when expert opinion is delivered without a formal analytical process, such as by Dephi.

### 7. Levels of Evidence and Grades of Recommendation for Methods of Assessment and Investigation

From initial discussions with the Oxford group it is clear that application of levels of evidence/grades of recommendation for diagnostic techniques is much more complex than for interventions.

The ICUD recommend, that, as a minimum, any test should be subjected to three questions:

1. Does the test have good technical performance, for example, do three aliquots of the same urine sample give the same result when subjected to ‘stix’ testing?

2. Does the test have good diagnostic performance, ideally against a “gold standard” measure?

3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

For the third component (therapeutic performance) the same approach can be used as for section 6.

### 8. Levels of Evidence and Grades of Recommendation for Basic Science and Epidemiology Studies

The proposed ICUD system does not easily fit into these areas of science. Further research needs to be carried out, in order to develop explicit levels of evidence that can lead to recommendations as to the soundness of data in these important aspects of medicine.

**CONCLUSION**

The ICUD believes that its consultations should follow the ICUD system of levels of evidence and grades of recommendation, where possible. This system can be mapped to the Oxford system.

There are aspects to the ICUD system that require further research and development, particularly diagnostic performance and cost effectiveness, and also factors such as patient preference.

II. BASIC EPIDEMIOLOGICAL CONSIDERATIONS

Epidemiology is the scientific study of the distribution and determinants of disease in people. Descriptive epidemiology is the description of disease prevalence, incidence, (and mortality) by persons, place and time, while the term analytical epidemiology describes the search for determinants of disease risk. The discovery of risk factors and protective factors may then in turn lead to primary or secondary prevention.

In order to collect knowledge about risk factors or natural history, observational studies are needed. Cohort studies and case-control studies are the most common. However, caution is always needed when interpreting the results from such studies, as associations found in epidemiological studies may not be the same as causes. Longitudinal study designs and appropriate control for confounding factors are preferred, as these increase the validity of epidemiologic studies. For practical and ethical reasons, experimental designs are seldom used.

Recommendations and conclusions should always be based on the best available evidence. Studies of interventions, and studies of risk factors generally cannot be randomised because they relate to inherent human characteristics or practices, and exposing subjects to harmful risk factors is unethical. No uniform guidelines for assessing the results of observational studies exist, and the level of evidence for risk factors from observational studies should be judged on the soundness of the exclusion of alternative explanations by statistical and other controls. But some initiatives for how to report meta-analyses of observational studies have been taken [3].

Studies of disease frequency should rely on a very specific definition of the condition under investigation. The absence of unifying definitions for the conditions reviewed here is a fundamental problem which has not been resolved. Definitions used and problems associated with them are discussed in the subsections for the particular populations below.

Prevalence is defined as the probability of experiencing a symptom or having a condition or a disease within a defined population and at a defined time point. The concept is important for establishing the distribution of the condition in the population and for projecting the need for health and medical services.

Incidence is defined as the probability of developing the condition under study during a defined time period. Incidence is usually reported for a one-, two- or five-year time interval.
Even in many of the recent studies reviewed analyses are very simple. Often only proportions or percentages are used to describe differences in different subgroups. Many analyses do not control for confounders (by stratification or multivariate analysis techniques). There is an obvious need for more advanced epidemiological analyses of risk factors and comorbidity, and strength of associations should be determined by relative risks and odds ratios.

The relative risk (RR) estimates the magnitude of an association between exposure and a condition, and indicates the likelihood of having the condition in the exposed group relative to those who are not exposed (e.g. do not have the risk factor). A RR of 1.0 indicates that the rates in the exposed and non-exposed groups are identical and thus that there is no association between the exposure and the condition in that specific dataset. A value greater than 1.0 indicates a positive association or an increased risk. A RR of 2.5 for UI indicates that there is a 2.5 times increased risk or that the persons in question are 150 percent more likely to have incontinence than those without the risk factor.

The odds ratio (OR) is the odds for having a risk factor in persons with a condition divided by the odds among those without the condition. An OR of 2.5 for UI my be interpreted as meaning that in this sample the odds in favour of having incontinence are 2.5 times higher among those with the risk factor than among those without.

For a condition with high prevalence, like UI or POP, OR and RR will not be identical, but in practice the results can be interpreted similarly. Results should always be given with a 95% confidence interval (CI).

Words like well established and established may be used about risk factors and findings with a high level of evidence in the literature. For less documented findings words like “indications of” or “data are suggestive” may be used.

**Summary points:**
- Descriptive epidemiology reports disease incidence, prevalence (and mortality) by persons, place and time.
- Analytical epidemiology searches for determinants of disease risk. There is a need for good longitudinal cohort studies.
- Variations in definitions and measurement issues are fundamental, and lead to problems with assessing the findings in epidemiological studies.
- There is a need for more advanced epidemiological analyses of risk factors and comorbidity using multivariable techniques, and strength of associations should be determined by relative risks and odds ratios.

**III. EPIDEMIOLOGY OF ENURESIS AND URINARY INCONTINENCE IN CHILDREN**

The International Children’s Continence Society (ICCS) has issued recommendations regarding terminology of bedwetting or nocturnal enuresis (NE) in 2006 with a stand alone updated document in 2014[4]. NE is the term for all urinary incontinence during sleep taking place in discrete episodes, regardless of the presence or absence of concomitant daytime symptoms. Monosymptomatic nocturnal enuresis (MNE) denotes bedwetting without any other lower urinary tract (LUT) symptoms, and non-monosymptomatic nocturnal enuresis (NMNE) should be used for those with any concomitant LUT symptom.

NE is caused by relative nocturnal polyuria [5] and/or nocturnal bladder over-activity [6], combined with the lack of arousal at the time when the bladder needs to be emptied. The most important cause is, of course, the lack of arousal, otherwise the child would have had nocturia.

Any other leakage of urine in children during both the day and night is referred to as urinary incontinence (UI), just as it is in the adult population. UI can be continuous or intermittent. Continuous leakage in children is often caused by a congenital malformation, such as ectopic ureter or extrophy epispadias complex. Other causes of continuous leakage can be neurogenic bladder in children with spina bifida, tethered cord or other spinal or sacral malformations. Daytime UI with no obvious cause, i.e. without neurological or congenital anatomic alterations, is often seen together with other urinary symptoms such as frequency, urgency and infections. Altogether these symptoms are referred to as functional LUT dysfunction, which is the term used to describe the entire spectrum of functional filling-voiding disturbances[4]. Several sub-classifications have been used for children who present with varying degrees of “functional” urinary symptoms. Some are based on urodynamic patterns, others on clinical presentation.

According to definitions by the ICCS[4], based on symptoms and flow-residual studies rather than invasive urodynamic investigations, incontinence as a result of a filling-phase dysfunction, is in most cases due to an overactive bladder (OAB), which can also be referred to as “urge syndrome” and “urge incontinence”. Children with OAB usually have detrusor overactivity, but this label cannot be applied to them without cystometric evaluation. When incontinence is
the result of a voiding-phase dysfunction, the diagnosis is often dysfunctional voiding (DV), which is induced by increased activity in the sphincter and pelvic floor during voiding. It is subdivided into staccato and fractionated voiding, and the terms cannot be applied unless repeat uroflow measurements have been performed. Voiding postponement (VD) is another common LUT dysfunction causing UI in children, but differs from the other since it is induced by a habitually postponement of voiding and not a LUT dysfunction per se.

NE and UI due to functional LUT dysfunction are the wetting problems addressed in this chapter. Both can be either primary (the child has not been dry for more than six months) or secondary (the wetting has recurred after a dry period lasting more than six months). If the complaints are secondary, they may signify psychological, neurological or even structural anomalies and therefore require careful consideration.

The healthy infant is socially incontinent but physiologically continent, because micturitions (about once every hour) are discrete and there is no leakage of urine between micturition [7]. Bladder control develops during the first four to six years of life and is a highly complex process, which is still not fully understood. Most children are toilet trained by the age of three years, although there is huge social and cultural variation. By the age of five years, the child is normally able to void at will and to postpone voiding in a socially acceptable manner [8]. By this age, nighttime and daytime involuntary wetting becomes a social problem and a cause for therapeutic intervention.

2. PREVALENCE OF NOCTURNAL ENURESIS (NE)

As bladder control is something that develops over time, longitudinal studies are the best way of defining the dynamics of this process. Studies giving us the prevalence for all children between five and 15 years of age, for example, are not appropriate, as all the developmental stages are clustered together. It is therefore better to give the prevalence for an age cohort, such as seven-year-olds. Furthermore, random sampling should preferably be used in order to be able to say anything about the population. These problems associated with understanding epidemiology were summarised by Krantz [9], who also reviewed the epidemiological studies that had been published by 1993.

One explanation for the variation in prevalence in different studies is the fact that some studies include only monosymptomatic enuresis (MNE), whereas others also include what is defined as nonmonosymptomatic enuresis (NMNE). Another explanatory factor is that the frequency of enuretic episodes differs or is not taken into account in some studies. Moreover, most epidemiological studies link primary and secondary enuresis together.

2.1. Prevalence of all night wetting (MNE+NMNE) according to age

Longitudinal cohort studies should be the ideal when analysing epidemiology in childhood NE, as there is a successive reduction in prevalence. Only a few of these studies are available [10-16] and cross-sectional studies at different ages therefore have to be used.

Most studies investigate cohorts of children in an age span of six to 12 years of age, for example, and give the prevalence for the entire group. Some of them also give the age-related prevalence [13,17-34] which is summarised in Table I. Cross-sectional studies of a specific age are also included [16,35-41] in Table 1.

</table>
In most studies (Table 1), the prevalence for seven-year-olds was between 7% and 10%. In two studies, the prevalence was higher; 15.1% and 16.4% for Turkish [21] and Korean [22] children respectively, despite the fact that the inclusion criteria were very similar in all the studies dealing with seven-year-olds (NE=night wetting once/month or more). Recently two cross sectional epidemiological studies from Yemen have showed markedly higher frequencies with 31%-45% NE among children six to eight years declining to 8.7% in adolescents 15 year or older[28, 32]. These two studies have smaller study populations compared to other studies cited and selection bias can therefore not be ruled out, but the findings are

*Smaller study populations (Total N in study 415-832) not included in meta analyses of total prevalence.

---

**Figure 1:** Prevalence of nocturnal enuresis (NE) by frequency of enuretic episodes and age. The data were obtained from metaanalyses of the epidemiological studies included in table III.1. NE>1 episode/6months: at 7 years [17, 20, 22-26, 35,36], 11-12 years [17, 20, 22-26,38] and 16-17 years [25,37,39]. NE>1 episode/week: at age 7 years [24, 25, 35,36], 11-12 years [24, 25,38] and 16-17 years [25,37].
interesting. The studies by Hellström [33] differ in NE criteria (once/3 months or more) and Järvelin [36] (once/6 months or more). The prevalence of more frequent wetting (once/week or more) was lower compared to the prevalence for all wetting (once/month or more) by age, which have been illustrated in Fig.1.

In 15 studies at age seven years [15-17, 20, 22-25, 30-31,33-37] (Table 1) the numbers of both non-enuretic and enuretic children were given and the definitions for enuresis were similar (MNE and NMNE, wetting once/1-3 months or more). A prevalence of 10.8% was obtained by metaanalyses of these studies (cohort of 22140 seven-year-old children, of whom 2392 were enuretic). Only a few studies included groups of children that were chosen at random from the population [17, 22, 25, 29 36].

At age 11-12 years, the prevalence of NE had decreased and from the studies shown in Table I the prevalence varied between 1.7% and 4.8%. In nine of the studies, the number of non-enuretics and enuretics were available and the definition of NE was similar (once/month or more), apart from Swithinbank's [38] study (once/three months or more). In these studies, the total number of children included was 11660, while the number of children with NE was 404, giving a prevalence of 3.5%. So, of those children with NE at age seven years, almost 15% spontaneously grew out of the wetting every year. In a recent Japanese study a higher resolution rate was reported in children with MNE compared to NMNE in children seven to 12 years of age (21% and 15%, respectively) [23]. Similar results were found in a study from Hong Kong in which the proportion of children with NMNE was significantly greater in adolescent boys than in boys aged five to ten years (32% vs 14.6%), even if the total prevalence of NE was decreasing as in other studies [25].

The variation in the prevalence of NE at 11-12 years between the studies is less than that seen at age seven years. The highest prevalence is no longer found in Turkey or Korea, as was the case at age seven years, but instead also comes from a non-randomised cross-sectional study of 11 to 12-year-old schoolchildren (n = 1145) in the UK (4.7%). It can be suggested that the high prevalence seen in the studies from Turkey and Korea at age seven is not due to differences in genetic predisposition, but rather to phenotypic differences, such as the age of toilet training and the subsequent attainment of bladder control, socio-economic status, or cultural differences.

At age 16-17, three cross-sectional studies show a further reduction in prevalence to 0.5-1.7%. Two of the studies re-investigate children who had previously been studied; at age seven years [37] and 11-12 years [38] respectively. The prevalence when the cohorts were added together was 1.3% (cohort=3819, NE=51) [25, 37, 39], which gives a spontaneous cure rate of 11% a year among those who wet at age 11-12 years.

In a study of 13,081 adults randomly sampled in the Netherlands[42], an overall prevalence of NE of 0.5% was found. There was no significant difference between age groups. Primary NE was reported by 50% of the men and 19% of the women, indicating that a small group of the enuretic children remain enuretic as adults.

### 2.2. Prevalence of monosymptomatic enuresis (MNE)

Very few studies make a distinction between MNE and NMNE and it is therefore difficult to obtain relevant figures for MNE (Table 2). In two studies from Scandinavia dealing exclusively with seven-year-olds, there was agreement between the studies; 6.4% [36] and 7.4% [35]. A Japanese study gave similar figures for MNE; 6.2% at age 7 years. In this latter study MNE corresponded to approximately 60% of all NE in ages from seven to 12 years [23]. When comes to studies in which all ages were mixed (5-12 years), eight studies were identified in which those without daytime voiding problems could be identified. However, the difference in prevalence of MNE varied in these studies from 3.5% to 15%.

### 2.3. Prevalence of NE versus gender

Almost all epidemiological studies of NE report a higher prevalence in boys than in girls, with the most reported ratio of 2:1 in western countries [16-24, 27, 30, 31, 35, 36, 38, 43-55]. It appears that the gender difference diminishes with age and becomes less visible and less proven among older children [37, 39,46] (Fig.2).
2.4. Prevalence of NE versus ethnicity

In a study from The Netherlands [19], a higher prevalence was reported in the Turkish/Moroccan group (14%) than in the Dutch children (6%) (OR 3.76 (95%CI 1.98-7.12)). An equally high prevalence was found in a Turkish study of children with NE [21] at age seven years (15.1%). In a study from Korea [22], the same high prevalence at age 7 years was identified (16.4%). However, other studies from South-East Asia had comparable [20, 23-25] or even lower levels of prevalence to those in western countries. In fact, two Chinese studies have shown a low prevalence of nocturnal enuresis [18, 47], 3.6% and 4.3% for children aged 4-12 and 6-16 respectively, which they attribute to earlier nocturnal urinary control in Chinese children, due to earlier toilet training.

2.5. Prevalence of NE versus frequency of wet nights and age

Yeung et al [25] showed in a large epidemiological study that the relative proportion of subjects with frequent bed-wetting increased with age. Overall 82% of the adolescence had >3 wet nights/week versus enuretic children aged 5-10 (42%) (Fig.3). Such a relationship is also evident in fig 1, in which the proportion of children with severe NE increase with age, even if the total number decrease. Further support for severe NE to remain in a higher proportion as compared to children with infrequent bedwetting was results in a recent study [15]. Findings in epidemiological studies also show a correlation between severity of the NE and NMNE [15, 17, 48], meaning that NE in

Figure 2: Prevalence of nocturnal enuresis (NE) >1 episode/6months, by gender and age. The prevalence data were obtained from metaanalyses of the following epidemiological studies: at age 7 [17, 23-25, 35,36], age 11-12 [17, 23-25,38] and age 16-17 [25, 37,39].

Figure 3: Prevalence of nocturnal enuresis by frequency of enuretic episodes and age. Data from [25].
adolescents often are combined with LUT dysfunction.

### 3. POTENTIAL RISK FACTORS FOR NE

Several risk factors have been established or suggested by epidemiological studies and the most important ones will be discussed here.

#### 3.1. Daytime UI and LUT dysfunction

Daytime UI, a symptom of LUT dysfunction, has in epidemiological studies been shown to be the strongest predictor for NE (OR 4.8 (2.9-7.9) and has been identified in a third of the patients (NMNE) [48]. However, poor concordance was revealed (kappa 0.25), which confirmed the two to be separate entities that should be evaluated and treated separately.

#### 3.2. Family history

NE is a hereditary disorder and this has been demonstrated in many studies (for example, [17, 18, 21, 30, 31, 33, 34, 36, 43, 45, 49]). The mode of inheritance appears to be autosomal dominant. Järvelin [36] showed that, if both parents were enuretics as children, the RR (95% CI) for the child to have NE was 16 (6.3-20.1), while if only one was enuretic, the RR was 7.8 (5.1-9.8). It has recently been shown that the risk for the child to have hereditary NE is increased with the severity of the enuresis. Children with severe NE (>2 episodes/week) were combined with odds ratio for maternal NE 3.63 (2.56-5.14), whereas mild NE (<2 episodes/week) had 2.14 (1.74-2.64) [50]. The association with paternal NE was less pronounced, but a similar increased association with NE compared to control group [65].

#### 3.3. Psychopathology

There are evident connections between childhood enuresis and mental well-being [13, 14, 47, 49, 55-58]. The children are increasingly negatively affected by their NE with increasing age [59]. Evidence is accumulating to show that psychological consequences are probably caused by the enuresis and not a cause of primary NE, which has been thought for a long time [56]. The findings presented by Feehan [14] support this latter statement, as he only found an association between psychopathology and secondary NE, while children with primary NE did not display a connection of this kind.

#### 3.4. Developmental delay and ADHD

Children with developmental delay and mental retardation have been shown to have a higher prevalence of NE [12, 19, 36, 60]. Spee-van der Wekke [19] found that children who were given special education in school, including both those with and without mental retardation, had an OR of 3.74 (95%CI 2.32-6.03) for NE. Perinatal events such as preeclampsia and low birth weight, possibly involving an increased risk of minor neurological dysfunction, have also been shown to be associated with NE [12, 36, 49]. A connection between NE and minor neurological dysfunction of this kind has also been shown by Lunning [61] in 12-year-old enuretic children. Furthermore, children with attention deficit hyperactivity disorders (ADHD) are more likely to have enuresis than the general child population [57, 62-64] The other way around was also confirmed in a case control study by Yosefichajaen finding a threfold increase of ADHD in children with MNE compared to control group [65].

#### 3.5. Sleep and arousal

The main pathology behind NE in children is the inability to wake up to the sensation of a full bladder. Parents often say that their enuretic child "sleeps very deeply". Some recent studies support this view. By using auditory signals [66], computerised EEG [67] or questionnaires [45], a defect in arousal has been largely validated. In the study by Neveus [45], the odds ratios were significantly high for a high arousal threshold (2.7), pavour nocturnus (2.4) and confusion when awoken from sleep (3.4). Computerised EEG energy analysis has indicated both greater depth of sleep and impaired arousal in enuretics [68]. Difficulty arousal from sleep has also been shown in children with NE compared to children with isolated day-wetting problems and controls, by using a scoring system in a questionnaire [69].

#### 3.6. Socio-cultural factors

Differences in the prevalence of NE [18, 21, 22, 47, 70] at early ages in different parts of the world are probably partly due to socio-cultural differences and not to differences in genetic predisposition [19]. It has been suggested that socio-economic status correlates with NE in some studies [17, 57], whereas in others no correlation was found [9]. Habits like tea-drinking in the evenings have also been identified as a risk-factor for NE [28, 32].

#### 3.7. Other risk factors

Obstructive sleep apnoea (OSA) has been associated with enuresis in some patients [71]. In an epidemiological study association between severe OSA and NE in girls was shown [27], but when including both sexes and all forms of OSA no difference was seen. In another study dealing with OSA patients versus controls, a significant correlation between NE and OSA was found (OR 5.1 (2.4-10.7) [72]. Removal of
large adenoids or tonsils causing upper airway obstruction in children with NE significantly reduced or cured NE [73]. Constipation (see co-morbidity below) may cause secondary NE or make primary NE persist [74]. Encopresis was shown as a risk factor for NE in an epidemiological study (OR 2.7 (1.6-4.4)), while no association with constipation could be identified [48]. The correlation between encopresis and NE was also confirmed in an epidemiological study from Brazil [16]. Children with Sickle Cell Disease are found to have increased prevalence of NE with studies reporting prevalence of 30-32% in paediatric populations with Sickle Cell Disease [75, 76]. Sexual abuse must also be included among the factors that may lead to NE [77], with increased prevalence of enuresis, compared to expected for age, in children referred for allegations of sexual abuse[78] Organic conditions such as infravesical obstruction and neuropathic bladder may also present as NE. In most cases, however, additional symptoms are present to make detection possible. Type1 diabetes was reported to be a risk factor for secondary MNE due to the polyuria seen at presentation [79].

4. PREVALENCE OF FUNCTIONAL INCONTINENCE IN CHILDREN

In children with functional LUT dysfunction, the OAB is far more common than dysfunctional voiding. In a urodynamic study of 1,000 patients with functional LUT dysfunction, approximately two-thirds had an overactive bladder and one-third had dysfunctional voiding [80]. Based on clinical information, another study comprising 226 children revealed that 76% were considered to have an overactive bladder and only 1% dysfunctional voiding. The difference illustrates that different inclusion criteria influence the rate of prevalence [81].

When considering the total prevalence of UI (all frequencies of UI included) (Table 3), there was a variation between 3.2% and 11.2% in different studies at the age of seven years. In the earliest studies the prevalence was lower (3.2%-5.0%), whereas in the studies performed later in the 2000 [16, 22, 24,82-84], the prevalence was higher 6.3%-11.2%. One explanation for the difference was probably an increased recognition of the problem in the population through information via media etc. At 11-13 years the reported prevalence varied between 0.9% and 12.5%. Swithinbank’s study [38] showed a very high prevalence (12.5%) and differed most from the rest (0.9%-4.2%). The difference could probably partly be explained by different limits for frequency of UI (occasionally [38] vs once/month or more). The fact that the studies were performed in different parts of the world was also a possible explanatory factor (UK, Turkey and Korea).

</table>

The frequency of UI decreased with age (Table 3), which was clearly demonstrated in the subjects with frequent episodes of UI (>1/week) (Fig.4). The prevalence at 7 years, 11-13 years and 15-17 years was

![Figure 4: Prevalence of day UI (including mixed day/night) >1 episode/week by age and gender. Data are from: at age 6 years [88], 7 years [24,35], 11-12 years [24,38] and 16-17 years [37].]

---

**EPIDEMIOLOGY OF ENURESIS AND URINARY INCONTINENCE IN CHILDREN**

---
2.6%, 1.1% and 0.3% respectively. There were only two authors who investigated the same cohort of children on two occasions; Hellström [35, 37] in Sweden and Swithinbank [38, 39] in the UK. According to the studies by Hellström, the reduction from seven years to 17 years was 0.2% per year in those with wetting at least once a week and 0.3% when including all kinds of wetting. Swithinbank reported a far higher frequency for all kinds of wetting at age 11-12 years but not at 15-16 years and the reduction in his cohort of children was therefore approximately 2% per year.

UI was more common in girls in most studies, especially in the older age groups (Table 3, fig.4). From the prevalence found in the different studies, daytime UI could be suggested to be 1.5 times more common in girls than in boys at age seven years, whereas at age 16 years the difference was even more pronounced: 5-10 times more common in girls than in boys (Table 3). Overall in a population based study in 2856 children between 4.8-12.8 years, female gender was an independent risk factor for UI (OR 5.4 (2.6-11.1)) [85].

4.1. Prevalence of overactive bladder (OAB)

In a Japanese study [82], the prevalence in children between 7 and 12 years of age, OAB was seen in 17.8%, with no significant difference between boys and girls. There was a gradual decrease in prevalence from 19.8% at the age of 7 years to 12.8% at 12 years.

4.2. Comorbidity

4.2.1 Prevalence of NE

NE in combination with UI is denoted as NMNE as mentioned above. NE has been identified as an independent risk-factor for day-UI (OR 7.2 (3.4-15.2)) [85]. Association of NE to day UI was more often reported in children with frequent UI (≥ 2 episodes/week), as compared to infrequent UI (< 2 episodes/week) at 7.5 years [84]. In boys NE was seen in 70-80% of those with frequent day UI compared to about 50% in those with infrequent. Corresponding figures for girls was about 55% and 30%, respectively.

4.2.2 Prevalence of Bowel problems

Urinary and faecal incontinence often coexist in different combinations. Constipation in childhood is a very common condition and when functional fecal incontinence is seen, constipation is often the cause. The term encopresis can be used synonymously with functional fecal incontinence. An increasing number of epidemiological studies reporting the frequency of bowel problems are accumulating, either in terms of constipation or functional fecal incontinence, in children with daytime wetting. Table 4 shows that the prevalence of bowel problems in day-wetting children approximately corresponded to a third of the children (21%-35%) [24, 69, 82, 83, 85, 86], with even higher prevalence in the subgroup with dysfunctional voiding (43%) [86]. A significant association between day-wetting and bowel problems was shown [24]. These results support the new treatment concept of day-wetting children, with treatment of bowel problems as the first step. MNE, on the other hand, seldom have bowel problems (0%-1%), whereas in NMNE it is more common (16%-24%) [69, 86].

In an epidemiological study from Japan including 5282 children, ages between 7-12 years, 81.5% were reported to have daily bowel movements. A significant higher prevalence of NMNE was found in those with constipation, compared to among those with regular daily bowel movements (3.4% vs 2.2%) [23].

5. POTENTIAL RISK FACTORS FOR DAY WETTING

5.1. Family history

Day wetting, also including those subjects with mixed day and night wetting, has been shown to be correlated to hereditary factors, in parallel to what is known about children with NE. However, the number of studies is limited (Table 5). Like for NE hereditary factors have been shown to be more pronounced in those with severe UI (>2 episodes/week), especially when paternal day UI is present (Table 5) [50,87].

Table 5: Day wetting vs family history (including mixed day/night wetting).

*Only children with mixed day and night wetting, **compared with 45% in dry children

5.2. Psychopathology

Children under stress as a result of marital separation, for example, have a higher incidence of diurnal or mixed UI, according to some authors [17, 49, 88]. Moreover, psychopathology investigated by Järvelin [49] using the Children’s Apperception Test (CAT) revealed a significant increase in the signs of repression, including an inability to express one’s emotions and feelings (p = 0.027), when comparing day wetting children with controls. Neveus [45] found that day-wetting children had more difficulty falling asleep (OR 2.4, CI 1.4-4) and he interpreted them as “anxious children”. Lettgren [89] found a significant increase in attention problems and delinquent behaviour in a certain form of day-wetting children (voiding postponement) using the Child Behaviour Check List (CBCL,
Achenbach). In a recent paper [90] similar results were found with the highest rate of psychiatric comorbidity in children with UI due to voiding postponement and the lowest in children with MNE. In the group with enuresis 65% were considered to have severe behavioural problems [86], meaning that children with both wetting and bowel problems are at the highest risk for psychopathology.

In a population-based study investigating psychological problems associated with day UI, 8213 children were included of whom 643 suffered from daytime wetting at median age 7.5 years [83]. Overall, the results indicated a rate of psychological problems that was twice the rate reported for children with no daytime wetting, particular notable was the increase in externalizing problems. After adjustment for developmental delay, gender, stressful life events, variables associated to family sociodemographic background and soiling, there was still an independent association of daytime wetting and behaviour problems (OR 2.04; CI 1.67-2.51). In another epidemiological study UI was found to be associated with parenteral considerations (OR 1.9 and 2.3 respectively), according to studies by Järvelin [36]. In another epidemiological study UI was found to be associated with parental concerns about the child’s social behaviour (OR 3.4 (1.4-8.3), [85]. It is not clear whether the behavioural problems described in these studies are a cause or a consequence of daytime wetting.

5.3. Minor neurological dysfunction and developmental delay

Children with minor neurological dysfunction have also been shown to have an increased rate of day wetting. Duel [62] found that children with ADHD are three times more likely to have day UI than controls (p<0.0005). Von Gontard and Niemczyk also found children with daytime urinary incontinence to have significantly higher risk for ADHD and opposite deficit disorder (ODD) symptoms [91, 92]. Also in children with delayed maturation or with mental retardation, the risk of day wetting is increased (OR 1.9 and 4 respectively), according to studies by Järvelin [36]. Perinatal events, which can also be suggestive of minimal brain dysfunction, have also been shown to be over-represented in day-wetting children. For example, Järvelin [49] found that the children of mothers who had suffered from toxaemia had an RR of 8.5 (CI:1.4-51.9) for day UI.

5.4. Other risk factors for day UI

Sometimes, functional day UI is difficult to distinguish from UI due to organic anomalies. The most prominent examples are the adolescent form of posterior urethral valves in boys and ectopic ureter and epispadias in girls.

In many papers, UTI is regarded as a risk factor for day UI. Järvelin [49] found an RR of 8.6 (2.3-32.3) for UTI in day UI children. Neveus [45] was able to demonstrate similar connections; OR 2.3 (1.3-3.9) and similar results were seen in Sureshkumar study [85]; OR 5.6 (2.0-15.6). However, these infections should probably be regarded as a consequence of the functional bladder disturbance with UI and not the other way round as a cause of the UI.

6. SUMMARY POINTS

6.1. Nocturnal enuresis (NE)

- The prevalence of NE at age seven seems to be around 11% for most countries, at age 11-12 years around 3.5% and at age 16 around 1.3%.
- The spontaneous cure rate seems to be around 15% annually between 7 and 12 years, and 11% annually between 12 and 17 years
- In an adult population the prevalence of NE seems to be 0.5%. The prevalence was 0.1% when including only those with a history of NE during childhood. Thus the risk for NE as adult if having the condition at 7 years of age can be calculated to 1%.
- Potential risk factors for NE in children include OAB, polyuria, family history, psychopathology, developmental delay, mental retardation, socio-cultural factors, sleep and arousal problems, sleep apnoea, constipation, sexual abuse and organic conditions such as infravesical obstruction.

6.2. Functional incontinence

- Children who are and remain dry in the day seem to attain their diurnal continence between age four and five years.
- Diurnal UI, or combined diurnal and nocturnal UI, in children is caused by overactive bladder in the great majority of cases.
- Prevalence for functional UI decrease with age. At age 7 years prevalence figures varies between 3.2% and 9%, with the highest prevalence in recent studies. At age 15-17 years the corresponding prevalence is 1.2-3%.
- Variation in prevalence figures is mainly dependant on differences in frequency of incontinence episodes in the studies.
- Potential risk factors for diurnal UI in children include bowel problems such as constipation and functional fecal incontinence, family history, psychopathology, socio-cultural factors, minor neurological dysfunction, developmental delay, organic anomalies such as infravesical obstruction in boys and sexual abuse.
IV. EPIDEMIOLOGY OF URINARY INCONTINENCE IN WOMEN

1. GENERAL COMMENTS AND DEFINITIONS

This section presents a narrative account of a targeted selection of high quality studies that illustrate what is currently understood about the prevalence, incidence, and risk factors for urinary incontinence (UI) including its common subtypes, stress UI, urgency UI, and mixed UI.

Current terminology for female UI is drawn from the 2010 IUGA/ICS joint terminology report [2], but in most instances is entirely compatible with current terminology for men [1], and children [4]. In considering the epidemiology of female UI, researchers have mainly addressed the epidemiology of the symptom of UI, defined as the complaint of involuntary loss of urine, and mixed UI (complaint of involuntary loss of urine associated with urgency), and mixed UI (complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing). A small number of studies have reported prevalence and risk factors for adult nocturnal enuresis (complaint of involuntary urinary loss of urine which occurs during sleep). With a lack of validated questionnaire items for less common subtypes, the current literature is almost silent regarding the population prevalence and risks for postural incontinence, continuous incontinence, insensible incontinence, and coital incontinence, although they are sometimes grouped as “other incontinence”. Finally, there remains a separate category of incontinence, so called “functional incontinence”, more typical of institutionalised older adults, for whom physical or cognitive impairment limits their ability to use a toilet.

There are a large number of urinary symptom questionnaires employed in epidemiological research all with varying evidence of validity (discussed elsewhere). Most questionnaires were initially developed using secondary care, i.e. hospital and institutional samples, with criterion validity demonstrated in comparison to bladder diaries, pad tests, or urodynamic

</tbody>
</table>
diagnoses. Quite widely varying terminology is used in the items assessing stress incontinence and urgency incontinence in different questionnaires (see Table 6), and some items do not capture all aspects of the standardised definitions. Even the surrounding context for the items is known to strongly affect prevalence estimates [94-95], and small variations in terminology from different questionnaires may have similar effects.

The optimal assessment of incontinence subtypes remains controversial [96-97], but it is clear that self-report of symptoms differs systematically from detailed clinical evaluation. In particular, for women, mixed incontinence is more common than would be expected by chance, at least using questionnaire evaluation [98], and is reproduced less frequently using urodynamics [99-100]. Stress and urgency incontinence have different treatment options, and are presumed to have different underlying pathophysiology. Caution is therefore needed when comparing epidemiological studies that either do or do not report a separate mixed incontinence subgroup, and when generalising from population level data on mixed incontinence to clinical practice.

Self-report of incontinence symptoms should reflect the woman’s own experience of incontinence, but may bear little relationship to felt or expressed need for treatment. Across multiple measures, incontinence severity is shown to be only a moderate predictor of incontinence specific quality of life impairment [101-102]. It is important therefore to characterise both the severity of symptoms, through frequency of leakage and/or quantity of loss, and the perceived bother or impact on activities. Most questionnaires in contemporary use, including the ICIQ-SF, ICIQ-FLUTS and DAN-PSS, therefore ask patients to report both the frequency of UI, and its perceived bother. Cautious interpretation should be made of high prevalence rates obtained with case definitions that do not incorporate some measure of symptom bother or impact.

Incontinence is a stigmatising condition in many populations [103], which creates a high risk for respondent bias in incontinence epidemiology [104-105]. Perhaps because of stigma, incontinence is also associated with low rates of presentation for care. Surveys assessing incontinence in healthcare settings may therefore also be highly prone to both medical surveillance bias, in which presentation to care for other reasons results in a diagnosis of incontinence; and Berkson bias [106], in which selection of cases from within hospitals tends to reduce generalisability to the population, and may suggest associations with spurious risk factors. We therefore focus on community or population based samples with response rate over 60% [107]. To further minimise differential effects of such biases, where possible we report outcomes stratified by age, by type of incontinence, and by major subgroups of interest.

The majority of work reviewed in previous editions of this chapter, originated from the OECD countries. There have been many recent studies from both BRIC and developing countries [108], which are now reviewed. Subsequent discussion excludes however the epidemiology of obstetric vesico-vaginal fistula, which is covered in a later chapter.

Table 1 Stress incontinence and urgency incontinence items from a range of validated questionnaires widely used in epidemiologic research

2. PREVALENCE

Among general population studies unadjusted prevalence estimates for the most inclusive definitions of UI (‘ever’ ‘any’ or ‘at least once in the past 12 months’) have ranged from 5% to 69% [109], with most studies reporting a prevalence of any UI in the range of 25% to 45%. This enormous variation between studies is seen both within and between countries, and with few studies reporting age standardised rates, largely precludes meaningful comparison between countries. If there is variation in true prevalence rates between countries, it is obscured by cultural differences in the perception of UI and willingness to report UI, as well as methodological differences [110], including in the wording of questionnaire items, in the method of administration of questionnaires, and perhaps most importantly, with differences in case definitions employed [111-112].

Very few studies have used the same survey tools and methods to report female UI general population prevalence in more than one country (Table 7). Three studies have attempted to assess the relative prevalence in western nations [113-115]. Across all countries surveyed, all these three studies find that SUI is the most common subtype, followed by MUI, and then UI. Hunskaar and colleagues surveyed 29,500 women in France, Germany, the UK and Spain [114]. By demonstration of similar age trends across all countries, they suggested both lower overall prevalence of incontinence in Spain, and a relative excess of urgency incontinence in France. The EPIC (Epidemiology of Incontinence) and EpILUTS (Epidemiology of Lower Urinary Tract Symptoms) studies [113, 115], used similar questionnaire items explicitly based on standard definitions. However, there was inconsistency between studies. The EpILUTS study found similar prevalence of each UI subtype in the US, UK, and Sweden, while the EPIC study reported a more than 3-fold variation in prevalence between countries, with Sweden having a prevalence of 29.5% and Italy only 9.3%. The disparity in results could be explained by differences in sampling methods, or different response rates (58%, 33% and 59% respectively).

A further study set in Senegal, Mauritania, and Chad, reports substantial variation in prevalence across countries, even after age stratification [116]. Finally, in a recent survey using identical methods across
Russia, the Czech Republic and Turkey (n = 3,130) [117], there was noted similar prevalences in Russia and Czech Republic, but an excess of urinary storage symptoms (including UI) in Turkey. Again, it is unclear whether such differences are due to linguistic differences in questionnaires, differences in response proportion, or true cultural or biological differences. The lack of consistency in between country comparisons, even for large surveys set in western nations, makes it impossible to assess the extent of true variation between countries. It also remains difficult to establish stable, meaningful prevalence rates for female UI, when there is no consensus about what constitutes significant UI. Again, extreme caution is needed in making direct comparison of crude prevalence rates.

Although between study comparisons of female UI prevalence are largely unrewarding, we can meaningfully compare within study distributions of UI by age and UI subtype. Table 3 summarises prevalence estimates by age for female UI from community or population based studies with response rate >60%, over the period January 2008 through December 2011. Again a 10 fold variation in unadjusted prevalence rates is evident between studies, so where available, overall prevalence rates are given by UI subtype, while age trends are depicted with sparklines. These depict the variation in age specific prevalence across the full age range of each study.

**Table 7: Population prevalence rates for female UI from studies sampling in more than one country.**

</table>
As in the studies comparing prevalence between countries, absolute prevalence rates vary widely in recent cross-sectional work. However, the distribution of UI subtypes is consistent. Isolated stress incontinence accounts for approximately half of all incontinence, with most studies reporting 10-39% prevalence. With few exceptions, mixed incontinence is found to be next most common, with most studies reporting 7.5-25% prevalence. Isolated urgency incontinence is uncommon, with 1-7% prevalence, and where recorded at all, other causes of incontinence occur with approximately 0.5-1% prevalence. In summary, current data provide very disparate estimates of population prevalence for UI in women. Approximately 10% of all adult women report leakage at least weekly. Occasional leakage is much more common, affecting 25%-45% of all adult women. Prevalence rates from cross-sectional studies uniformly demonstrate an association with age, which is explored in more detail in the subsequent section on risk factors.

3. INCIDENCE AND REMISSION

Many prospective longitudinal studies have examined UI in women, either in the general population, or focused on pregnancy, menopause or old age. However, interpretation and comparison of incidence and remission rates is fraught with difficulties. Incontinence is not intuitively a condition, with fluctuating severity, indeed the popular perception in both the medical community and the general public, is of a chronic condition. However misclassification due to the unreliability of symptom assessment tools may cause the appearance of symptom fluctuation. Measuring the short term test re-test reliability for the BFLUTS questionnaire [118], the DAN-PSS [119], the IIQ [120], or any of the other commonly used questionnaires suggests that only 80-85% of item responses are stable over even a brief retest period. Thus even when a longitudinal study is able to use the exact same item for assessment across even relatively long periods of follow up, the effect of misclassification due to questionnaire unreliability may obscure a true effect of incidence or remission. Even non-differential misclassification bias, can have serious consequences both for estimates of absolute cumulative incidence, and relative incidence risk, and such effects are largest for conditions such as UI, with high prevalence and low incidence [121]. Other methodological differences may also cause wide variation. Questionnaires that use different recall periods (e.g. any leakage in last week, any leakage in last year, any leakage ever) will produce different estimates of incidence and remission. Due to changes in standard definitions, many studies have also used different case definitions at baseline and follow-up. Finally, although loss to follow up itself is very variable between studies, differential loss to follow-up is observed in almost all studies, and must substantially decrease generalisability.

Annual incidence rates for broad definitions of UI (“monthly” or “any”) range from 0.9% to 18.8%, while rates for weekly UI show less variation at 1.2-4.0%. There is a significant negative correlation between the length of a study and its reported annualized incidence rate, suggesting that short studies of 1-2 years overestimate incidence due to a dominating effect of misclassification. Limiting comparisons to studies with >5yr follow up suggests incidence of 1.3-4.9% even for inclusive definitions of UI. Fewer studies have reported remission rates, and again estimates vary widely between 1.2 and 42%. Again limiting the comparison to longer studies of >5yrs suggests rates of 2.1 to 5.0%. Overall these results are compatible with findings from cross-sectional studies, with modest increases in UI prevalence across the whole female population of 0.5-1% per year. Although the extent of cohort effects has rarely been reported, current data suggests that earlier cohorts are less likely both to report incontinence [122-123], and to seek care for it [124].

4. POTENTIAL RISK FACTORS

This section summarises the most important reported demographic, social, environmental, and lifestyle correlates of urinary incontinence in women. Familial risk factors for incontinence and prolapse are considered together in the section on genetic epidemiology.

While a majority of previously cited studies have reported associations with incontinence, great caution is again needed in assigning these as causal risk factors. As already seen, a large majority of studies are cross-sectional in design, providing no evidence of causation, since the temporal association of the putative risk factor and the onset of incontinence cannot be assessed. Where possible we therefore try to focus on risk factors for incident UI, from longitudinal studies. Again though, with the exceptions of mode of delivery, menopause hormone therapy, and weight loss, there remains a dearth of interventional studies. Even the highest quality observational studies may suffer from residual or unmeasured confounding, further limiting conclusions about causality.

4.1. Age

The age distribution for incontinence of all causes reported in the widely cited EPINCONT study [125], depicts a steady increase in moderate and severe incontinence throughout the adult lifespan, but with a distinct peak in slight incontinence around the time of the menopause. Other large studies have, however, reported a steady increase in prevalence for both slight and severe UI, without a distinct menopausal peak [126]. The timing and causes of a fifth and sixth decade peak has been explored in a number of high quality longitudinal studies of menopausal transition, discussed subsequently. Where such a peak is identified from cross-sectional studies, it is most pronounced for stress incontinence [114-115]. Across most cross-sectional studies isolated stress incontinence declines into old age, as mixed incontinence becomes relatively more common [125,128]. Besides methodological differences, disparity in age ranges, severity thresholds, and proportion of each subtype of incontinence probably therefore explains the modest differences in age trends seen in Table 3. These age trends, drawn from cross-sectional studies, may in any case be biased by cohort or period effects.

While most cross-sectional studies find an increase in prevalence into old age, some high quality studies have identified a peak in all cause incontinence, with a decline in the eighth and ninth decade [129]. Such a large disparity might be explained by sampling strategies that include or exclude institutionalized adults. The epidemiology of UI in this vulnerable group deserves special attention, and of course remains of key interest to geriatricians. The epidemiology of incontinence in nursing home residents has been the subject of one systematic review [130]. Only one primary study provides data from more than one country, allowing cross-border comparisons. From a population
of 279,191 elderly people in care homes, from Denmark, France, Iceland, Italy, Japan, Sweden, and the US, the prevalence of female urinary incontinence was relatively stable at 42.0-72.5% [131, with much of that variation accounted for by differences in age structure, and proportion of residents with functional or cognitive impairment. Indeed variability in prevalence estimates for female care home residents across the entire literature is much less than for the general population [130], ranging from 42.0% in Japan [129] through to 78.4% in the US (using a much more inclusive definition) [132]. Urinary incontinence is associated with nursing home admission from the community [133]. This may in part explain the apparent steeper increase in prevalence with age in nursing homes compared to community dwelling samples [132]. Loss to follow up certainly limits our ability to accurately assess age trends in the elderly from cross-sectional studies.

Given the difficulties in establishing robust incidence estimates, most longitudinal studies do not provide good evidence of age trends in incidence. Studies have variably reported no change in incidence with age, or a stable incidence in middle age, with a sharp increase in old age. However, the large Nurse’s Health Study cohort [134] provided good evidence of a decrease in incidence of stress UI following the menopause, which has more recently been explored in analyses of the SWAN study [135], the 1946 British Birth Cohort [127], and the Hordaland Women’s Cohort [136-137]. All these studies provide consistent evidence of a peak in incontinence at the time of the menopause, with pre- and peri-menopausal status being associated with increased incidence of UI and decreased remission of UI compared to post-menopause. As will be discussed in the section on menopausal replacement therapy, part of this peak may be iatrogenic. Consistent with evidence from cross-sectional studies [114,125], the peak is attributable mainly to mild stress incontinence.

While the association between age and female UI is clearly important for planning healthcare resource allocation, in many studies this is not an independent association. Other risk factors associated with age, including parity, co-morbidities, and BMI attenuate the association with UI [126], and additional adjustment for relevant co-morbidities typically eliminates the association [138]. Confounding factors adequately explain the association between age and UI, and therefore UI in women should not be considered as an intrinsic consequence of the aging process itself.

4.2. Obesity and Adiposity

Obesity is perhaps the most clearly established risk factor for UI in women. There is a wealth of cross-sectional, longitudinal, and interventional data demonstrating positive association between BMI and UI, which has been subject of several systematic reviews [139-140]. Across a wide range of studies obese women have approximately double the risk of UI. A typical pattern of association, taken from the large Nurses’ Health Study II [141] (n = 83,355) is demonstrated in Figure 2. The ORs for UI by severity are plotted against BMI, from underweight through to obese. Although the Nurses’ Health Study II is limited to middle aged women, such findings are consistent across all age groups, both within studies [142], and between studies [139]. This association is quite minimally attenuated by adjustment for other risks for UI.

Data from the EPINCONT survey also demonstrate the same positive association between BMI and more severe incontinence. Additionally they indicate that such associations hold for the major subtypes of incontinence (Figure 3), but are most pronounced for mixed UI, and relatively modest for UUI. Similar findings were reported for data from the Heart and Estrogen/Progestin Replacement Study [143] and the 1946 British Birth Cohort [144], with the associations

![Figure 5: Associations between BMI and UI severity from the Nurses' Health Study II. Original figure created based on data reported in Danforth et al. [141].](image-url)
with BMI being greater for stress or mixed UI compared with urgency UI.

The temporal association between BMI and UI is also established with data from the 1946 British Birth Cohort, SWAN, MRC Incontinence [145] and the Nurses’ Health II studies demonstrating that earlier onset of obesity is associated with increased risk for UI in middle age [127], and that both higher BMI and greater weight gain are associated with increased risk of incident UI [145-147]. Although again it is hard to compare between studies, it appears that BMI may be a greater risk factor for incident UI than for prevalent UI adding credence to the association [147]. As for cross-sectional studies, the association is stronger for incident stress UI and mixed UI, compared with incident urgency UI [145, 147].

There is adequate evidence [149-150], that obesity increases intra-abdominal pressure, predisposing to stress incontinence, while metabolic syndrome associated with obesity predisposes to urgency incontinence [151-154]. Consistent with this, waist circumference and waist to hip ratio appeared to be associated only with stress UI, and not with urgency UI in the SWAN [147] and HERS studies [143]. More recent data from BACH [155] and KNHNES [156] indicate that measures of central adiposity are also correlated with urgency UI.

Finally, intervention studies for weight reduction have reported that even modest weight loss is associated with improvement or resolution of both stress and urgency UI, with the probability of resolution correlated to the degree of weight loss [149,157-160]. Despite the complex interplay between weight and other risk factors for UI, we still have robust evidence to support a causal role of BMI in the development of UI.

4.3. Parity, pregnancy & mode of delivery

Parity is considered by the laity as among the most important risk factors for UI. This is reflected in almost all large cross-sectional surveys (Figure 4). Some early studies reported a threshold effect at one delivery and little or no additional risk with increasing parity [161-163], but in most subsequent work, increasing parity is associated with increased risk of UI. A single delivery is typically associated with adjusted OR of around 1.3-1.6 for UI, and further deliveries linearly increasing the risk up to an adjusted OR of 1.5-2.0 [126,141,147,164].

As expected these effects are strongest in the third and fourth decades, with substantial attenuation through middle age, and in many studies no persistent effect in old age [142,164-166], as other risk factors come to dominate. Although the EPINCONT [164] and SWAN [147] studies reported only association between parity and stress or mixed UI, other studies have also suggested, a reduced but significant association with urgency UI [167-168].
Table 10. Prevalence of urinary incontinence in the first post-partum year among primiparous women by type of delivery

There is a substantial difference in effect between vaginal delivery and caesarean delivery, that has also been the subject of two systematic reviews [169-170]. Over short term follow-up meta-analysis of data from four large cross-sectional studies [171-174], suggested a significant protective effect of caesarean on stress UI (OR 0.56) and mixed UI (OR 0.70). For long term follow up, meta-analysis of 15 studies again found almost double the risk of stress incontinence after any vaginal delivery (spontaneous, or assisted) compared to any caesarean section (adjusted OR 1.85, absolute risk difference 8.2%), with a smaller effect on urgency incontinence (adjusted OR 1.30, risk difference 2.6%). In meta-regression of long term studies the effects on stress incontinence were much more pronounced for younger women, further adding to our confidence in assigning a causal role for vaginal delivery.

Generally across all observational studies, women delivering exclusively by caesarean have similar prevalence for UI as age matched nulliparous women. While the existing interventional studies remain significantly underpowered, the same direction of effect for caesarean is still seen [175].

Pregnant women, and those in the early post-partum period are typically excluded from population-based studies of UI, but a large body of work considers the specific epidemiology of UI in and around pregnancy. A systematic review including 33 population-based studies, each with response rate over 50% [105], concluded that the prevalence of UI in the first three months post-delivery was 30%, with infrequent stress UI being the most common. The difference in UI rates between women delivering vaginally and those delivering by caesarean is evident immediately after delivery. As demonstrated in Table 5 (adapted from Abrams et al 2009 [109]), there is a gradual decrease in prevalence during the first post-partum year.

Despite the protective effect of caesarean, for many women the onset of incontinence is during pregnancy itself. The point prevalence of UI is low in the first trimester, rising rapidly in the second trimester and increasing slightly in the 3rd trimester [176-177]. In the population based Norwegian Mother and Child Cohort Study, (n = 43,279), the prevalence of stress incontinence from before to during pregnancy, rose from 9% to 31% in nulliparous women, and from 24% to 42% in parous women [178]. In contrast, mixed incontinence showed a similar rise in both groups (from
6% to 16% and from 8% to 20%, respectively). Urgency incontinence remained virtually unchanged in both groups at less than 5%. In follow up of these women, the onset of incontinence during pregnancy was strongly predictive of post-partum UI (adjusted RR 2.3, 95% CI 2.2-2.4), with little modification by mode of delivery. Such an effect seems to persist into long term follow up [179-182], even for women who return to full continent in the immediate post-partum period. It seems that the temporary physiological changes during pregnancy may reveal women with a predisposition to incontinence in later life, in a manner analogous to gestational diabetes [183].

There are other suggested potentially modifiable obstetric risk factors, including induction of labour, forceps delivery, and use of episiotomy. Regardless of conflicting observational evidence of an effect of episiotomy (for example references 184-187), there are a large number of interventional studies that have not shown either harm or benefit [188]. Similarly while forceps delivery has conflicting evidence from observational studies (for example references 187,189-191), within the context of the second stage of labour, maternal urinary incontinence is of secondary importance in decision making regarding choice of delivery instrument [192]. In a similar vein, while induction and augmentation of labour, and use of epidural anaesthesia have each been identified as being associated with both early postpartum and persistent UI [193-196], it is doubtful whether this should have any effect on current obstetric practice.

Many other suggested obstetric risk factors, including age at first delivery, and birth weight, are perhaps not meaningfully modifiable. Several studies have suggested that older age at either first or last birth is associated with UI [144, 197-199], although more recent data from the RRISK study suggested a U shaped distribution [195], with very young mothers also at increased risk. Inadequate adjustment for socio-economic class may explain all these effects. Numerous studies have suggested that greater birth weight at a single delivery, or maximum weight of infant across all deliveries may also be associated with UI [162,165,195,200-202]. Although elective caesarean would be protective, birth weight is still challenging to predict, and again pragmatic randomised interventional trials are needed before making clinical recommendations.

4.4. Menopausal Replacement Therapy

Menopausal oestrogen replacement therapy was once widely prescribed as a treatment for urinary incontinence during or after menopause, on the basis of rather heterogeneous data from clinical trials [203], and inconsistent associations in cross-sectional studies [196,204]. While current evidence overall continues to support prescribing of topical oestrogen [205], the Nurse’s Health Study [206], the Heart Estrogen/Progestin Replacement Study (HERS) [207], and Women’s Health Initiative (WHI) Hormone Replacement Trial [208] all provided strong evidence that oral oestrogens, with or without combined progestogens were associated with increased incident UI. In the placebo controlled HERS trial, women randomised to conjugated oral oestrogen plus medroxyprogesterone were more likely to experience worsening of their incontinence over 4 years (38% vs. 27%, p<.001) [207]. In the randomised WHI trial, continent women receiving oestrogen, with or without progestogen, were approximately twice as likely compared to women receiving placebo to have developed stress incontinence at 1 year (16% vs. 9%, p<.0001) [208]. The risks of mixed and urge incontinence were also significantly increased, though more modestly. Further trials including oestrogen arms have subsequently been reported during development of selective oestrogen receptor modulators (SERMs), confirming these findings [209]. Some SERMs have themselves been associated with an increased risk of UI [210] (Albertazzi & Sharma, 2005), although raloxifene appears safe [209].

4.5. Hysterectomy

Hysterectomy is among the most common major procedures performed for women in Western nations. Many women date the onset of incontinence to a hysterectomy, but uncontrolled case series and small randomised trials have produced conflicting results. Evidence from large population-based observational studies has increasingly suggested a causal link, although the underlying pathophysiological mechanism is poorly understood.

Among a sample of 1,517 Taiwanese women aged 65 years and over, hysterectomy was associated with OR 1.8 for UI, with no difference between abdominal and vaginal hysterectomy [211]. Earlier trials had, however, suggested either no effect [212-213], or rather more modest effects [214]. Where an association is found, it is strongest with case definitions consistent with "severe UI" [141,215-216], perhaps reflecting high rates of mild UI in controls. Using a sample of more than 900,000 women from the Swedish Population Register, abdominal hysterectomy for benign disease was associated with a hazard ratio of 2.1 for subsequent stress UI surgery, while vaginal hysterectomy for prolapse was associated with a hazard ratio of 6.3 [217]. Similar results were observed comparing hysterectomy and endometrial ablation in the Scottish Morbidity Returns database [218]. Recent data from a randomised trial of levonorgestrel-IUS versus hysterectomy [219] does confirm this effect. In follow up of 236 women, increased incidence of stress UI (OR 1.83 95%CI 1.01-3.22) was first apparent at 10 year follow, with significantly higher rates of treatment for both stress and urgency UI.

Overall hysterectomy appears to be associated with development of subsequent incontinence symptoms, and particularly with the need for stress UI surgery.
One potential mechanism is loss of pelvic floor support at the time of surgery. The data from observational studies should still be considered cautiously, as findings may be influenced by both healthy responder bias and medical surveillance bias, the latter of which may also affect unblinded interventional studies.

4.6. Diet

Many dietary constituents including coffee, tea, alcohol and carbonated beverages have all implicated in the pathogenesis of UI. Dietary data are difficult to obtain reliably [220], and women may change dietary intake in response to UI, making cross-sectional studies of diet and UI difficult to interpret.

The consumption of coffee or other caffeinated drinks as a risk factor for UI has been most widely studied. While some studies report a positive association associated with an increased risk of UI [221-224], others have either report no association [225-227], or a protective effect [145,228]. Even within the large EPINCONT study there were conflicting findings regarding coffee, with a positive association with mixed UI, but a negative association with stress UI [148]. The WHI study demonstrated a dose-dependent positive association between caffeinated coffee and urge UI, but not for decaffeinated coffee or for other UI subtypes [229]. The EPINCONT study suggested a positive association between tea drinking and stress UI or mixed UI [148], while analysis of the Swedish Twin Registry Cohort showed an association only with overactive bladder [228]. The Leicester MRC Incontinence study is one of two studies to have used food frequency questionnaires, and found no association with tea [145]. It is unclear whether tea consumption contributed significantly to the overall association between UI and dietary caffeine in the WHI study [229]. At a population level the overall picture is therefore unclear, despite suggestive evidence of improvements in symptoms reported from interventional trials of caffeine reduction [230].

Anecdotally, alcohol consumption may be acutely associated with urinary urgency and urgency incontinence. A positive association between alcohol consumption and UI has been reported by some studies [231], but is found to be either protective [145, 232], or of no significance [148] in other studies. Differences between studies may reflect confounding associations between age and alcohol consumption.

The most comprehensive assessment of diet as a risk factor for UI comes from the Leicester MRC study [145]. Besides effects reported above, this study also found increased incidence of stress UI with increased intake of carbonated drinks, and reduced incidence of overactive bladder with increased intake of bread, potato and vegetable consumption. While these effects certainly provide interesting avenues for further research, there is no evidence of a causal association, and instead these dietary components may be surrogates for other unidentified socioeconomic risks. Overall there is a lack of consistency in reports of dietary associations with UI that most likely reflects methodological limitations rather than differences between populations.

4.7. Socio-economic status

Socio-economic status (SES) is strongly correlated with many of the other risk factors for UI including parity, BMI, diabetes, depression, smoking and timing of menopause. Higher SES is consistently associated with increased care seeking for UI, but there is conflicting evidence of association between SES and UI prevalence, or its bothersomeness. While many studies do include some measure of SES as a potential confounder, its effect is frequently not reported. Table 6 summarises some of the major studies that have reported associations, to highlight inconsistencies both by SES definition and UI definition. In the table a positive association is cited where women of higher SES, i.e. higher income/more education, report a greater prevalence of UI.

4.8. Smoking

Data from observational studies on smoking are also quite inconsistent. It has been reported to be an independent risk factor for UI in women in some cross-sectional studies [145,148, 233-235] but not in many others [138,236]. Within studies that do find an association, former smokers have a risk intermediate between never smokers and current smokers, and some dose response effect is evident, adding plausibility.

However, with one exception longitudinal studies have consistently failed to find a significant association between either past or current smoking and incident UI in multivariate analysis [147,212,213,237,238]. Only in the Leicester MRC study [145] was current smoking associated with increased risk for incident stress UI. The conflicting data from cross-sectional studies and lack of association between smoking and incident UI in most prospective studies suggests that smoking is probably not a causal risk factor for UI.

4.9. Exercise

Evaluating associations between physical activity and incontinence remains complex. It is clear that high impact exercise such as gymnastics [239-240], or trampolining [241-242] leads to stress UI, with a dose dependent deleterious effect. However, women who suffer with UI, and particularly stress UI, may feel less able to engage in such sports [243]. Furthermore with increasing interest in core training as a treatment for UI [244], there are theoretical reasons to believe that low impact exercise might have a direct therapeutic effect. With these competing mechanisms at play, unsurprisingly cross-sectional studies have again produced conflicting evidence (see for example references 138, 245-246). However, among cross-sectional studies, comparison of low impact and high impact exercise is suggestive that as hypothesised, high impact sports might be harmful, while low impact sports might be protective [148,247].

Evidence from longitudinal studies overall suggests that exercise does have a protective effect against incident UI, but perhaps only mediated via an effect on weight. In the Leicester MRC study, women who reported that they exercised less frequently were at increased risk for both incident stress UI and overactive bladder (OAB) in a model that adjusted for physical functioning, although notably this association was eliminated in a full model, adjusting for obesity [145]. In a study of 4,291 older women exercise at baseline was not associated with incident UI at 10 year follow up after multivariate adjustment [238]. Perhaps the strongest evidence comes from the Nurses’ Health Study [248]. In this population of US nurses aged 54-79, a higher level of physical activity across 14 years of follow-up, was associated with a reduced risk of UI overall, and specifically stress UI, although after adjustment for BMI and other factors, the overall effect was small.

4.10. Comorbidities: Diabetes, Urinary Tract Infection, Cognitive Impairment, Ischaemic Heart Disease, Physical Impairment, and Depression

In cross-sectional studies many different comorbidities have been associated with UI in univariate analysis [204, 249-250]. However, in most cases these have no explanatory power, being neither a cause nor consequence of UI, but only associated with other known or unknown mediators of UI, or differentially diagnosed due to medical surveillance bias. In this section, we therefore concentrate on studies that are able to adjust for a wide range of confounders, and again give priority to associations of incident UI.

*Defined using either quality of life questionnaire, or symptom bother rating.*
Many cross-sectional studies have reported urinary incontinence to be more common in women with either type 1 or type 2 diabetes, than among women with normal glucose levels, even after extensive adjustment for known risk factors [147,172,212,249,251-252]. There are conflicting data regarding a dose dependent association, e.g. between HbA1C and UI severity [251,253]. Longitudinal evidence is also conflicting. In the Nurses Health Study cohort [254], Type 2 diabetes was a slight but significant predictor of incident UI (RR=1.21), and the magnitude of the association was seen to increase both with duration of diabetes and with severity of incontinence. Despite significant associations with prevalent UI in the SWAN study, no association with either incident UI [147], or worsening UI was found [147]. Perhaps the best evidence however comes from recent analyses of women enrolled in the Epidemiology of Diabetes and its Complications study. Over 7 years of follow up, more than 10 years after a diagnosis of type 1 diabetes, HbA1C was shown to be a powerful predictor of incident incontinence (odds ratio 1.41, per % HbA1c increase), even after careful adjustment. There are plausible pathophysiological mechanisms by which diabetes might induce incontinence, and it seems likely based on the totally of current evidence that it truly has a causal role.

Acute urinary tract infection (UTI) is a direct cause of transient UI [255], but caution is required regarding a causal association with chronic UI. UTIs are often diagnosed and treated based on symptoms alone, and causal association with chronic UI. UTIs are often transient UI [255], but caution is required regarding a causal role.

Prevalent UI has a clear association with dementia [260-261], but until recently longitudinal studies did not identify an association with incident UI. One longitudinal study of 6,349 community dwelling women found that a decrease in mental functioning as measured by the modified mini mental status exam (MMSE) was not associated with increased frequency of UI over 6 years, but did predict a greater impact [262]. Despite strong associations with baseline UI in the Canadian Study of Health and Aging, moderate or severe cognitive impairment, again defined by the modified MMSE, was not associated with incident UI over 10 years [238]. However, in a sample of 12,432 women aged 70-75, followed up for 9 years, the Australian Longitudinal Survey of Women’s Health did demonstrate an association with diagnosed dementia (OR 2.34) [263]. In a 9 year follow up of 1,453 women aged 65 years and over enrolled in an US HMO, diagnosed dementia was strongly associated with incident diagnosis of UI (RR 3.0 95%CI 2.4-3.7) [264]. Given the strength and consistency of associations with prevalent and incident UI, and given that treatment for reversible dementias can improve UI [265-266], a causal role seems certain.

Ischaemic heart disease is associated with many risk factors for UI, but perhaps because of Neyman’s bias, caused by exclusion of participants who have died, cross-sectional studies have often failed to identify an association with UI itself even in univariate analysis [204,267]. The BACH study reported a strong association only among black participants (OR 2.52) in multivariate analysis [138]. In the Leicester MRC study [250], a history of ischaemic heart disease was associated with baseline stress UI and OAB only in univariate analysis, and with no association with incident symptoms. In contrast, the Nurses’ Health Study found that coronary heart disease was associated with incident weekly UI (OR 1.46), and incident severe UI (OR 1.79) [212]. If ischaemic heart disease is a risk factor for incident UI, its effects might be mediated by cardiac failure [264], or polypharmacy [268-269].

Several cross-sectional studies have documented an association between depression and incontinence [147,172,214,270,271,272]. In the SWAN study, depression was not associated with incident UI, but in the UAB Study of Aging, in a sample of 490 women aged 65 years and older, baseline depression was weakly associated with incident UI (OR 1.2) over 3 years of follow-up [273]. Similarly in the Health and Retirement Study participants (n = 5,820), major depression was a modest predictor of incident UI (OR 1.46) over six years of follow-up, and including extensive adjustment for confounders. Baseline incontinence did not predict incident depression in the same study. In a follow up of women aged 65 years and older enrolled in an HMO, diagnosed depression was also associated with incident diagnosed UI over 9 years (OR 1.6) [264]. Although it seems plausible that the stigma of UI leads to depression (for example by reducing a woman’s social network), current evidence supports causality in the opposite direction, most likely as depression increases the bother of UI symptoms.

Functional impairments, particularly mobility limitations, a history of falls, arthritis, dizziness, use of a walking aid, and poor lower extremity strength, have been correlated with UI in many community-based and nursing home studies [138,261,270,272]. In the Nurse’s Health Study osteoarthritis and functional limitations were plausibly associated only with incident urge UI (RR 1.86 and 2.10 respectively), not with incident stress UI or mixed UI [254]. In a study of 2,025 older women, improvement in Activities of Daily Living was associated with remission of urge UI at 3 year follow up [272]. Other longitudinal studies have shown similar findings [262,273]. It remains unclear
whether UI is a direct consequence of difficulties in getting to the bathroom and/or removing clothing, or whether mobility limitations and UI may both be consequences of general frailty in older age or of an underlying systemic illness.

### 4.11. Ethnic Variation

Ethnic variation in any disease provides only limited evidence for any underlying genetic predisposition. Environmental or cultural differences rather than genetic differences may explain differences in prevalence between populations. As there are very wide variations in UI prevalence between studies, meaningful comparison by race and ethnicity can be made only where such data has been reported within one study. Almost all population-based studies comparing the prevalence of UI among women from one or more racial or ethnic groups originate from the US, which may limit generalisability of conclusions. Results are summarised in table 7. In general, across all studies, white women have a higher prevalence of UI, and in particular stress UI than all other groups.

The starkest and most consistent contrast is in rates of stress UI for black and white women. In most studies, black women have half the prevalence of stress UI compared to white women, with differences persisting after adjustment for age, parity and BMI. In comparing prevalence of mixed and urge UI for white and black women, there is less consistency. Most studies suggest similar prevalence of urge UI and mixed UI, however, the BACH survey found very high rates of mixed UI [138] among black women, while the EPI study reported very high rates of pure urgency UI [257]. These cross-sectional data are supplemented by longitudinal studies. In SWAN [147], black women were at half the risk of incident stress UI, but nearly double the risk of incident urgency UI. In the Nurse Health Studies [274], black women had lower risk of both overall UI, and stress UI after adjustment. The consistency of this difference across both cross-sectional and longitudinal studies, employing different case definitions suggests a real difference in prevalence rather than simply reporting bias.

EPIDEMIOLOGY OF URINARY INCONTINENCE IN MEN

1. GENERAL COMMENTS

The epidemiology of UI in men has not been investigated to the same extent as for females. However, progress has been made during recent years, particularly in the reporting of population-based studies of urinary incontinence among men and more specifically, of urinary incontinence associated with prostatectomy. In addition, more reports have been published on the risk factors for the development of UI in men.

In almost all community based studies, the prevalence rates of UI continue to be reported to be less in men than in women by a 1:2 ratio. The type and age distribution of UI appear to be different between the sexes, and risk factors, although less investigated in men, seem to be different from women. It is also important not to consider UI as an isolated problem in men, but rather as a component of a multifactorial

5. SUMMARY POINTS

Despite a vast literature, there remain many uncertainties about the aetiology of UI. Despite wide consensus on the definitions of the symptoms of incontinence and its subtypes, there is no universally accepted threshold for clinically or biologically significant incontinence, and no objective tests that can be applied in the community. For these reasons, even the prevalence of incontinence is not well established, and the incidence and remission are even less clear.

Despite a number of high quality longitudinal studies, the literature on risk factors for incontinence is very heterogeneous. Among young and middle-aged women, only age, BMI, parity and mode of delivery are unambiguously associated with incontinence, and for all of these, the association with stress UI is greater than with urgency UI.

V. EPIDEMIOLOGY OF URINARY INCONTINENCE IN MEN

1. GENERAL COMMENTS

Typically smaller groups of East Asian or Hispanic women have been included in these studies, which precludes clear conclusions. Broadly though, Asian women report lower prevalence of both stress and urge UI. There is less consistency in comparisons of Hispanic and non-Hispanic white women, with some studies reporting higher, and others lower overall prevalence. This heterogeneity may be explained, at least in part, by differences in prevalence among sub-populations, with Mexican-American women being at higher risk than other Hispanic women [275], or differences in extent of adjustment for covariates.

These studies therefore clearly demonstrate wide variation in self-report of incontinence, and particularly stress incontinence between women of different ethnicities. There may be substantial differences between women of different ethnicities in major risk factors for incontinence, including BMI, and perhaps parity, which might explain differences in incontinence. However, variation in prevalence might also reflect true differences in genetic susceptibility, particularly since in some studies the wide disparity in rates persists even after adjustment for the major known environmental risk factors.

problem. Often other urogenital symptoms (LUTS) such as weak stream, hesitancy, and dribbling, or erectile dysfunction, exist.

Post-prostatectomy incontinence has been studied and reported with increasing regularity in the last few years. Since radical prostatectomy is being performed with increased frequency, and incontinence is one of the main complications of the procedure, a specific review of UI in the postprostatectomy patient population is presented in this section. In addition to epidemiological studies, we included clinical trial data on postprostatectomy incontinence.

### 2. PREVALENCE

Several surveys from the general population have been conducted to determine the prevalence of UI in men (Table V.1). Prevalences ranging from 1 – 39% have been published. The wide span of results may be explained by the variation in the population studied, the definition of incontinence used and the methods used in the surveys. A systematic review of 21 studies reported a prevalence of UI in older men ranging from 11-34% (median = 17, pooled mean = 22%), while that among middle-aged and younger men was from 3% to 5% (median = 4%, pooled mean = 5%). In the same review, the prevalence of daily UI in men ranged from 2-11% (median = 4%, pooled mean = 5%) [112]. A more recent systematic review of 69 prevalence studies on UI in community-dwelling men showed pooled overall prevalence rates from 4.81% to 32.17%, with prevalence increasing with age [329]. A wide definition of UI, older age, inclusion of institutionalized men, and the use of self-reporting methods tend to result in higher prevalence rates [112,330,331]. For any definition of UI, there is a steady increase in prevalence with increasing age (Table 13).

Due to differences in pathological anatomy and pathophysiology of UI in men and women, there is a different distribution in incontinence subtypes. Recent studies confirmed our previous reports of the predominance of urge incontinence (40-80%), followed by mixed forms of UI (10-30%), and stress incontinence (<10%) [258]. The pooled prevalence rates in a systematic review confirmed that such distribution pattern across the different types of UI is consistent across the different age groups [329].

</table>

The higher percentages of the urgency and mixed types of incontinence are more significant in studies involving older people. In fact, the increasing prevalence of any UI by age in men is largely due to the contribution of urgency UI rather than stress incontinence. One study demonstrated an increasing rate of urgency UI from 0.7% between age 50-59, 2.7% between 60-69 and 3.4% for 70 years and older respondents. Stress UI was steady at 0.5%, 0.5% and 0.1% for the above groups respectively [332]. A similar trend of increasing proportions of urge and mixed UI with increasing age is demonstrated in the large population-based study in the US [333], and a smaller population-based Canadian study [284]. On the other hand, Maral and coworkers reported increasing prevalence also of SUI with age, from 0.9% between age 35-44, to 1.2% between 45-54, 3.8% between 55-64, and 4.9% at age 65 and older [334].

Most studies report a significant fraction of other/unclassified type of UI. One study reported that a majority of men with UI had overflow and functional types of incontinence [225], while another found constant dribbling in 7% of their respondents [335]. Terminal dribbling or postvoid dribbling is another type of leakage in men that is difficult to assign to the conventional subtypes of UI. In an Australian survey, 12% of respondents reported frequent terminal dribbling [336].

When it comes to severity, the distribution in men follows that of the women. Estimates for severe UI in older women tend to be about twice as high as for older men [258]. Available data have shown that overall prevalence of UI in men is largely due to mild UI. Men reporting moderate to severe UI are significantly less than those reporting mild UI [337,338].

Very few studies have studied the impact of race or ethnicity on the prevalence of UI among men. A four-country study presented lower prevalences of reported UI among men from Korea (4%) and France (7%) than in men from Britain (14%) and Denmark (16%) [339]. On the other hand, unpublished data from the MESA study did not indicate differences in prevalence among white male respondents compared to African American respondents. Similarly, the National Health and Nutrition Examination Survey did not find any difference in prevalence of UI by racial/ethnic group [340].
Literature on the incidence of male UI is very scarce. No recent studies have reported on this issue. The MESA study [258] found a one-year incidence rate for men older than 60 years at 9-10%. In a population-based survey in the UK among men with at least 40 years of age, the one-year incidence of UI was noted to be 3.8% [341]. A review of a health organisation database of males at least 65 years old revealed an UI incidence of 23.8 per 1000 person years. Malmström [342] analysed the age of onset of UI for each age cohort. Mean debut age for all men was 63 years. The mean duration was about 8-10 years in the cohorts. A longitudinal population based study in Sweden showed that 8.6% (212/2471) of those without UI at the initial survey was found to have UI at the survey done 11 years later [343].

Substantial remission rates for UI in males were noted by the MESA study, higher among men (27-32%) than women (11-13%) [258]. A similarly high one-year remission rate of 39.6% was noted among British males [341]. In the Swedish longitudinal study, 47.8% (55/115) of those found to have UI at the initial survey did not present with the problem at the time of the follow up survey 11 years later [343].

One possible explanation for the difference in the published incidence and remission rates in men compared to women is the predominance of urge type incontinence among men, and its close relation to overactive bladder with and without UI. Another factor is the close association between urge UI and prostate gland disease, infections, or bowel dysfunction, all of which are relatively amenable to treatment or may improve even without treatment.

3. POTENTIAL RISK FACTORS FOR UI

There is relative little research concerning conditions and factors that may be associated with UI in men, and clear risk factors are more seldom scientifically documented. However, a few available studies have identified potential risk factors, which are described below.

3.1. Age

As in women, increasing age is correlated with increasing prevalence of UI (Table V.2). Multivariate analysis in several studies has shown that age is an independent risk factor for incontinence [333,338,344-349]. Compared to women, however, there seems to be a more steady increase in prevalence in men with increasing age. The National Health and Nutrition Examination Survey in the US reported an odds ratio for moderate to severe UI of 1.8 (95%CI 1.6-2.0) for every 10-year increase in age in a cohort of 5,297 men 20 years or older [340].

3.2. Lower Urinary Tract Symptoms (LUTS) and Infections

In postal and telephone surveys of community-living incontinent men, a majority has experienced a variety of other medical conditions, many of which may cause or aggravate UI. LUTS like urgency, nocturia, feeling of incomplete voiding and reduced flow are typically associated with UI [231,350-352]. In one study, UI was reported by 15% of men without voiding symptoms, frequency or urgency and by 34% of those with such symptoms [350].

Studies have also reported that urinary tract infections and cystitis are strongly associated with male UI [332,335], with an odds ratio of 3.7 for UI in men reporting cystitis [332] and an odds ratio of 12.5 among men with recurrent infections [225]. The metaanalysis of 5 studies including the previously mentioned studies showed a significantly higher risk of UI among men with UTI, with a pooled odds ratio of 3.6 (95% CI 2.17-6.00) [329]. It should be noted that most reports indicating a positive association between UTI and incontinence involved men aged older than 60 years.

3.3. Functional and Cognitive Impairment, Physical Activity

Mobility problems such as use of a wheelchair or aids to walking, as well as diagnosed arthritis or rheumatism or having a fall the last year, were significantly greater among incontinent than continent men [204,335]. The Canadian National Population Health Study involving 25,400 men found that those afflicted with arthritis were more likely to have UI with an odds ratio of 1.59 (95% CI 1.07-2.38) [353]. The same study demonstrated that men with back problems were 2x more likely to have UI (OR 2.1, 95%CI 1.50-2.93). A Japanese study on community dwelling men noted that UI is more likely among men whose activities of daily living (ADL) are impaired, specifically those who are unable to change clothes and unable to walk outside, with odds ratios of 17.4 and 4.36 respectively [332]. A Canadian study found odds ratios of 1.8 and 6.4 for partially and totally immobile men aged 65+, respectively, for daily UI compared to those with normal ambulatory function. Similarly, the Silver Network Home Care project among the frail older persons in Italy showed that those with higher ADL scores (i.e., greater functional impairment) had 2-4x higher odds of having UI [344]. A survey of nursing home residents in Wisconsin identified dementia and poor ADL as risk factors for the occurrence of UI [346]. In general, most studies find similarities between men and women (see subsection on women) for functional and cognitive impairment as risk factors for UI.

Corollary to this, the association between physical activity and UI has been studied by Kikuchi and co workers among the elderly, community-based population in Japan [354]. They found that men with middle level
physical activity was associated with a lower UI prevalence compared to those with low level physical activity, with an odds ratio of 0.38 (0.17-0.78). High level physical activity showed similar relations but was not statistically significant.

### 3.4. Neurological disorders

Many specific neurological diseases may lead to UI [355]. Detrusor hyper-reflexia is seen commonly in mengingo-myelocele patients and in spinal injuries, Parkinson's disease and multiple sclerosis. Areflexic bladder dysfunction due to a cauda equina lesion or diabetes might cause overflow or a paralysed pelvic floor and hence stress incontinence. A metanalysis of five studies showed that men who suffered stroke were at an increased risk for UI with a pooled odds ratio of 2.68 (95% CI 1.31-5.45) [329]. Men who had suffered a stroke were at increased risk for incontinence with an odds ratio of 7.1 [332]. The Canadian National Population Health Survey showed that stroke in men increased their odds of having UI by 8x (OR = 8.26, 95%CI 3.63-18.8) [353]. A case control study by Jorgensen [356], age-matched long-term stroke male survivors with controls showed a higher prevalence of UI among stroke survivors compared to controls (17% vs 9%). In addition, among UI sufferers, the stroke survivors were found to have higher frequency and more leakage than controls. In a study of 235 stroke patients, the occurrence of UI correlated with motor weakness (OR 5.4), visual defects (OR 4.8, and dysphagia (OR 4.0) [357].

### 3.5. Diabetes

The results of studies on the association of diabetes mellitus with UI are conflicting. Several reports have not found diabetes as a factor significantly associated with UI in men. This includes the Canadian population-based study involving more than 25,000 men showing no increased risk for UI among men with diabetes [353]. However, the Japanese survey found that diabetics had twice the odds of having UI than non-diabetics [338]. An earlier review reporting the pooled analysis of 6 studies showed that diabetic men were significantly more likely to have UI with an odds ratio of 1.36 (95%CI 1.14-1.61) [329].

### 3.6. Alcohol

Two recent reports showed significant association between alcohol consumption and UI in men. A Japanese survey showed an odds ratio of 1.84 (95%CI 1.2-2.82) [338], and a survey among Chinese men showed an odds ration of 1.42 (95% 1.1-1.8) [348].

### 3.7. Prostatectomy

A well known iatrogenic cause of male incontinence is prostatectomy, but the attributable risk for this factor in the population of men with UI is varied. In a Norwegian survey of elderly men with UI almost a third had undergone prostatectomy. [351].

In a cross sectional study among men in Vienna, Schmidbauer and associates identified previous prostatectomy to be associated with UI [231].

TURP seems to be followed by an incidence of stress incontinence of about 1%. A randomised controlled trial comparing TURP, laser prostatectomy and evaporation of the prostate for benign disease showed comparable incontinence rates immediately and up to 12 months postoperatively [358].

Radical prostatectomy seems to induce UI at a much higher rate than TURP. The overall prevalence of post- radical prostatectomy incontinence ranges from 2 to nearly 60% (Table V.4). This wide range may be explained by many factors, including differences in study characteristics, population characteristics, study site, the definition used, and the timing of assessment of continence in relation to the surgery. The era in development of the procedure has also been found to be associated to the prevalence rates [359], as well as the various procedural modifications of the surgery (see below).

RRP: radical retropubic prostatectomy

RPP: radical perineal prostatectomy

RP: radical prostatectomy, unspecified or combined

Lap RRP: laparoscopic retropubic prostatectomy

RARP: Robotic-assisted radical prostatectomy

Post-prostatectomy incontinence rates elicited from symptoms reported by patients are generally 2-3x higher than those from physicians’ observations. Studies that have performed both assessments in the same population confirm this observation that doctors underestimate postprostatectomy incontinence by as much as 75% [360-363]. A higher incontinence rate is also seen after self-reported questionnaire assessment compared to pad testing [364-365].

Incontinence rates after prostatectomy seem to steadily decline with time and plateaus 1-2 years after surgery [366-371] (Table V.5). This emphasises the need of a long follow-up period to establish continence status postprostatectomy. An actuarial study among 647 postprostatectomy men estimated UI rate of 13% at one year and 7% at two years postsurgery [372]. The Prostate Cancer Outcomes Study reported that the 5-year postprostatectomy incontinence rate among 1,288 men was 14%, which was higher than the 10% rate reported after 2 years [373].

</table>

The technique of radical prostatectomy impacts on UI rates. Modifications associated with lower UI rates include the perineal approach [374-375] and preservation of neurovascular bundle [376-379]. Bladder neck preservation affords earlier return to continence compared with bladder neck resection, but with similar UI rates after one year [380-381]. One study showed earlier recovery of UI after tennis racquet reconstruction and bladder neck preservation compared with bladder neck resection with puboprostatic ligament preservation, but with similar UI rates at one year [366,382-384]. However, continence status assessed more than 12 months after surgery showed even lower rates of UI after bladder neck preservation (11.6%) compared to resection (4.9%) in one study [366]. Bladder neck intussusception was found to be associated with earlier return to continence in several prospective studies [385]. The literature on the impact of neurovascular preservation on postprostatectomy continence rates is conflicting [386-387].

With the increasing performance of minimally invasive surgery, several studies have investigated the impact of these forms of surgery on postoperative continence rates. Several systematic reviews with metaanalysis of studies comparing continence rates for open, laparoscopic and robotic radical prostatectomy, similarly, did not show any significant difference in the postoperative continence rates between the 3 techniques [388-390]. However, a prospective study of 239 men showed that UI after laparoscopic procedures seems to be higher initially but approximates that of open techniques by one year. A more recent systematic review that focused on robotic radical prostatectomy showed better continence recovery after robotic prostatectomy compared with open retropubic prostatectomy (OR : 1.53, p = 0.03) or laparoscopic radical prostatectomy (OR : 2.39, p = 006) [390].

Older age at time of surgery has been found to be associated with a higher prevalence of post-prostatectomy UI [368,377,391-398], with one study showed a doubled risk for every 10 years of age beginning at age 40 [399]. Another showed that age at surgery predicted% per year [398]. However, other studies failed to demonstrate that age is an independent predictor for incontinence [400-401]. Several studies suggested that rather than absolutely affecting final continence, elderly men need a longer time to achieve continence after surgery [402-403].

Similarly, patient weight and body mass index have been identified as a risk factor for postoperative incontinence [377, 404] or as a predictor of a longer interval before return to continence [368]. One cohort study showed that men who were not obese and were active were 26% less likely to be incontinent at 58 weeks postoperative (RR 0.74, 95% CI 0.52–1.06) [394].
Other factors have been found to be associated with a higher prevalence of post-prostatectomy UI, although not consistently. Such factors include prior TURP, preoperative lower urinary tract symptoms, obesity, clinical stage, PSA, prostate volume and Gleason score [365,377,392-393,396,405]. A retrospective analysis of 156 patients who had undergone preoperative MRI of the prostate and were followed up post-prostatectomy showed that time to return to continence was associated with the variation in the shape of the prostatic apex. The prostatic apex that does not overlap with the membranous urethra was found to be significantly associated with an early return of continence. The 5-year cohort study of the Prostate Cancer Outcomes Study found that among prostatectomy patients, race and ethnic differences were related to urinary incontinence, with African-Americans having better recovery compared to non-hispanic whites and Hispanics [406].

Adjuvant radiotherapy has not been found to affect post-prostatectomy incontinence rates when assessed beyond 1 year [407-408].

### 3.8. Factors of Unclear Association with UI in Men

A 9 year study of Janssen [409] showed increasing rates of UI with increasing BMI among the older men and women. However, multivariate analysis failed to show increased BMI (overweight and obese levels) as an independent risk factor for the development of UI.

In a study including a younger population in Australia, obesity was noted to be associated with UI with an odds ratio of 3.2 (1.2-9.0) [410]. In this study, however, being merely overweight was not associated with UI.

Several studies in the older persons have shown an association between physical activity and UI among women that is not seen among men [339,354].

### 4. SUMMARY POINTS:

- The epidemiology of UI in men has not been investigated to the same extent as for females. But it appears that UI is at least twice as prevalent in women as compared with men. There seems to be a more steady increase in prevalence with increasing age than for women.
- Most studies find a predominance of urgency UI, followed by mixed forms of UI and stress UI the least. Most studies have a large fraction of other/unclassified types.
- Literature on incidence and remission of male UI is still very scarce.
- Clear risk factors are more seldom scientifically documented, but several medical correlates have been reported. Established risk factors predisposing men to UI include increasing age, presence of lower urinary tract symptoms (LUTS), urinary tract infections, functional and cognitive impairment, diabetes, alcohol intake, neurological disorders, and prostatectomy.
- Substantial gains have been achieved on the study of the epidemiology of UI in men compared to the previous years. The conduct of more population-based prevalence studies permitted a better understanding of the problem of UI among men.
- UI after radical prostatectomy is frequent, ranging from 2-57%. Rates steadily decline from the time of surgery and plateaus at 1 to 2 years postoperatively.
- Factors affecting post-prostatectomy UI include the age at surgery, obesity, type of prostatectomy, and certain modifications in the technique.
- There is not enough evidence to demonstrate any significant difference in continence rates between open, laparoscopic and robotic-assisted radical prostatectomy.
- Comparative studies of surgical procedures to address prostate disease and their various modifications should be performed to better assess their impact on postoperative continence rates.

### VI. EPIDEMIOLOGY OF OVERACTIVE BLADDER AND NOCTURIA

**1. GENERAL COMMENTS AND DEFINITIONS**

Overactive bladder (OAB) and nocturia have been neglected topics in the medical literature [476-478]. Earlier research on epidemiology of urinary symptoms focused either on lower urinary tract symptoms (LUTS) suggestive of benign prostatic hyperplasia (BPH) in men or on urinary incontinence in women [479]. However, there has been increased research interest in OAB and nocturia during last two decades [477-478, 480].

OAB can be bothersome [481-483], and is associated with comorbidity [484], impaired quality of life [483], and reduced emotional well-being and work productivity [485]. Nocturia is a common cause for sleep maintenance insomnia [486-488]. Nocturia can be bothersome [489-496], and is associated with impaired mental health, physical health and quality of life [496-498]. Both OAB and nocturia have been reported to be associated with increased risk of falls and fractures [499-506] and nocturia also with mortality [505, 507-510]. Indeed, urinary urgency and urgency incontinence, the cornerstone symptoms of
OAB, and nocturia are among the most bothersome urinary symptoms both at individual and population-level [511].

In general, the definition of any condition is a critical factor in evaluating its epidemiology: OAB and nocturia are not exceptions to this rule [478, 512]. To facilitate discussion and research related to LUTS, the International Continence Society (ICS) has produced standardisation reports [513-514]. We will use the ICS definitions as basis of this chapter. However, we acknowledge that these definitions are not perfect and we encourage further research and discussion [480, 512-516].

OAB is a term to describe the clinical problem of urgency and urge incontinence from a symptomatic rather than from a urodynamic perspective. Previously various terms, such as ‘irritable bladder’ or ‘unstable bladder’ have been used. According to the ICS, OAB is a symptom-defined condition characterised by urinary urgency, with or without urgency urinary incontinence, usually with increased daytime frequency and nocturia [513-514]. The ICS defines urinary urgency as sudden compelling desire to pass urine, and the term OAB is appropriate if there is no proven infection or other obvious pathology [513].

It has been known for a long time that among healthy people urine production is lower during the night than during the day [517]. Urologists have traditionally defined nocturia as frequency of urination at night without reference to urine amount, while internists have assumed that nocturia results from an increased amount of urine produced with less focus on other urinary symptoms [518]. By the ICS definitions, nocturia refers to waking at night one or more times to void, and nocturnal polyuria (NP) to the production of an abnormally large volume of urine during sleep [519]. Nocturnal urinary incontinence or nighttime bed wetting (enuresis) differs from nocturia.

According to the ICS, as stated earlier, nocturia is also a component of OAB. However, there is a debate on the definitions, especially regarding urinary urgency and OAB [480, 516, 520-530].

Sometimes OAB has been divided into ‘OAB wet’ (OAB with urgency urinary incontinence) and ‘OAB dry’ (OAB without urgency urinary incontinence). In this part of the chapter we focus on the epidemiology of OAB – without distinction between OAB ‘wet’ and ‘dry’ – and nocturia. ‘OAB wet’ (i.e., urgency urinary incontinence) is covered separately in urinary incontinence sections (epidemiology of UI in women and epidemiology of UI in men).

2. PREVALENCE OF OVERACTIVE BLADDER

Prevalence estimates from as low as 2% [531] up to 53%[532] have been reported. Many studies on OAB have reported prevalence estimates between 10% and 20% [533-539] and the most cited articles estimate a prevalence of between 12% and 17% % [533, 535, 540]. However, many of the studies have been limited by not measuring bothersomeness.

In Table 1, we have reviewed all population-based studies assessing prevalence of OAB in adults of both genders. To identify these studies, a Medline search (English-language articles published before June 2016) was carried out on with the strategy (Overactive bladder.mp) or (OAB$.mp) and (prevalence.mp). Non-population-based (i.e. based on doctor attendances or similar) studies or studies not conducted among both sexes are not included in Table 18.

Among these population-based studies identified, different populations, different sample selection and different data collection methods were often used (Table 1). Sample sizes varied between 913 and 162,906, median being 3,366 individuals. Nine (39%) out of 23 studies did not report any response proportion. Among those 14 studies which reported, as many as eight (58%) had response proportion less than 50%. There was significant heterogeneity in symptom assessment, exclusion criteria, case definitions (some studies used grading of symptom severity whereas others did not), and in the time period during which the occurrence of symptoms was asked (Table 1). Hence, dissimilarities in study procedures likely explain the differences in prevalence estimates. Overall, median prevalence estimate of the studies is 16.5% (range 2-35% in men, and 3-41% in women) (Table 1). However, estimates of the prevalence of OAB have been smaller in many recent studies compared to earlier estimates (Table 1).
Table 18: Overview of published population-based studies assessing prevalence of OAB in both sexes (PubMed indexed English-language articles as of June 2016, in chronological order).

</table>

a. In the European study, in five out of six countries, telephone interview was used (excluding Spain, where direct interviews were conducted due to lower proportion of households with telephone). Study sample was obtained from telephone number listings (except Spain, where electoral census data was used).
b. Out of 11,740 participants (of 17,231 households contacted), 5,539 were considered ineligible. To calculate response rate, the number of respondents was divided by eligible participants (the former response rate). If same proportion of non-participants, as there were ineligible among participants (47%), were also considered ineligible, response rate was greater (the latter response rate).

c. Out of 7,487 individuals, 3,239 completed the questionnaire (response proportion 43.4%).

d. Invitation to complete email survey was sent to 88,150 members of the Internet-based panel. Of the members, 51,546 responded but 7,947 were excluded due to high rates of missing or inconsistent data, or discontinuation of the survey. Finally, 30,000 participants were randomly selected from the pool of respondents with completed surveys.

e. Invitation to complete email survey was sent to 5,002 members of the Internet-based panel. Of the members, 3,058 responded, but only 2,106 members completed the survey. Finally, 2,000 participants were randomly selected from the pool of respondents with completed surveys.

f. Invitation to complete email survey was sent to 38,469 members of the Internet-based panel. Of the members, 18,591 responded, but number of members completing the survey was not reported. Finally, 10,000 participants were selected from the pool of respondents with completed surveys.

g. Authors reported that a large proportion of individuals asked to participate declined. However, the number of individuals asked to participate was not reported.

h. Out of 5,503 individuals, 63.3% completed the questionnaire (n=3,483).

i. In this study, individuals “were considered to have urgency if they reported difficulty postponing urination, had a strong urge to urinate (fairly often, usually or almost always) in the last month or a strong urge to urinate in the last 7 days (4 or more times).”

j. Time period was not reported in the article. However, authors cited the original OABSS articles, which states that “patients were instructed to circle the score that best applied to their urinary condition during the past week” (Homma et al. Urology 2006).

k. ICS, International Continence Society; OAB, overactive bladder; UTI, urinary tract infection.

l. Cut-off point (threshold) used for normal vs. abnormal symptom occurrence. Reviewed only for studies using current ICS definition of OAB.

m. Time period during which the occurrence of symptoms was asked.
Only a few population-based studies have evaluated OAB prevalence using the ICS definition and reported bother. Assessing perceived bother associated with OAB substantially decreases the prevalence estimates. In the FINNO Study (conducted in Finland among women and men aged 18-79) [483], as many as 54% of men and 57% reported any (at least rarely) urinary urgency. However, prevalence of at least moderate bother from urgency was 7% for men and 9% for women. Overall, more than 96% of individuals with rare urgency reported no or small bother from it whereas 65% of individuals with urgency often and more than 70% with urgency always reported moderate or major bother (scale: none-small-moderate-major) [483]. These results are in concordance with two international studies [481-482]. In the EpiLUTS study (conducted in the US, UK and Sweden among people aged 40–99) [482], 22.4% of men and 35.7% of women reported urinary urgency at least sometimes (in scale: never-rarely-sometimes-often-almost-always) (Table 1). However, prevalence estimates were substantially lower when bother was taken into account. Only 6% of men and 12% of women reported “quite a bit” or more bother from urgency (in scale: not at all-a little-bit-somewhat-quite a bit-a great deal) [482]. Bother analysis from the EPIC Study [481, 540] showed also that infrequent urinary urgency is not considered as very bothersome by most individuals. Out of OAB cases, 46% did not report symptom bother from it [6]. All these results suggest that i) bother measurement is essential in estimating the clinically relevant prevalence of OAB, and ii) most studies have overestimated the prevalence of patient-important OAB [480-483] (Table 1).

3. INCIDENCE OF OVERACTIVE BLADDER

The natural history of OAB has been systematically reviewed little more than 5 years ago (English articles published between January 1, 1990, and September 20, 2009) [559]. Authors identified 7 longitudinal studies of OAB. OAB incidence varied between 3.7% and 8.8%; and included studies provided evidence for dynamic nature of OAB [549]. Indeed, longitudinal studies have confirmed that OAB prevalence increases with age but also that OAB is a dynamic condition [560-566].

In a population-based study (conducted in between 1991 and 2007 in Gothenburg, Sweden) [562], the number of women with OAB with urgency incontinence (“OAB wet”) increased from 6% to 16%, however, the proportion of women with OAB without UUI (OAB dry) did not differ significantly (11% vs. 10%). Among women with OAB dry in 1991, 23% remained OAB dry, 28% reported symptom progression to OAB wet and approximately half reported remission of OAB by 2007, supporting the concept of the dynamic nature of OAB. The rate of remission of OAB symptoms was greater for women who were OAB dry (49%) compared with those who were OAB wet (26%).

Finding that OAB is a dynamic condition was also reported in Australian and Japanese studies [565-566]. In the CHAMP study conducted among 1,705 men aged 70 or more living in a defined region of metropolitan Sydney [565], one in three older men with OAB had sustained remission of symptoms without medical or surgical interventions. Of the men with OAB at baseline, 29% received treatment for OAB or benign prostatic enlargement over 5 years. In the Japanese longitudinal community-based “Fujisawa-kyo study” among more than four thousand men and women aged 65 years or more [566], the incidence rate of OAB was 12% and remission rate 30%.

4. POTENTIAL RISKFACTORS FOR OVERACTIVE BLADDER

The causes and risk factors of urinary urgency and/or OAB are not well studied. Available studies, that have identified potential risk factors, are summarised below.

4.1. Age

In numerous cross-sectional studies older individuals reported more OAB than younger ones (Table 1). Furthermore, longitudinal studies have confirmed that OAB increases with age [559]. Besides increasing age, also having urgency in childhood predicts having urgency in later life [567-568].

4.2. Gender

In Table 1, we summarised population-based studies assessing prevalence of OAB among both. In most studies, OAB was more common among women (Table 1). In only three (13%) out of 23 studies, the prevalence estimate of OAB was larger for men than for women. However, these three studies [537, 548, 557] did not include younger age groups, and typically OAB is more common among women than men especially in younger ages.

4.3. Obesity

In a British, prospective study, obesity was a risk factor for the onset of an OAB (OR 1.5, 1.0-2.1) in women [484] but not among men [561]. Ten studies were included in a recent systematic review examining the link between OAB and obesity [569]. There was a statistically significant link between obesity (measured by BMI) and OAB in eight studies. However, four of the studies that found a positive correlation were found of low methodological quality. BMI. Three studies examined the relationship between OAB with waist circumference, two found relationship whereas one did not. Overall, unfortunately most
studies were cross-sectional and did not often adjust for major confounders.

4.4. Life style

In a prospective study among British women, neither alcohol, coffee nor tea consumption were risk factors for the onset of OAB (defined as having either urgency, UIU, or a combination of these) but use of carbonated drinks was [484]. Among men, neither tea, coffee nor wine consumption were associated with onset of OAB, but a negative association between beer intake at baseline and subsequent OAB onset was found [561]. However, this may be explained by a systematic misclassification error (individuals decrease or cease alcohol consumption due to ill health) [570-571], residual confounding (moderate drinkers have many other favouring lifestyle factors) [572-573], or direct biological effects. In a Swedish population-based study in young female twins [574], tea (but not coffee) drinking was associated with an increased risk for both OAB and nocturia. However, after controlling for confounders (including zygosity of twins) these associations did not remain significant. Concurring with these studies, among non-care seeking women [575], coffee or alcohol consumption was not associated with OAB. In a population-based study among women in Southern Sweden [576], OAB was not associated with alcohol consumption.

In a prospective British study, smoking was a risk factor for the onset of an OAB (defined as having either urgency, UIU, or a combination of these) in women but not in men [561]. In a population-based study among Finnish women aged 18-79 [577], urgency was approximately three times more common among current and twice as common among former than never smokers. Parallel associations for urgency with smoking intensity suggested a dose–response relationship [577]. Other supporting findings have also been reported [578-581]. However, some other studies did not find smoking as a risk factor for urgency [548, 574, 576].

A prospective study among British men did not provide evidence of any specific dietary patterns as a risk factor for onset of OAB [561]. Furthermore, physical activity was not significantly associated with OAB onset in men [561]. Contradictory results were found among non-care seeking women [575] where physical activity was associated with decreased OAB.

4.5. Race/Etnicity and socioeconomic status

Evidence regarding the role of race/ethnicity on OAB prevalence is limited. In a small Taiwanese study [582], higher prevalence of urgency (7.7% vs. 4.3%, p=0.02), was found in indigenous woman than in non-indigenous women. In the US part of the EpilUTS study [578], OAB was reported by 26% of White, 33% of Black, 27% of Asian and 28% of Hispanic men. In the multivariate analysis, OAB was significantly more common among African-American (OR 2.0, p<.001) and Hispanic (OR 1.7, p<.001) male participants. The authors reported no statistically significant differences among women after multivariate analysis, despite wide variation in crude prevalence (27% for Asian women, 43% for White, 46% for African-American and 42% for Hispanic) [578]. Hospital-based studies have reported no difference in the prevalence of OAB by race/ethnicity [593-594].

4.6. Reproductive factors and pelvic surgery

Urinary urgency is a common symptom during pregnancy [585]. In a Taiwanese study [586], only 1% of women reported having urgency before pregnancy, whereas corresponding estimates were 16% in the first, 25% in the second, and 31% in the third trimester. Other studies have also found increasing prevalence of urgency with advanced gestational age [587-588]. However, in a Nigerian study, women in 3rd trimester did not report more urgency than women in 2nd trimester [589]. Although one quarter of pregnant women reported urgency, it was associated with moderate or severe bother for only 5% of symptomatic women.

The association between parity and urinary urgency is controversial. Some studies reported no association for parity with urgency or OAB [484, 575, 590-591], whereas others found increased prevalence of urgency among parous women [582, 592-595]. However, there were substantial differences in methods between these studies. Regarding mode of delivery, most studies demonstrated no effect on prevalence of urgency or OAB [548, 590, 594-597]. On the other hand, contrary findings have also been reported [598-599]. In a Swedish prospective study, weekly urgency was reported in late pregnancy by 2.6% of women in the elective vaginal delivery and by 2.7% of the women in the elective cesarean section group [598]. Corresponding figures were 7.9% for vaginal delivery and 2.7% for cesarean section groups at 9 months post-partum [125] concurring with the results of a cross-sectional US study [599]. In a recent US study [581], for women with a history of at least one operative vaginal birth, the adjusted odds of OAB was more than quadrupled (OR 4.9, 95% CI 2.2-11; women who had delivered all their children by pre-labour cesarean as reference).

The association between the postmenopausal period and increased urgency or OAB has been reported in several studies [553, 592, 594-595, 600-601]. Impact of hormone therapy on OAB is unclear. The Cochrane Incontinence Group review of urinary incontinence and oestrogens (urgency or nocturia not as the primary objective of the study) found that there were less nocturnal voids and urgency episodes among women treated with local (but not systemic) oestrogen [602]. There were no significant differences in OAB prevalence among women using either oral contraceptives or a levonorgestrel-releasing intrauterine device, in comparison to noncontraceptive users in a population-based study among young, Swedish women [603].
Radical hysterectomy is related to increased prevalence of pelvic floor problems [604]. For instance, patients treated for cervical cancer reported urgency 2-3 times more often than the matched controls: 36% of those with history of radical hysterectomy and pelvic lymph node dissection, 49% of those with surgery and adjuvant radiotherapy, and 48% of those with primary radiotherapy reported experiencing urgency [605]. However, the relationship between urgency and hysterectomy for benign indications is less clear. Many studies did not find significant association of hysterectomy with urgency [590-591, 606-611]. However, some studies reported less [601, 612-615] and some more [548, 584-585, 616] urinary urgency after hysterectomy. No differences by route of hysterectomy on urgency have been found [611, 615-618]. Both prolapse surgery and stress incontinence surgery are associated with risk of (de novo) urgency or urgency incontinence in both hospital based, and population based studies [580, 591, 619-620].

4.7. Specific conditions

There is a paucity of studies concerning conditions and co-morbidities that may be associated with OAB, and clear causal risk factors are even less often documented. Few available studies have identified potential risk factors, which are described below.

4.8. Benign prostatic hyperplasia

Instead of OAB/urgency, observational, clinic-based studies have assessed the relationship between detrusor overactivity and benign prostatic hyperplasia obstruction. Although patients with detrusor overactivity are less likely to get symptom improvement after BPH surgery than those without detrusor overactivity, many patients report less urgency after BPH surgery [621]. Similar findings were reported in a prostatectomy study among men aged 47-85, 32% (n=49) reported urgency pre-operatively and 13% post-operatively (n=20) [622]. In another study, detrusor overactivity was present in 68% of patients (n=21) at baseline and in 31% (n=10) at follow-up (mean 2 years) in the prostatectomy group [623]. However, many patients remain symptomatic after prostate surgery, and prognostic factors for success remain largely unknown [624].

4.9. Pelvic organ prolapse.

In community-based studies [584, 625-626], pelvic organ prolapse was associated with 2-6 times higher risk of having urgency incontinence. Concurrent with this findings, hospital based studies have also found pelvic organ prolapse as a risk factor for urgency incontinence, and in interventional studies urgency incontinence is often (but not always) relieved [628].

4.10. Mental health

In the BACH survey [629], urinary frequency, urgency, and nocturia were associated with previously experienced sexual, physical, and emotional abuse for both genders and for all ethnic groups of the study (White, Black, Hispanic). Concurring results were found in a German, clinic-based study where 31% of women with OAB reported almost twice as often earlier physical or sexual abuse as did the women with stress urinary incontinence (18%) or women without urinary symptoms (18%) [630]. In an Iranian study, individuals with OAB had a higher prevalence of anxiety (28.2 vs. 8.8%; p=0.001) and depression (38.2 vs. 18.2%; P = 0.02) [538] agreeing with finding from multinational EpiLUTS study and longitudinal Japanese where increased depression and anxiety were found among individuals with OAB [566, 631]. Furthermore, postpartum depression has also been reported to be associated with urgency incontinence [632].

5. PREVALENCE OF NOCTURIA

Most earlier studies assessing the prevalence of nocturia have been conducted among elderly men [643-651]. They consistently found that nocturia 1) is a very common symptom and 2) increases with ageing. These finding have recently been confirmed in comparative studies conducted in both sexes [489-490, 495, 498, 540, 546, 652-663] (Figure 8).

We have reviewed all population-based studies assessing prevalence of nocturia in adults of both sexes. To identify these studies, a Medline search (English-language articles published before June 2016) was carried out on with the strategy (nocturia.mp) and (prevalence.mp). Non-population-based (i.e. not based on doctor attendances or similar) studies, studies not conducted among both sexes of adults, studies with narrow age range (less than 40 years), or studies with percentage data unavailable are not shown in Figure 1.
In the FINNO Study, conducted among men and women aged 18 to 79 [656], approximately one out of eight men and women reported at least two voids per night. In addition one third reported one void per night. Young women reported clearly more nocturia than young men, prevalence of nocturia in men and women equalised only in the sixth to seventh decade of life, and in older age groups men had more nocturia than women. Many other studies have supported these findings: higher prevalence of nocturia among young women than young men, and an equalization of prevalence in middle age [495, 498, 540, 546, 660, 664-665] (Figure 1). As the gender difference has been found across different continents (Europe, Asia, Australia and North America) it probably not due to specific country, lifestyle or cultural factors. The reasons for the excess of nocturia among older men remain unknown, but prostatic enlargement is likely to be the predominant factor.

The Krimpen study, conducted in the Netherlands among elderly men [666], is one of the few studies where nocturia was assessed by using frequency-volume charts. One and a half or more voids/night (average of information on two to three nights) was present in 60% of men aged 70-78 years, whereas at least 2.5 voids per night was present in 20%, respectively. These estimations are comparable to questionnaire studies: most elderly people void at least once per night [665] (Figure 1).

### 6. INCIDENCE OF NOCTURIA

A recent systematic review and meta-analysis summarised the incidence and remission of nocturia [667]. Authors conducted a comprehensive search of PubMed, Scopus, and CINAHL databases and abstracts of major urological meetings until end of August 2015 and found 16 eligible studies [668-683]. Of the 16 included studies, 10 (62%) were at high risk and six (38%) at low risk of bias. Of these 16 studies, 14 (88%) accurately assessed nocturia both at baseline and at follow-up, nine (56%) had little missing data in the follow-up, and eight (50%) used representative source populations. Pooled estimates from 13 studies [670-683] with 114 964 person-years of follow-up demonstrated that annual incidence was strongly associated with age: 0.4% (0–0.8%) for adults aged less than 40 years; 2.8% (1.9–3.7%) for adults aged 40–59 years; and 11.5% (9.1–14.0%) for adults aged at least 60 yr. Of those with nocturia, each year 12.1% (9.5–14.7%) experienced remission.

### 7. RISK FACTORS FOR NOCTURIA

The causes and risk factors of nocturia are not very well understood [510, 647]. Available studies, that aimed to identify potential risk factors, are summarised below.

#### 7.1. Age

There have been numerous studies showing that elderly subjects have more nocturia than younger people (Figure 1) - age is one, if not the most important correlates of nocturia. For instance, in a community-based US study, less than 5% of those aged 18-24 reported two voids per night while the corresponding figures were approximately 15% and 25% for those aged 45-54 and 65-74 respectively [490]. Besides increasing age, also childhood nocturia and enuresis has been suggested to predict nocturia in later life [567, 683].

#### 7.2. Gender

Although there is no remarkable difference in overall prevalence of nocturia between genders, in more detailed age specific analyses differences have emerged between the genders (Figure 1). Many studies found higher prevalence of nocturia among young men and women aged 18 to 79 [656], approximately one out of eight men and women reported at least two voids per night. In addition one third reported one void per night. Young women reported clearly more nocturia than young men, prevalence of nocturia in men and women equalised only in the sixth to seventh decade of life, and in older age groups men had more nocturia than women. Many other studies have supported these findings: higher prevalence of nocturia among young women than young men, and an equalization of prevalence in middle age [495, 498, 540, 546, 660, 664-665] (Figure 1). As the gender difference has been found across different continents (Europe, Asia, Australia and North America) it probably not due to specific country, lifestyle or cultural factors. The reasons for the excess of nocturia among older men remain unknown, but prostatic enlargement is likely to be the predominant factor.

The Krimpen study, conducted in the Netherlands among elderly men [666], is one of the few studies where nocturia was assessed by using frequency-volume charts. One and a half or more voids/night (average of information on two to three nights) was present in 60% of men aged 70-78 years, whereas at least 2.5 voids per night was present in 20%, respectively. These estimations are comparable to questionnaire studies: most elderly people void at least once per night [665] (Figure 1).

### 6. INCIDENCE OF NOCTURIA

A recent systematic review and meta-analysis summarised the incidence and remission of nocturia [667]. Authors conducted a comprehensive search of PubMed, Scopus, and CINAHL databases and abstracts of major urological meetings until end of August 2015 and found 16 eligible studies [668-683]. Of the 16 included studies, 10 (62%) were at high risk and six (38%) at low risk of bias. Of these 16 studies, 14 (88%) accurately assessed nocturia both at baseline and at follow-up, nine (56%) had little missing data in the follow-up, and eight (50%) used representative source populations. Of those with nocturia, each year 12.1% (9.5–14.7%) experienced remission.

### 7. RISK FACTORS FOR NOCTURIA

The causes and risk factors of nocturia are not very well understood [510, 647]. Available studies, that aimed to identify potential risk factors, are summarised below.

#### 7.1. Age

There have been numerous studies showing that elderly subjects have more nocturia than younger people (Figure 1) - age is one, if not the most important correlates of nocturia. For instance, in a community-based US study, less than 5% of those aged 18-24 reported two voids per night while the corresponding figures were approximately 15% and 25% for those aged 45-54 and 65-74 respectively [490]. Besides increasing age, also childhood nocturia and enuresis has been suggested to predict nocturia in later life [567, 683].

#### 7.2. Gender

Although there is no remarkable difference in overall prevalence of nocturia between genders, in more detailed age specific analyses differences have emerged between the genders (Figure 1). Many studies found higher prevalence of nocturia among young men and women aged 18 to 79 [656], approximately one out of eight men and women reported at least two voids per night. In addition one third reported one void per night. Young women reported clearly more nocturia than young men, prevalence of nocturia in men and women equalised only in the sixth to seventh decade of life, and in older age groups men had more nocturia than women. Many other studies have supported these findings: higher prevalence of nocturia among young women than young men, and an equalization of prevalence in middle age [495, 498, 540, 546, 660, 664-665] (Figure 1). As the gender difference has been found across different continents (Europe, Asia, Australia and North America) it probably not due to specific country, lifestyle or cultural factors. The reasons for the excess of nocturia among older men remain unknown, but prostatic enlargement is likely to be the predominant factor.

The Krimpen study, conducted in the Netherlands among elderly men [666], is one of the few studies where nocturia was assessed by using frequency-volume charts. One and a half or more voids/night (average of information on two to three nights) was present in 60% of men aged 70-78 years, whereas at least 2.5 voids per night was present in 20%, respectively. These estimations are comparable to questionnaire studies: most elderly people void at least once per night [665] (Figure 1).
women than young men, and an equalization of prevalence in middle age [495, 509, 540, 546, 639, 656, 665]. Prostatic enlargement has been suggested as predominant factor for potential nocturia excess among elderly men [665].

### 7.3. Obesity

Several studies have shown the relation between overweight/obesity and nocturia. Obesity was associated with more than three-fold risk of nocturia in a Swedish study among middle-aged women [685], and with more than two fold-risk in the FINNO Study [686]. Confirmatory findings have been reported in numerous studies [687-692]. In the longitudinal TAMUS study among men aged 50 or more [693], obese men had double the risk for nocturia compared with normal weight men. The frequency of nocturia at baseline did not increase the incidence of obesity at follow-up.

### 7.4. Life style

Most studies have not found an association between nocturia and either alcohol [489, 673, 689, 694-695] or coffee/caffeine [650, 684, 693, 696-697] consumption. In some studies moderate alcohol consumers had less nocturia than abstainers [693, 698-699]. However (as discussed earlier in 'Risk factors of overactive bladder'), these findings may be due to systematic misclassification error or residual confounding [570-573].

Most studies have not found an association between nocturia and smoking [508, 651, 666, 689, 693, 695-696]. Some conflicting results have also been reported: in Swedish and Chinese studies [685, 692] smoking was associated with increased nocturia but in Austrian [489] and Japanese [694] studies, with decreased nocturia.

Physical activity has been reported to be protective against LUTS in men [700-702], and against nocturia in both genders [663, 685]. In an Austrian study [489], no relation was found between nocturia and physical activity. However, exercise programme has been shown to improve nocturia in non-randomised trial [703].

### 7.5. Race/Ethnicity and socioeconomic status

In several US studies, African Americans were approximately twice as likely to report nocturia as other groups [687, 690, 704-706]. This effect was attenuated, although remained significant [700, 705], with adjustment for socioeconomic status and comorbidity. Furthermore, care-seeking black women reported also more commonly nocturia than other groups [707-708]. Conflicting results were found in a Kaiser Permanente study [709]. In the EpiLUTS study conducted in the USA, UK and Sweden [684] and in a Kaiser Permanente study [710], Blacks and Hispanic had more nocturia when compared to White. Less is known about the relationship between ethnicity and nocturia outside the US. In small studies in Taiwan [582, 711] and Scotland [712], associations of nocturia and ethnicity have been found. In the Scottish study, nocturnal polyuria was more common in the Caucasian men compared to Asian men.

### 7.6. Reproductive factors and pelvic surgery

Nocturia is a very common symptom during pregnancy. In all studies most pregnant women report nocturia at least weekly, in many studies most women report having nocturia every night [582-589, 596, 713-714]. Typically the occurrence of nocturia increases during pregnancy. In an Indian study [714], nocturia (defined as more than one void per week) was reported by 50.6% of women before pregnancy (retrospective information), by 58.6% of those in the first, 71.9% in the second and 77.0% in the third trimester. In Finnish and Chinese studies [591, 692], parous women reported slightly more nocturia than nulliparous women, contradicting earlier reports (conducted among perimenopausal women) of no association [593, 715]. The relationship between nocturia and parity could be due to pregnancy itself rather than trauma to the urinary tract during delivery [716] supported by finding of no difference in nocturia between primi- and multiparous women in the same Finnish study [716] and by a finding of no difference between vaginal delivery and caesarean section in a Swedish prospective study [598]. In these studies, the postpartum period was also associated with increased nocturia [591, 598].

In a population-based Swedish study of young women, no difference in nocturia was found among oral contraceptive users and non-users, however, levonorgestrel-releasing intrauterine device (compared with non-contraceptive users), reported less nocturia (OR 0.53, 95% CI 0.32-0.89) [605].

Danish and Finnish population-based studies have reported more than double the risk of nocturia after menopause [591, 593], consistent with other studies [602, 657, 715]. One study attributed this to aging rather than to menopausal transition [717]. In the Finnish and Swedish studies [591, 715], there were indications of increased nocturia among women using menopausal hormone therapy, but the findings were statistically insignificant. In a small randomised trial [718], there was no difference in nocturia among those with menopausal hormone therapy or placebo. Similar findings were reported in a randomised trial of vaginal oestradiol and placebo after sling surgery [719].

The relationship between nocturia and hysterectomy is unclear, with hysterectomy being a protective factor [609, 614, 616], risk factor [593, 710], or not associated with nocturia [591, 603, 610]. Surgery for stress urinary incontinence was not associated with nocturia in a population-based study [591].
7.7. Specific conditions

7.7.1 Benign prostatic hyperplasia and prostate cancer

Benign prostatic hyperplasia (BPH) constitutes a well-recognised risk factor for nocturia [666, 696, 720]. In the FINNO Study [696], half of the subjects with physician-diagnosed BPH reported at least two voids per night; however, only a third of the men with nocturia reported BPH. However, nocturia is the least specific LUTS associated with BPO and medical treatment to relieve BPO has less effect on nocturia than on other LUTS [721-722]. Furthermore, nocturia has been reported as one of the most persistent LUTS following prostate surgery [622, 723]. In a study on men with bothersome LUTS, those receiving finasteride had an effect indistinguishable from placebo [724]. Many men with LUTS express a fear of prostate cancer [725], however, whether LUTS (including nocturia) are suggestive of prostate cancer is not clearly established [726]. In the large HUNT-2 study [727], LUTS severity was positively associated with the subsequent diagnosis of localised prostate cancer but not with advanced or fatal disease. More than 70% of men with physician-diagnosed prostate cancer reported at least two voids/night, while 7% of men with nocturia reported prostate cancer in the FINNO Study [696]. Whether men with nocturia are only more vulnerable to be diagnosed with prostate cancer (due to use of prostate-specific antigen), prostate cancer causes nocturia, or nocturia is a side-effect of various prostate cancer treatments remains unclear [496, 728]. The impact of radical prostatectomy on nocturia has been neutral or negative (i.e. increased nocturia) [729-731].

7.7.2 Nocturnal polyuria

A systematic review and meta-analysis summarised the relationship between nocturia and nocturnal polyuria [731]. Authors conducted a search of PubMed and Embase databases for studies written in English, German, French or Dutch with original data on adult participants in an investigation of the relationship between nocturia and nocturnal polyuria. Fifteen studies met the inclusion criteria. Quality scores of studies were generally high for internal validity but low for external validity. Standardised mean difference of 0.6 (95% CI 0.3-0.9) for nocturnal voids between nocturnal polyuria and nonnocturnal polyuria cases was found. Risk ratio for nocturnal polyuria in individuals with nocturia was 1.41 (1.37-1.44). Authors concluded that "the association between nocturia and nocturnal polyuria is apparent and robust. However, the clinical importance of the association appears to be less obvious than previously suggested based on single studies. The observed high prevalence of nocturnal polyuria, as a result of the International Continence Society definition, may be responsible for this discrepancy." The ICS defines nocturnal polyuria as an increased proportion of the 24-hour output of urine volume occurring at night [513]. However, there is a paucity of studies providing reference values. The Krimpen study authors suggested that nocturnal urine production exceeding 90 ml/hr is abnormal [666, 733] but concluded that "nocturnal urine production as an explanatory variable for nocturnal voiding frequency is of little value." The fundamental pathogenesis of nocturnal polyuria remains largely unknown.

7.7.3 Overactive bladder

Urinary urgency was a clear risk factor for nocturia in the FINNO Study (OR 7.4, 95% CI 4.5-12 for men, and OR 4.9, 95% CI 3.2-7.7 for women) [696]. However, while half of subjects with urgency also reported at least two voids per night, only one in three with nocturia reported urgency [544]. The finding that most people with nocturia do not report frequent urinary urgency (Figure 2), has been reported also in the EPIC and EpilUTS studies [482, 540].

7.7.4 Diabetes

An association between diabetes and nocturia has been noted in most [655, 684, 687, 689, 692, 696, 699, 720, 734-741], but not all reports [654, 666, 673]. In the BACH Survey [687] and in a Danish study at ages 60-80 years [689], nocturia was associated with double the risk of diabetes. In these surveys [687, 689], gender differences were not reported. In the FINNO Study [696], diabetes was associated with nocturia after adjustment for other factors only in women. On the contrary, in a Chinese study, association was found for men, but not for women [663].

7.7.5 Hypertension

It has been suggested that essential hypertension and nocturnal polyuria are part of the same pathophysiological process [738]. In Japanese, US and Chinese studies [655, 673, 670, 692], hypertension was associated with nocturia, although effect sizes were modest (ORs between 1.5 and 1.6). In another Chinese study [663], association of nocturia and hypertension was found in women, but not in men. In studies conducted in Europe [654, 656, 669], neither nocturnal polyuria nor nocturia were associated with hypertension. In a secondary analysis from the BACH survey [739], monotherapy with calcium channel blockers in women, and combination therapy with loop diuretics in men was associated with nocturia but no other associations for nocturia with any other anti hypertensive was found [739]. While the treatment for hypertension may cause [479, 739] or alleviate nocturia [741] in some cases, appropriate methods are of particular importance when trying to assess the relationship between hypertension and nocturia.
7.7.6 Coronary disease

Earlier (male) studies [654-655, 666] did not find a relationship between nocturia and cardiac disease. However, in these studies, an association between cardiac symptoms/disease and nocturia was found in the preliminary analyses before multivariate modeling. In more recent studies [508, 663, 687, 696, 699] coronary disease has been shown to be associated with nocturia.

7.7.7 Depression

In Swedish and US population-based studies [498, 742], depression and antidepressant use were both associated with increased prevalence of nocturia whereas in a Finnish study a relationship was found only among men using antidepressants after adjustment for other factors [696]. In another Finnish study (among men aged 50 or more), those with depressive symptoms at study entry were at almost triple risk for moderate or severe nocturia than those without depressive symptoms but nocturia had no effect on depressive symptoms during 5-year follow-up [743]. In a Kaiser Permanente study [710], increasing anxiety/depression scale was associated with increasing nocturia.

7.7.8 Sleep apnoea and snoring

In clinic-based studies [736, 744-747], nocturia was associated with sleep apnoea. In US studies conducted among community-dwelling older adults, subjects with increased apnea-hypopnea index had greater mean nocturia episodes, nighttime urine production and atrial natriuretic peptide excretion [748-749]. Snoring was one of the three most important nocturia population-level risk factors for both sexes in the FINNO Study [696] concurrent with a Swedish urology clinic study [750].

7.7.9 Neurological diseases

Most patients with multiple sclerosis have bladder dysfunction, which may also lead to nocturia [751-752]. Nocturia was also associated with stroke and cerebrovascular disease [699, 734, 753]. Moreover, in a study among Parkinson’s patients, severity of disease was also associated with increased nocturia [754]. Furthermore, a relationship of nocturia with restless legs syndrome has been reported [696].
8. SUMMARY POINTS

- Overactive bladder (syndrome) (OAB) has been defined as urinary urgency, with or without urgency urinary incontinence, usually with increased daytime frequency and nocturia (in the absence of infection or other obvious pathology).
- Prevalence of OAB has been estimated from as low as 2% up to 53%.
- Recent population-based studies have shown that less than 10% of people have OAB with at least moderate bother, suggesting that bother measurement is essential in estimating the clinically relevant prevalence of OAB.
- Longitudinal studies have shown that OAB increases with age, and that OAB is a dynamic condition, with not only substantial progression but also remission rates.
- OAB may be associated with an increased risk of falls, fractures, and impaired quality of life.
- While age is a clear risk factor for urinary urgency and/or OAB, other risk factors have not been that well studied.
- Individuals with benign prostatic hyperplasia, pelvic organ prolapse and mental health problems typically report urinary urgency more often than those without.
- Nocturia is one of – if not the - most common lower urinary tract symptom with similar overall prevalence in both genders.
- The prevalence of nocturia is higher among young women than young men, but the prevalence increases more strongly with age in men.
- The literature on the incidence of nocturia remains relatively sparse. The incidence of nocturia has been shown to increase with age but also remarkable fluctuation has been identified.
- Two episodes of nocturia constitute meaningful nocturia, affecting quality of life and perceived health, while a single episode does not.
- Nocturia has been associated with an increased risk of falls, fractures, and death.
- Risk factors for nocturia include conditions of the lower urinary tract, but also a range of systemic conditions, including but not limited to prostatic hyperplasia, urinary urgency/overactive bladder, obesity, sleep apnoea, parity, and the postmenopausal state.

9. FUTURE NEEDS

- Due to the relatively recent research in OAB and nocturia, most data currently available are cross-sectional, hence, more prospective studies are needed.
- Natural history of OAB and nocturia need more research – progression and remission of these symptoms is not yet well understood.
- Better understanding of relationship of different ‘overactive bladder symptoms’ would be beneficial.
- With prospective studies examining risk factors for incident OAB and nocturia will be possible, however, definition of incident OAB and nocturia may be challenging due to fluctuating character of these symptoms.
- Overall, further studies should be conducted with proper study designs and population-based sampling in order to decrease the risk of bias.

VII. EPIDEMIOLOGY OF PELVIC ORGAN PROLAPSE

1. GENERAL COMMENTS AND DEFINITIONS

Pelvic organ prolapse (POP) refers to loss of support for uterus, bladder, colon or rectum leading to prolapse of one or more of these organs into the vagina. Prolapse is thus a continuous condition when measured by visual inspection of the vaginal wall during valsala. For clinical purposes, the degree of POP is commonly described as above the introitus, at the introitus, or beyond the introitus with or without valsala. The International Continence Society first developed a standardised definition for the condition of POP in 1996 [755]. The ICS Pelvic Organ Prolapse Quantification (POQ) examination defines prolapse by measuring the descent of specific segments of the reproductive tract during valsala strain relative to a fixed point, the hymen. The POPQ system describes the anatomical findings of pelvic organ prolapse without consideration for symptoms and bother perceived by the woman. Validation of this system has shown it to be highly reliable [756]. The stages of prolapse severity are arbitrarily defined, and there is no clear differentiation between normal anatomic variation and mild POP. For research purposes there is consensus for use of the POPQ system until further evidence might clarify the distinction between normal variation and mild prolapse [757].

Determining POP based on self-reported symptoms is difficult because of the lack of specificity and sensitivity of most symptoms attributed to pelvic organ
prolapse [758] and the fact that prolapse above the level of the hymeneal ring is usually asymptomatic [759]. The only exception appears to be a sensation of bulging into the vaginal [760] which is most strongly associated with prolapse at or below the hymeneal ring [761-762]. A recent study of 110 women found that a question asking about a feeling of something bulging in or dropping out of their vagina had a sensitivity of 84% and a specificity of 94% for POP at or beyond the hymeneal ring on examination [759]. Seeing prolapse would presumably be even more specific, but is too uncommon to be useful as a definition.

2. PREVALENCE OF POP

Since the 3rd ICI, several additional studies have reported the prevalence of POP in a general population [763-768]. Reports from the Women’s Health initiative (WHI) Oestrogen Plus Progestin Trial, and randomised controlled trial, have been included [763,765-766]. While not actually population-based, the women in the trial were recruited from the community rather than women seeking gynaecological care, and provide important information on the prevalence of POP based on pelvic examination.

The prevalence of POP based on a sensation of a mass bulging into the vagina was remarkably consistent, ranging between 5 and 10 percent. The study by Eva et al., which reported a substantially higher prevalence included in the definition of POP, pelvic heaviness or digital pressure on the perineum or in the vagina to aid with defaecation [769]. The prevalence of observed prolapse in women enrolled in the WHI trial is similar to the prevalence found in the one population-based study that also used pelvic examination [770], although the prevalence of each type of prolapse was higher in the WHI study [762]. In both studies, prolapse occurs most frequently in the anterior compartment, next most frequently in the posterior compartment, and least in the apical compartment.

Table 19: Prevalence of pelvic organ prolapse (POP) defined by symptoms or observed on pelvic examination in the general population.

Note: Studies reported by Handa, Nygaard and Bradley are all subsets from study reported by Hendrix.

Two studies that examined prolapse by race found that Black women had the lowest prevalence and Hispanic women the highest after controlling for multiple other factors in multivariate analysis [762,768]. The study reported by Rortveit et al based on symptoms found adjusted odds ratios of 0.4 (95% CI=0.2-0.8) for Black and 1.3 (95% CI=0.8-2.2) for Hispanic women, with White women as the referent group [768]. Hendrix et al reported adjusted odds ratios of 0.6 (95% CI=0.5-0.8) for Black and 1.2 (95% CI=1.0-1.5) for Hispanic women compared to White women for POP based on genital examination [763].

3. INCIDENCE

Only two studies could be located that reported the incidence of new POP. Both studies were done on sub-groups of women enrolled in the WHI Oestrogen Plus Progestin Trial. The first study of 412 women enrolled at the University of California, Davis site, used a standardised pelvic examination repeated every 2 years over 8 years [763]. The incidence of new cystocele, rectocele and uterine prolapse was 9%, 6% and 2%, respectively. Annual rates of remission from grade 1 (prolapse to above introitus) was relatively common for each type of POP (24%, 22% and 48%, respectively) but less common from grade 2 or 3 (prolapse to or beyond introitus) (9%, 3% and 0%, respectively). In a second study of 259 post-menopausal women with a uterus were examined using the POP-Q at baseline and annually for 3 years. POP was defined as prolapse to or beyond the hymeneal ring. The incidence of new POP was 26% at 1 year and 40% at 3 years, with remission rates of 21% at 1 year and 19% at 3 years [765].

Several studies have reported the annual incidence of surgery for POP in the US and at least one in the UK. A longitudinal study of over 17,000 women in the UK, age 25 to 39 at baseline, reported an annual rate of prolapse surgery of 0.16% [763]. This rate is consistent with the rate of approximately 0.2% per year reported in the US [764-765]. One US study reported an annual incidence rising with age from 0.05% in women age 30-39 to 0.5% in women age 70-79 with an estimated lifetime cumulative risk of surgery from prolapse of 7% to 11% [766]. A recent US study reported similar surgical rates: 0.07% for women 18-39, 0.24% for women age 40-59, and 0.31% for women age 60-79 [765]. Surgical rates drop substantially after age 80 [766-767]. Estimating rates of prolapse surgery has the advantage of using hospital discharge data on procedures, which is highly accurate for the procedure performed, but less accurate for the indications for the procedures, particularly when a procedure may have more than one indication.
4. RISK FACTORS

4.1. Bowel dysfunction and pelvic organ prolapse

Women who seek urogynecological care report a high prevalence of bowel symptoms [773]. However, bowel dysfunction is highly prevalent among women in general and it has been estimated that up to 27% of the female population in industrialised countries are affected by constipation [774]. The overall prevalence of constipation and associated symptoms in women with pelvic organ prolapse ranges between 20-53% depending on definition of disorders [775-777]. Although definitions of disease differ between studies it is widely acknowledged that bowel dysfunction is a complex condition with a multifactorial aetiology. Bowel dysfunction comprises a wide variety of symptoms including constipation, rectal emptying difficulty, faecal urgency and irritable bowel syndrome (IBS). Neurophysiologic assessments have shown that damage to the pelvic floor musculature nerve supply can occur as a result of chronic constipation [778]. Other predisposing factors comprise low socio-economic status, pelvic floor surgery, depressive disorders, thyroid dysfunction, physical disability and inactivity, and food habits [779].

Current epidemiological evidence on the association between bowel dysfunction and pelvic organ prolapse are at odds. A number of studies suggest that women with pelvic organ prolapse are significantly more likely to experience constipation and other symptoms of bowel dysfunction [768,777,780-782] whereas others show a weak or non-existent association [762,776,783-784]. In a case-control study, manually assisted defaecation was present in 19.7% of women with prolapse compared to 4.4% of control subjects (p<0.001) [777]. In a randomly selected population based study, irritable bowel syndrome and constipation were both strongly associated with pelvic organ prolapse (OR 2.8 95% CI 1.7-4.6, and OR 2.5 95% CI 1.7-3.7 respectively) [768]. Varma et al., [769] suggested that among randomly selected women, with symptomatic pelvic organ prolapse more than doubled the risk for obstructed defaecation (OR 2.3 95% CI 1.5-3.7). A retrospective questionnaire based survey of women with and without prolapse concluded that constipation as a young adult was an important factor in the development of uterovaginal prolapse [780]. In a case-control study, women with prolapse were at increased risk for constipation even after adjustment for dietary fibre intake (OR 2.9, 95% CI 1.1-13.5) when compared to women without prolapse [781]. Also in a low income setting constipation has been identified as a risk factor for symptomatic pelvic organ prolapse [785].

In the cross-sectional Women’s Health Initiative (WHI), cystocele and rectocele were only weakly associated with constipation (OR 1.1 95% CI 1.0-1.2) [762]. Similar weak associations between prolapse and bowel dysfunction have been observed in other large cross-sectional studies [776,783-784]. Overall severity and prevalence of bowel dysfunction has shown poor correlation with findings of pelvic organ prolapse at radiological imaging [786-788]. Also at clinical examination, increasing vaginal descent and prolapse severity, show a generally weak (or absent) association with symptoms related to bowel dysfunction [758,775,789-791]. In a substudy of the WHI, no specific bowel symptom was associated with increasing loss of pelvic organ support in any vaginal compartment [784]. When considering compartment-specific pelvic floor defects, most studies suggest that increasing posterior vaginal wall prolapse and perineal descent are correlated to more symptoms of obstructive defaecation [758, 776, 788]. In a cross-sectional study of 260 women with pelvic organ prolapse, women with posterior vaginal wall prolapse were more likely to incomplete emptying (41% vs 21%, P=0.003), straining at defaecation (39% vs 19%, P=0.002), and splinting with defaecation (36% vs 14%, P<0.001) compared with women without posterior vaginal wall prolapse. But there was no significant association between bowel symptoms and increasing severity of prolapse [792].

The association between bowel dysfunction other than specifically obstructive symptoms and pelvic organ prolapse has been poorly investigated. In a random population-based study of 2109 racially diverse women women with IBS (prevalence =9.7%) had higher odds of reporting symptomatic pelvic organ prolapse (OR 2.4; 95% CI, 1.4-4.1) compared to those without IBS [793]. It has also between suggested that anal sphincter dysfunction such as paradoxical anal sphincter reaction is more common in patients with a rectocele as compared to women without rectocele at defaecography [794].

4.2. Pelvic surgery and POP

Even though the suggestion that hysterectomy increases the risk for pelvic organ prolapse has wide acceptance, longitudinal studies confirming a temporal association are few and previous studies do not often differentiate between various types of hysterectomy. A number of cross-sectional and retrospective studies implicate hysterectomy as an independent risk factor for pelvic organ prolapse. However, due to a delay of onset, large population samples and a sufficiently long duration of follow-up are required to determine an association with adequate certainty.

In a nationwide cohort study, Altman et al. [795] reported that 3.2% of women who had undergone hysterectomy had pelvic organ prolapse surgery, compared with 2.0% in non-hysterectomised controls, corresponding to a risk of 1.7 (95% CI, 1.6-1.7). In this Swedish study, vaginal hysterectomy had the
highest risk for subsequent prolapse surgery (HR 3.8, 95% CI 3.1 to 4.8) in comparison to non-hysterectomy controls. These results were corroborated by Cooper et al. in a large study from Scotland showing an increased risk for prolapse surgery among women after hysterectomy, compared to endometrial ablation [796]. These register-based data are largely in agreement with the longitudinal Oxford Family Planning Association study by Mant et al. [797] reporting increased overall incidence rates for prolapse surgery following hysterectomy. Although not separating various hysterectomy techniques, Mant et al. determined that the risk of prolapse following hysterectomy was 5.5 times higher (95% CI 3.1-9.7) in women whose hysterectomy was performed for prolapse as opposed to other benign conditions. In a large register-based survey from Denmark (n=154,882) [798] it was determined that the highest cumulative incidence of subsequent POP surgery 32 years after hysterectomy was found among women where pelvic organ prolapse was the indication for hysterectomy and also that the posterior compartment was the predominant location for prolapse occurrence post-hysterectomy. A history of hysterectomy has also been identified to increase the risk for prolapse in several cross-sectional and retrospective studies [799-800]. Specific risk factors for posthysterectomy prolapse have been assessed in two case-control studies. Both Dällenbach et al. [801] and Forsgren et al. [802] reported that pelvic floor surgery before hysterectomy was the strongest risk factor for developing posthysterectomy pelvic organ prolapse (OR 7.9, 95% CI 1.3-48.2 and OR 2.8, 95% CI 1.0-7.7 respectively). The risk of prolapse repair was 4.7 times higher in women whose initial hysterectomy was indicated by prolapse [801]. Vaginal vault prolapse involves the loss of vaginal apical support and may by definition only occur after hysterectomy [803]. Marchionni et al. [804] reported a 4.4% overall incidence of vaginal vault prolapse after hysterectomy but in women where uterine prolapse was the indication for hysterectomy the incidence was 11.6%. In a register-based study Forsgren et al. [805] showed that the greatest risks for prolapse surgery (HR 4.9, 95% CI 3.4-6.9) were observed subsequent to vaginal hysterectomy for pelvic organ prolapse but having a vaginal hysterectomy also for other indications significantly increased the risk for subsequent pelvic organ prolapse surgery compared to other modes of hysterectomy. Similar observational results were shown by Cooper et al. [796]. It has also been suggested that pelvic surgery other than hysterectomy may predispose women to subsequent genital prolapse including: rectopy for rectal prolapse (OR 3.1; 95% CI 1.4-6.9) [806]; gynaecological surgery in general (OR = 3.9, 95% CI 1.8-8.8) [807]; and retropubic colposuspension procedures are associated with a near 30% risk of subsequent vaginal vault and posterior vaginal prolapse at long-term evaluations [808-809]. In a prospective cohort study of 374 women, the 10-year re-operation rate was 17% after traditional prolapse or incontinence surgery [810]. Having undergone pelvic organ prolapse or incontinence surgery prior to the index operation increased the risk of re-operation to 17% compared with 12% for women who underwent a first procedure (p=.04) [810].

4.3. Obstetrical factors and POP

For ethical and practical reasons, randomised controlled trials to study the causal effects of vaginal and caesarean delivery on the pelvic floor will never be performed. Observational studies will therefore remain the main source of knowledge on this subject. Nonetheless it is widely accepted that childbirth is a significant risk factor for pelvic organ prolapse, presumably due to overt or occult pelvic floor tissue trauma. Controversy does, however, remain with regard to the protective effect of caesarean section and if specific obstetrical events should be considered as risk modifiers. Due to a delayed onset of pelvic organ prolapse in relation to giving birth, studies on the subject need a long duration of follow-up as well as large study populations to be able to elucidate the possible causative events. Therefore, the majority of studies on the subject are typically designed as cross-sectional surveys or retrospective cohort or case-control studies. It is, however, encouraging that long term longitudinal data are starting to emerge and in recent years several studies with follow-up periods extending beyond 10 years have been published.

Pregnancy in itself has been identified as a risk factor for stress urinary incontinence. With regard to pelvic organ prolapse, the association is less well substantiated. In a clinical case-control study, all 21 nulliparous non-pregnant women had POP-Q stage 0 or 1, whereas 47.6% of 21 nulliparous pregnant women had pelvic organ descent corresponding to stage II (p<0.001) [811]. Overall POP-Q stage was higher in the third trimester than in the first (p=0.001). Also Sze et al. [812] found that in 94 nulliparous women evaluated at the 36 week antenatal visit and six weeks postpartum, POP-Q staging increased.

A large number of studies identify childbirth as one of the strongest predictors for developing pelvic organ prolapse later in life. [762,768,797,799,813-820]. It is also a recurrent observation that the number of childbirths is associated with the risk of prolapse although there are data to suggest the contrary [821]. In the prospective Oxford Family Planning Association study [797], childbirth was the single strongest risk factor for developing prolapse in women under 59 years of age and the risk increased by every childbirth. Similar findings derived from the WHI, [762] where a parity of one conveyed an overall two-fold risk increase for prolapse compared to having no children, after which each additional childbirth added a 10-20% risk increase. In a case-control study, Tegerstedt et al. [817] found that the risk for symptomatic pelvic organ prolapse increased with number of childbirths and were 3.3-times higher among mothers of...
four than among mothers of one. Similarly, Rortveit et al. [768] found that the risk of prolapse increased in women with one (OR 2.8 95% CI 1.1-7.2), two (OR 4.1, 95% CI 1.8-9.5), and three or more (OR 5.3, 95% CI 2.3-12.3) vaginal deliveries compared with nulliparous women. In a questionnaire based cross-sectional study among 2,640 middle-aged women the number of vaginal deliveries was a risk factor for past or present symptomatic prolapse [818].

Whether or not caesarean section prevents loss of pelvic organ support has been debated but today the vast majority of studies show that elective caesarean section does indeed decrease the risk of pelvic organ prolapse later in life [813-824].

In 4,458 randomly selected women, vaginal childbirth increased the risk of prolapse by 1.82 (95% CI 1.04-3.19). (66) In a nested case-control study, Uma et al. [816] found that caesarean section was associated with a significantly reduced risk of pelvic floor surgery compared with spontaneous vaginal delivery (OR 0.16, 95% CI 0.05-0.55). In a case-control study, Chi- affarino et al. [822] found that women who were delivered by cesarean section were at significantly lower risk for prolapse (OR 0.3 95% CI 0.1-1.0). In a register-based cohort study of women having their first and all subsequent deliveries by cesarean (n = 33,167), and an age-matched sample of women only having vaginal deliveries (n = 63,229) between 1973 and 1983, Leijonhufvud et al. [823] found that women only having vaginal deliveries had a significantly increased overall risk of subsequent prolapse surgery (hazard ratio, 9.2; 95% CI 7.0-12.1) compared with women only having cesarean deliveries. Among women with vaginal deliveries only the incidence rate for prolapse surgery increased steadily, reaching its peak close to three decades after first delivery. This corresponds with data from other long-term studies with more than a decade of follow-up (see below). In women with cesarean deliveries only the incidence rate for POP surgery showed very little variation over time and being notably lower compared to the vaginal delivery cohort 10 years after first birth for the duration of the observational period. There are some reports suggesting that in the long term, caesarean delivery does not provide a significant risk reduction pelvic floor morbidity.

Figure 10: Rate of pelvic organ prolapse surgery in relation to mode of delivery and time from first childbirth [823].

A number of specific obstetrical events and interventions have been implicated as risk factors for the development of pelvic organ prolapse. In one study, maternal age and use of epidural analgesia was associated with an increased need for pelvic organ prolapse.

COMMITTEE 1. EPIDEMIOLOGY OF URINARY INCONTINENCE (UI) AND OTHER LOWER URINARY TRACT SYMPTOMS (LUTS), PELVIC ORGAN PROLAPSE (POP) AND ANAL (AI) INCONTINENCE
surgery [814]. Handa et al. [827] found that operative vaginal birth significantly increased the risk for all pelvic floor disorders and pelvic organ prolapse in particular (OR 7.5, 95% CI 2.7-20.9). In a long term longitudinal study Volløyhaug et al. [824] found that operative vaginal delivery was associated with increased risk of pelvic organ prolapse (OR 1.73, 95% CI 1.21-2.48) when compared with non-instrumental vaginal delivery. There were no differences in the risk for pelvic organ prolapse when comparing forceps and vacuum delivery.

In a case-control study, Chiaffarino et al. [822] found that after forceps delivery women had an OR of 3.6 (95% CI 1.0-13.5) for developing pelvic organ prolapse, but after adjustment for vaginal delivery the odds were no longer significant (OR 1.3 95% CI 0.6-3.1). Also Moalli et al. [828] concluded that forceps delivery posed a risk for prolapse and a case-control study found no significant association with maternal age, instrumental delivery (forceps or vacuum), or labour as compared with spontaneous vaginal delivery. The other hand, Uma et al. [816] found no significant association between pelvic organ prolapse and forceps delivery (OR 0.9, 95% CI 0.7-1.2); infant birthweight >4.0 kg (OR 0.9, 95% CI 0.5-1.7); episiotomy (OR 1.46, 95% CI 1.0-2.10); and labour prolonged >12 hours (OR 1.51, 95% CI 1.00, 2.27). Similarly both Gyhagen et al. [819] and Glazener et al. [820] found no significant association of increased risk between instrumental delivery and pelvic organ prolapse compared with spontaneous vaginal delivery.

### 4.4. Miscellaneous risk factors and POP

A wide variety of risk factors for pelvic organ prolapse, others than those addressed above, have been identified in the literature. Most of these have been investigated as part of larger multivariate analyses based on cross-sectional surveys or retrospective case-control studies. Overall, these associations are largely of level III-IV evidence and further research is needed to disentangle the effects and interactions of environmental risk factors for prolapse.

Several somatic risk factors for pelvic organ prolapse have been identified. Generalised connective tissue disorders such as Ehlers-Danlos disease and Marfans syndrome [829-830] have been linked to an increased risk for pelvic organ prolapse. In a community-based study of prolapse in rural West Africa, chronic anemia was the strongest risk factor for prolapse after parity and age (OR 2.1 95% CI 1.1-3.4) [831] and also chronic obstructive pulmonary disorders. Skeletal abnormalities such as thoracic kyphosis, lumbar lordosis and pelvic dimension changes have been associated with an increased risk for prolapse [832-833]. Women with joint hypermobility have a significantly higher prevalence of genital (and rectal) prolapse in comparison to women with normal mobility [834-835]. Weak associations have also been shown for osteoporosis and rheumatoid arthritis [825]. Obesity may be associated with increased pelvic floor symptoms and more severe symptomatic prolapse [818-819, 836-837] yet increasing body mass index and obesity has not consistently been identified as risk factors for prolapse as compared to stress urinary incontinence [838-839]. Other factors that have not convincingly demonstrated any significant linkage to prolapse include the presence of chronic obstructive pulmonary disease and diabetes mellitus [785, 800, 839]. Pulmonary impairment has been shown to more common in women with loss of pelvic organ support compared to those without [840]. In a study by Rogowski et al. [841] the diagnosis of metabolic syndrome was associated with the severity of pelvic organ prolapse in urogynecological patients (OR 3.5, 95% CI 1.5-8.2) as compared to those without.

A low educational level (OR 2.16, 95% CI 1.10-4.24) [842] and low annual income [843], are socio-economic factors which have been associated with an increased risk for pelvic organ prolapse. In 21,449 non-hysterectomised Italian women, higher education was associated was a protective factor for uterine prolapse [826]. However, despite significant differences in educational level, smoking habits, alcohol consumption, and socio-economic indices, the prevalence of pelvic organ prolapse did not differ between Croatian urban and rural women [844]. Interestingly, risk factors for pelvic floor disorders including pelvic organ prolapse among women in developing countries were similar to those in industrialised countries (increased age and parity). In a review study across 16 low-income and lower middle-income countries the mean prevalence for pelvic organ prolapse was 19.7% (range 3.4-56.4%) but risk factors were similar to those described in studies from more affluent countries but additionally pelvic organ prolapse and other pelvic floor disorders were associated with other factors including poor nutrition and heavy physical work [845-846].

A physically strenuous occupation has also been shown to influence the risk for pelvic organ prolapse. In a register based study of 28,000 Danish assistant nurses exposed to repetitive heavy lifting, the risk for prolapse was higher among the nurses compared to controls (OR 1.6 95% CI 1.2-2.2) [847]. Women who were laborers/factory workers had significantly more severe prolapse than other job categories (p < 0.001) in a cross-sectional study of women presenting for routine gynecological care [848]. Also, hard physical training may increase the risk for prolapse as women attending paratrooper training, were more likely to present stage II prolapse compared to controls (RR=2.7 95% CI 1.4-5.4) [849].

### 5. SUMMARY POINTS

- Most studies have used a cross-sectional design and there are limited longitudinal data to suggest
a causal relationship between symptoms of obstructed defaecation and pelvic organ prolapse or vice versa.

- Posterior vaginal wall prolapse and perineal descent are the specific pelvic defects most frequently associated with symptoms of obstructive defaecation.
- Current evidence suggests that hysterectomy increases the risk for subsequent pelvic organ prolapse in general.
- Vaginal hysterectomy and hysterectomy performed for uterine prolapse are the strongest risk factors for having secondary pelvic floor surgery.
- Childbirth is associated with an increased risk of pelvic organ prolapse later in life and increasing number of childbirths is positively associated with the risk.
- Long-term prospective study data consistently show that caesarean section decreases the risk for pelvic organ prolapse and that caesarean section is associated with a decreased risk of subsequent pelvic floor morbidity in comparison to vaginal birth.
- Current understanding of how specific obstetrical interventions influence the risk of pelvic organ prolapse is poor but instrumental delivery may increase the risk of developing pelvic organ prolapse.
- Life style factors and socio-economic indices may be associated with the risk of pelvic organ prolapse in both industrialised and non-industrialised countries.
- A number of somatic diseases and conditions have been linked to the occurrence of prolapse but the cause-effect relationship is undetermined.

1. FAMILY STUDIES

The existence of both acquired and inherited risk factors for incontinence was first recognised more than 150 years ago (H. Thompson, 1854), by observation of familial aggregation. However, familial aggregation provides limited evidence of heritability, since it fails to control for the effects of shared environmental factors. For incontinence, exposures to all major lifestyle risk factors are likely to be at least partly determined by socio-cultural values that are shared within families. Such effects are at least plausible for family size, smoking, socio-economic status, care seeking behaviour, physical exercise, dietary and drinking habits, and toilet training. As incontinence is considered stigmatizing in all populations, family studies may be at risk of differential misclassification bias. This might be expected to have particular impact on the validity of estimates obtained from studies employing the family history method, and any study with non-random sampling of families, for example those relying on probands recruited in secondary care, or those recruiting volunteers via advertisement. Finally, while age correction of risks is possible, to account for increasing disease prevalence with age, this has typically not been employed in family studies of incontinence.

Although family studies may not provide robust evidence, there have been many studies that examined prevalence of incontinence among relatives of women with incontinence [204, 851-855]. Despite considerable variation in case selection and sampling methods, almost all studies have demonstrated increased risk for urinary incontinence among first-degree relatives of probands. This appears to have a plausible biological gradient, with higher risks among relatives of women with severe incontinence.

The most modest estimates come from the EPINCONT study, which is also least likely to be affected by bias, with the direct ascertainment method employed in a large population representative sample [854]. With a total sample of 8,125 pairs of probands and their daughters or younger sisters, they found less than two-fold increased risk of stress UI among daughters of women with stress UI (RR 1.52 95%CI 1.28-1.81), and a non-significant but directionally

VIII. THE GENETIC EPIDEMIOLOGY OF URINARY INCONTINENCE AND PELVIC ORGAN PROLAPSE IN ADULT WOMEN

Geneticists have historically pursued a specific sequence of studies to establish the genetic basis of diseases [850]. The first step was measurement of familial correlations, followed by formal twin or adoption studies. Analysis of segregation patterns in extended pedigrees was used to identify the likely mode of inheritance. This information was used to inform linkage studies, designed to identify putative chromosomal risk loci. Only once these steps were complete would association studies be attempted. Although it remains relevant to establish the heritability of a trait, this traditional sequence of investigations has been supplanted by the success of Genome-wide association studies (GWAS), with many new discoveries now coming from association studies without the prior steps. Nonetheless here we recapitulate the history of our understanding of urinary incontinence as a complex genetic disease, with multiple genetic and environmental risk factors, and review the studies that formed the basis for the genetic epidemiology of incontinence.
consistent increased risk of urge UI among daughters of women with urge UI (RR 1.80 95%CI 0.83-3.92). Similarly, in a survey spanning 11 countries in South and East Asia (n = 5,502), a family history of OAB was also a modest predictor of OAB symptoms including urge incontinence (OR 1.62 95%CI 1.42-1.83)[854]. In the studies that have used multivariate analyses, it appears that these familial risks are attenuated but not eliminated by adjustment for classic risk factors for incontinence including age, parity, and BMI.

Risks seem particularly elevated in relation to incontinence surgery. For example in a registry based study of 3,678,556 Swedish women, surgery for stress UI among sisters was associated with greatly increased odds (OR 6.09 95%CI 5.73-6.48) [857]. This exaggerated association might be a consequence of low rates of presentation for care, such that care seeking rather than the underlying symptoms are particularly familial. In contrast to the twin studies discussed in the next section, family studies have demonstrated much more clearly that stress rather than urge incontinence is familial. This might be a reflection of more stigma around urgency incontinence, or simply lack of statistical power for a rarer condition.

*RR adjusted for age, BMI, and parity **RR adjusted for age, BMI, and parity and restricted to subgroup of daughters of mothers with severe UI $ RR adjusted for age and parity. Note: unadjusted risks generally higher across all outcomes, indicative of substantial concordance/correlation in age, BMI, and parity between family pairs.
Three studies have also assessed family history as a risk factor for incident post-partum incontinence, with some evidence of familial aggregation [317,858-859]. Again, however, estimates from these studies may be compromised by use of the family history method, rather than direct ascertainment. A single large study has assessed correlations between adult incontinence and childhood daytime wetting, using the ALSPAC cohort [860]. Using a sample of 8,145 children aged seven they reported excess risks associated with incontinence in the children for incontinence among their mothers (OR 2.64, 95%CI 1.38-5.07) and particularly among their fathers (OR 5.47, 95%CI 2.39-12.50).

In summary, a family history of incontinence is associated with approximately two to three fold increased risk. Such an effect appears to hold for all subtypes of incontinence, although the evidence is more robust for stress UI. Among adults there is plausible evidence that family history is associated with both earlier onset, and more severe phenotype. Additionally, there is also clear evidence that this familial predisposition stretches right across the lifecourse. These effects are however partly explained by known environmental risk factors, and family studies cannot exclude the risk of further unmeasured confounding from shared environmental risks. For this we should consider evidence from classical twin studies.

### 2. TWIN STUDIES

Twin studies compare the concordance in a trait or condition between monozygotic (MZ) twins and same-sex dizygotic (DZ) twins, to estimate heritability. Heritability, and here specifically broad-sense heritability, is defined as the proportion of phenotypic variation (VP) that is due to variation in genetic values (VG). For genetically determined traits higher concordance is observed in MZ twins compared to DZ twins, while for entirely environmentally determined traits, concordance should be the same in both types of twin pairs.

This idea is illustrated by consideration of a fully penetrant autosomal single gene disorder, which will display 100% concordance in MZ twins, while in DZ twins will have only 50% concordance for a gene with dominant mode of inheritance. A fundamental assumption of analyses of classic twin studies is that both types of twin pairs share equal environment. This assumption is clearly violated both prenatally, and in later life. This bias can be further investigated in studies of twins reared apart, or in adoption studies, but these designs have not been applied to the study of incontinence. A second central assumption is that MZ twins are genetically identical, which again is violated both by epigenetic effects, and by somatic mutation.

Three major twin resources have been used to assess genetic influences on incontinence: the US Twins Days festival, the Danish Twin Registry, and the Swedish Twin Registry. The Twins Days festival relies on volunteers, and the resulting recruitment bias is likely to overestimate concordance for many traits for both MZ and DZ twins. In the sample of 1,764, predominantly MZ, middle-aged twins from Twins Days, concordance of symptomatic stress urinary incontinence was 79.5% for MZ and 78.6% for DZ twins [861]. Such a result suggests no significant genetic contribution to stress urinary incontinence at all.

Among a sample of 2,336 twins surveyed as part of four studies from the Danish Twin Register, concordances for both MZ and DZ twins were much lower not only for stress urinary incontinence, but also for urgency and mixed incontinence [862]. With cohorts for middle-aged and elderly women, heritability was calculated separately in each age group. As in the Twins Day sample, genetic factors were not significant for stress incontinence in middle-aged women, but rose to a heritability of 39% in the elderly women. Similarly heritability increased with age for urgency incontinence (42% rising to 49%), and mixed incontinence (27% to 55%).

Women participating in the Swedish Twin Register have provided relevant data as part of two separate analyses [863-864]. Treatment codes corresponding to stress incontinence and prolapse surgery from a nationwide surgical register were used to estimate heritability for a sample of 16,886 twins aged >50. Concordances for surgical treatment were low, but produced heritability estimates of 41% for stress incontinence surgery, and 43% for prolapse surgery. Similarly for female twins aged 20-46 from the same register (evaluable sample 4,550), using self-completed questionnaires, produced an estimate of 34% heritability for stress incontinence. From the same survey, heritability was estimated for urgency incontinence (37%), mixed incontinence (18%), “any” incontinence (51%), nocturia (48%), and urinary frequency (40%). It was however noted that because of sample size limitations, an absence of genetic effects cannot be entirely precluded for stress, urgency, or mixed incontinence.

The mechanism of these probable genetic effects has also been explored in analyses of joint hypermobility and pelvic floor mobility in twins [865-866], which is one pathophysiological correlate of stress incontinence. These data suggest heritability of 59% for oblique bladder neck descent on Valsalva in nulliparous twins aged 18-24, with a shared genetic component to both pelvic floor and elbow mobility.

In summary, twin studies to date have suggested significant heritability for stress incontinence and urgency incontinence with genetic variation potentially contributing up to half of population phenotypic variation. Heritability appears to be highest for urgency incontinence, with apparent heritability increasing with age as environmental factors reduce in importance.
This is consistent with our understanding of childbirth as a major environmental determinant of incontinence. Genetic predisposition to incontinence may manifest at a preclinical stage in pelvic floor hypermobility. Together with data from family studies this provides strong evidence of genetic risk factors for incontinence.

3. SEGREGATION ANALYSES

Despite the large number of family studies of incontinence in adults, there have been few studies to examine segregation among extended pedigrees. Studies of families affected by nocturnal enuresis [865], have however included some adults affected by urgency incontinence. Analysis of different enuretic families has usually suggested autosomal dominant inheritance with high penetrance, but low penetrance and autosomal recessive modes have also been reported. These findings could be a consequence of selection or ascertainment bias. In contrast results from more recent association studies strongly suggest that polygenic inheritance is most likely across the population as a whole.

4. LINKAGE STUDIES

A linkage study can be used to map a condition to one or more genomic loci by demonstrating co-segregation of the trait among an extended family with specific genetic markers. The association between two SNPs is measured using Linkage Disequilibrium (LD) statistics, typically D’ or r2. With the success of the International HapMap Project [868] and the 1000 Genomes Project [869], LD has been established for the majority of all known common SNPs. Although there are more than 60 million catalogued human SNPs (“dbsnp-announce” RELEASE: dbSNP Build 138 for Human and Cow,” n.d.), common SNPs less than 10 kb apart are often highly correlated. Thus without a requirement for dense genotyping, linkage studies can successfully identify loci containing a causal genetic variant [870]. Given the power constraints of assembling extended families for study, this technique is most successful for monogenic or oligogenic traits in which the causal variants have large effect sizes. Several linkage studies have been conducted using families of children affected by nocturnal enuresis, and two studies have considered uniquely adult symptoms. Earlier reports suggested a range of loci associated with nocturnal enuresis [867, 871], and in the largest attempted replication using a collection of 32 families with at least three members with nocturnal enuresis, there was evidence in favour of a locus at chromosome 22q11 (cumulative logarithm (base 10) of odds (LOD) score 3.63), and weak evidence for loci at 13q13 (cumulative LOD score 1.53) and 12q (cumulative LOD score 1.95) [872]. Allen-Brady and colleagues [873] genotyped women from 32 families, including 70 patients needing surgical treatment for prolapse. There was strong overlap with other pelvic floor disorders including a high prevalence of treatment for both stress and urgency incontinence. Using a set of 27,157 markers from a pre-designed array, they observed a significant peak at 9q21 (maximum HLOD 3.41), and further suggestive peaks at 9q31(maximum HLOD 1.90), and 1q42(maximum HLOD 1.89). Subsequent unpublished work from the same group did not however replicate these findings specifically for stress incontinence surgery [874] but suggested separate loci on chromosomes 2, 4, 8, 10 and 11 (maximum HLOD scores 2.15-2.98). Such problems with replication of linkage studies [875] have been recognised right across medicine, and may be particularly pronounced with multiple common variants each with small true effect sizes.

5. GENE ASSOCIATION STUDIES

A recent systematic review has summarised all prior candidate gene and genome-wide association studies [876]. Replication is an essential step in establishing the validity of genetic associations, and yet meta-analyses were possible for only three polymorphisms. Variation in the beta-3 adrenoceptor, particularly of the rs4994 SNP, also known as Trp64Arg, has been extensively investigated in association with obesity, type 2 diabetes mellitus, and other metabolic syndrome phenotypes. The beta-3 adrenoceptor is highly expressed in bladder, and mediates detrusor muscle relaxation [877]. A beta-3 adrenoceptor agonist has recently been approved for treatment of overactive bladder symptoms [878-879]. Two conference abstracts [879-881] and one published paper [882] provided relevant information on the common rs4994 missense mutation, of which two could be included in meta-analysis. In the initial report, in a heterogeneous Japanese sample of 13 men and 31 women, with diverse urological pathologies including neurogenic bladder and benign prostatic hyperplasia, the rs4994 SNP was not associated with LUTS (OR 1.20 95%CI 0.32-4.47) [879]. Results were not available stratified by gender, and could not be included in quantitative synthesis. Subsequent reports used larger samples of Japanese women (n=100) [883], and Brazilian women (n=49) [882], and looked specifically at the overactive bladder phenotype, finding a large effect size (pooled OR 2.46 95%CI 1.67-3.60), with no heterogeneity. Despite a lack of information about genotyping QC, and some risk of population stratification, this large effect size confers some protection from bias, providing moderate epidemiological credibility.

rs1800012 also known as the Sp1-binding site polymorphism of collagen, type I, alpha 1, modifies transcription factor binding and gene expression. It has been most extensively studied in association with os-
teoporosis, where the minor allele is modestly associated with reduced bone mineral density and increased fracture risk [884]. Collagen, type I, alpha 1 is a major structural component of the vaginal epithelium and endopelvic fascia [885]. The available data on gene and protein expression in pelvic tissue from women with prolapse or stress incontinence are heterogeneous but suggest increased COL1A1 expression with reduced type 1 collagen content (see a previous comprehensive review [885]).

Two studies of Polish [886] and Greek [887] women reported associations of the same polymorphism with stress incontinence, in both cases using a combined symptomatic and objectively measured case definition. The pooled effect size was large (OR 2.09 95%CI 1.35-3.22) with no heterogeneity (I2=0%). There was significant deviation from Hardy-Weinberg equilibrium in one sample, and therefore only weak epidemiological credibility for this finding.

Matrix metalloproteinase-1, also known as interstitial collagenase, is one of a number of enzymes that cleave collagen type 1. The MMP1 gene is upregulated in pelvic tissues of women with prolapse [886]. Common variants of this gene have been extensively studied in association with chronic obstructive pulmonary disease [889], cardiovascular disease [890], and a number of cancers including of lung, colon and breast. Two studies tested associations with SUI and between stress incontinence and both the rs2165241 and rs1048661 variants of LOX -L1, lysyloxidase-like-1 [895]. Following the Venice recommendations [896], these nominally significant but unreplicated associations are all assigned weak epidemiological credibility.

Finally there remain a number of candidate gene studies of incontinence for which no replication has been reported. Statistically significant associations have been suggested between incontinence and the CAG copy number variant of AR, the androgen receptor [893], between incontinence and the rs6313 polymorphism of HTR2A, the serotonin 2A receptor [894], and between stress incontinence and both the rs2165241 and rs1048661 variants of LOX-L1, lysyloxidase-like-1 [895]. Following the Venice recommendations [896], these nominally significant but unreplicated associations are all assigned weak epidemiological credibility.

As the first genome wide association studies (GWAS) for incontinence are reported, these results from candidate gene studies are all likely to be overturned. Initial GWAS results from the WHI found no replicable loci for urgency incontinence [897], while a subsequent consortia of European and US studies have reported as a conference abstract one replicated locus for stress incontinence close to the EN1 gene and one for urgency incontinence close to the EDN1 gene [876]. Notably no previously suggested gene for incontinence was re-identified in either of these studies.

Family studies and twin studies have provided convincing evidence of genetic predisposition to incontinence, with genetic variation contributing up to half of population phenotypic variability. Heritability is most pronounced for urgency incontinence. Although some families may be affected by severe dominant monogenic forms of incontinence, for the general population no clear mode of inheritance is apparent, consistent with our understanding of both stress and urgency incontinence as complex polygenic conditions. Linkage studies have not yielded consistent results, nor led to identification of any candidate genes. The few available candidate gene studies are underpowered for large genetic effects, but suggest the possibility of ADRb3 as a candidate gene. Emerging results from GWAS are likely to substantially change our understanding of the genetic architecture of these conditions.
It has been shown that women are more willing to report AI than men [901]. In addition, the character (incontinence of solid faeces, diarrhoea, or flatus, or merely anal seepage) and frequency (daily versus episodic) of reported AI varies greatly in each report. So, prevalence depends heavily on the definition of AI.

The variation in prevalence of AI seen in a sampling of surveys in Table 21 further demonstrates how difficult the ascertainment of AI is. The border between occasional dyschezia which may be associated with minor illness, travel or diet and a disabling disease that requires intervention to return a patient to acceptable function is not clearly drawn. Many questionnaires have been developed and “validated” for the detection of AI. At least three were published at the time of the last update of this volume. No systematic review of these many questionnaires has yet to be published. The most insightful of prevalence studies has recently been published from New Zealand [902]. The authors studied adults, not excluding those in custodial care. Acknowledging the difficulty in prevalence estimation, they used three different questionnaires. The first simply asked if the participant had incontinence and if they were troubled by it, the second was a well known quantitative instrument and the third a quality of life instrument specific to faecal incontinence. In the cohort examined there were those who were totally continent, those that exceeded thresholds in all three instruments and were undeniably incontinent and those who had positive responses on only one or two of the questionnaires (Figure 11). The authors surmised that two out of three positive responses constituted clinical AI, though the threshold for the quality of life instrument was very high (i.e. perhaps too sensitive). From the Figure 1 it can be seen that the prevalence of AI varied from 12.6% to 26.8% for each individual instrument, 4.6% were positive for all three and 13.2% were positive for two of three, which was the authors’ definition of AI.

Figure 11: Co-occurrence of fecal incontinence in each of 3 diagnostic measures. FISI = Fecal Incontinence Severity Index; FIQLS = Incontinence Quality of Life Scale.

2. PREVALENCE

Because therapeutic interventions are not the subject of this chapter, the epidemiology is descriptive and not derived from randomized clinical trials (aside from the pre-partum intervention described below), the level of evidence will be at best 2, and the strongest evidence will come from systematic reviews in which there was a predefined search strategy and application of quality assessment tools that were designed specifically to minimize bias in referral or ascertainment.

2.1. Adults

In an effort to resolve the widely varying reported prevalence figures (Table 21), three systematic reviews of the published frequencies have been undertaken in community dwelling adults (above age 15 in the second) [903-905]. All three reviews were based on protocols including: A defined search strategy; Each study presented a PRISMA statement; Prospective continence assessment to minimise recall bias; Response rate > than 50%; a validated continence assessment tool; a representative community based population; appropriate outcome reporting.

Not every study included in these three systematic reviews adhered to these criteria, but the risk of bias in each study was assessed by these criteria and the highest quality studies described separately. None of the three was able to find a study that did prospective continence assessment to minimise recall bias; Response rate > than 50%; a validated continence assessment tool; a representative community based population; appropriate outcome reporting.

One more important study of prevalence not cited in the above reviews was the National Health and Nutrition Examination Survey (NHANES) of the USA. This is done periodically, the most recent data on continence being from the 2010 NHANES [906]. This has been reported in a number of publications. The population screened is careful constructed to be representative of the entire non institutionalized or care home dwelling USA population and data collected with validated instruments in the participants own home. The prevalence was found to be 8.4% for FI (CI: 7.2-9.8%). Significant associations with FI included: diabetes, stool frequency (diarrhoea), poor health, and male gender if UI is included in the regression model. Not associated were obesity and parity.

2.2. Children

The reported prevalence of AI in children can be broadly divided into two facets: in those children born with congenital anomalies of the anus and rectum—either congenital aganglionicis (Hirschprung’s Disease) or imperforate anus—and those children without congenital anomalies. Among those children that were born with congenital anomalies, despite surgical correction of the defect, life long defaecation difficulties are common, occurring in roughly half of affected children [907-909]. Problems with psychological health and development because of the defaecation disorder also common in this group, as is a generally depressed quality of life [910]. These disorders are not very rare, occurring in 3 to 5 per 10,000 live births [911].

Among children without congenital defects of the anal canal, bowel control has been found to be complete in one Swiss cohort in 33% by age 1 year, 75% by age two and 97% by age three. Nevertheless in this longitudinal study, a quarter of the boys and one tenth of the girls had a major period of incomplete bowel or bladder control between the ages of 6 and 18. At least annual encopresis occurred in 2-3% of these children, boys more frequently than girls [912]. In the Wisconsin Family Health Survey the prevalence of AI in children from the ages of 5 and 16 years was 12/1367 (0.88%) with the gender distribution being 7 boys and 5 girls (Wisconsin Family Health Survey: unpublished data). The common disorder for all children and then adults in this discussion is faecal retention with overflow and seepage.

3. INCIDENCE

Clinical trials have provided incidence data after a therapeutic interventions, but usually without a preliminary continence assessment. This is best seen in two Cochrane reviews of therapy for anal fissure [913-914]. AI incidence rates varied widely from 0% to 30%, to fissus only, and the duration was unspecified in the trials. Medical therapy was less likely than surgery to cause AI (0.23, 0.02-2.1), and certain operations (anal stretch) were more likely to cause AI than others (sphincterotomy) (4.2, 1.9-9.4). None of
4. RISK FACTORS

4.1. Age

Three systematic reviews and NHANES have analyses of the association of age and anal incontinence and found advancing age to be the most consistent of all assessed associations [903-906].

4.2. Gender

Most discussions of the aetiology of AI have been based upon the assumption that women, particularly for individuals under the age of 65 years, are far more at risk for AI than men. Injury to the pudendal nerve or sphincter muscle from prior obstetric trauma is described as the primary risk factor [915-917], followed by irritable bowel syndrome (a disease thought to be more prevalent in women) [918], and other aetiologies such as diabetes a distant third [919]. Yet each population based-survey of the prevalence of AI has shown a surprisingly high prevalence in males (Table 17).

Of the two systematic reviews that looked specifically at prevalence, only two assessed the role gender played and in that review gender was not associated with incontinence in any age group [904-905]. In NHANES when UI is included in the regression model, male gender was a significant risk factor [906]. In the search for this updated review, 26 publications assessed prevalence of AI, two in both genders and 24 only in women. Clearly, aetiologies other than childbirth must be sought. This represents a rather gross imbalance in research on this topic.

4.3. Obesity

Four reports have demonstrated an increased risk of AI in obese women, a Kaiser cohort, a cross sectional survey in a specialty clinic and two case control studies [952-955]. One longitudinal study found a reduction in anal leakage (again not necessarily a direct correlate with incontinence) in women after bariatric surgery and weight loss, although other factors including diet and activity change may have been responsible for the improvement [956]. However One systematic review and NHANES found no association of FI with obesity [905-906]. Another review from Kaiser data also showed no association of FI with obesity [957].

4.4. Childbirth and mode of delivery

A meta-analysis of published reports that assessed anal sphincter integrity after vaginal delivery and correlated this with continence stated that 77%-83% (depending on parity) of anal incontinence in parous women was due to sphincter disruption [958]. Another systematic review that looked only at post partum factors in prospective cohorts found that the only predictor of AI was 3rd-4th degree sphincter rupture during birth [959]. Three things are implied by the conclusion or the first review: first, that incontinence in men, children, of elderly onset (or even in middle aged women) and in nulliparous women, or women having caesarean delivery (CD) has a completely different cause than in women who have ever delivered vaginally (VD). There is scant epidemiologic evidence that this is the case [960]. Second, it is implied that sphincter repair would be effective treatment for anal incontinence in almost all parous women. Yet repair of a disrupted sphincter has less than a perfect track record. Even more importantly, there is a reported rapid decay in function after repair that is far too great to be explained by age alone [961-968]. Third, if direct trauma to the anal sphincter (and not intra-pelvic nerves) were the major cause of anal incontinence, then CD should be effective in preventing incontinence.

However a systematic review has shown that this is not the case [968]. Twenty-one reports have been found eligible for inclusion in the review, encompassing 31,198 women having had 6,028 CD and 25,170 VD as index events prior to anal continence assessment. Only one of these reports demonstrated a significant benefit of CD in the preservation of anal continence. In that report AI rates exceeded 39% in both groups, suggesting a problem with ascertainment. The greater the quality of the report, the closer its odds ratio approached 1.0. This review was updated for this current summary searching Medline, EMBASE and the Cochrane data base of clinical trials from 1966 to April 2016. Ten new studies were added to the meta-analysis and of the older review [971-980] three excluded because there cohorts had less than 250 participants and fewer than 50 reported CDs, leaving 27 included studies. With these new studies now CD was found to be less likely to result in FI than VD (Odds Ratio 0.83, CI; 0.73-0.94. Figure 12). However when quality criteria were applied to the studies included, specifically follow-up after delivery of at least six months and adjustment of the Odds Ratio (OR) for at least age (see above) and in most cases also for parity and obesity, the difference in FI risk between CD and VD was not significant (OR 0.93; CI 0.77-1.13, Figure 13). The importance of duration of follow up is shown in (Figure 14), in which a single cohort was measured for FI at three months post partum, six years and twelve years. The apparent advantage of CD in the 2001 report is clearly gone six and twelve years later. From other studies (Figure 12), it is apparent that this equalisation occurs by six months. This entire analysis included 46,724 deliveries, 8901 of which were CD in reports from 1997 to 2011. No difference in risk was seen between emergency (in labour) CD and elective CD.

In another publication increasing parity as an isolated risk factor does increase risk of AI [951], but not in NHANES [906].

Figure 14: A single cohort reported three times by MacArthur, et al. AI was assessed 3 months post part (2001), 6 years post part (2005) and 12 years post part (2011).
But why does not CD prevent anal incontinence, especially when associating perineal trauma with loss of bowel control is not just intuitive, but sometimes visibly obvious? Certain aspects of VD are clearly causally related to anal incontinence: significant laceration, forceps, and some episiotomies [982-983]. However this review demonstrates that other factors need to be explored. One must look to pregnancy and not just labour and delivery as an initiating factor. Further evidence in favour of this comes from the sphincter repair literature cited above. The rapid decay in function suggests that another defect is present besides a gap in the sphincter that remains after the early effects of sphincter repair wear off. Trauma at the pelvic inlet during pregnancy or in early labour [984] is a possible explanation. Sphincter dysfunction has been demonstrated in women who have had CD [985]. Further indirect evidence for the possibility that injury higher in the pelvis may be related to AI in pregnant women can be found in the association between hysterectomy and AI, an association seen more often with abdominal hysterectomy (TAH) than vaginal hysterectomy (VH), and for faecal only [986] (Odds Ratio of TAH vs. VH for faeces: 1.2, 0.3-4.7, Odds Ratio for gas: 18.9, 1.1-327). Pelvic nerve injury during surgery is the postulated reason for this difference. Further support for this is that one of the strongest predictors of FI after birth is FI during the pregnancy [985].

4.5. Nursing home residence

The most common association with AI by far is nursing home residence. A very thorough discussion of this is [988], which combines data from NHANES, The National Study of Residential Care Facilities (NSRCF), the National Home and Hospice Care Study (NHHCS) and the Minimum Data Set (MDS). The prevalence of AI has been reported to be ≈ 7-8% for community-dwelling persons, and may rise with increasing age to greater than 10%, among nursing home residents the prevalence approaches 50% [945-947]. This is partly explained by FI being one of the most common reasons for nursing home admission. In a large survey of 18,000 Wisconsin nursing home residents, risk factors for fecal incontinence (FI) were directly observed by nursing home personnel [946]. Urinary incontinence (UI) was the greatest association with FI (OR = 12.6, 11.5-13.7), followed by the loss of ability to perform daily living activities (6.0, 4.7-7.7), tube feeding (7.6, 5.6-10.4), physical restraints (3.2, 4.7-7.7), diarrhea (3.3, 2.7-4.2), dementia (1.5, 1.4-1.7), impaired vision (1.5, 1.4-1.7), constipation (1.4, 1.3-1.6), fecal impaction (1.5, 1.1-2.1), stroke (1.3, 1.2-1.5) male gender (1.2, 1.1-1.3), age and body mass index. Inverse associations were noted with heart disease, arthritis and depression.

4.6. Diarrhoea

The importance of diarrhoea or liquid stool in FI cannot be overemphasized. One case series noted that 51% of individuals with chronic diarrhoea were incontinent [899]. In the Wisconsin Family Health Survey of AI [901], 10 of the 25 subjects with FI lived in Milwaukee when the city experienced an outbreak of waterborne disease [989]. Non-infectious causes of diarrhoea must also be considered, such as inflammatory bowel disease [988] and those initiated by sports activities such as running [991-992].

4.7. Surgery

AI originating from surgery would seem fairly insignificant in the general population, since prior anal surgery has not been an apparent risk factor in any of the larger surveys. Several operations nonetheless frequently can result in AI. Examples are midline internal sphincterotomy, lateral internal sphincterotomy, fistulotomy, fistulotom y, ileo-anal reservoir reconstruction, low anterior rectal resection, total abdominal colectomy, and ureterosigmoidostomy. The risk of lateral internal sphincterotomy for anal fissure causing AI was previously thought to be insignificant when compared to midline sphincterotomy. But a recent reappraisal of this operation has shown that the AI risk may be 8% [993]. The risk of AI after fistulotomy has been reported to be as high as 18% to 52% [994]. New approaches to fissure and fistula have recently been developed specifically to lower this risk [994-995]. However incontinence after haemorrhoidectomy has also been reported to be as high as 33%, an operation in which no sphincter is divided [996]. This suggests either that division of the anoderm, not the sphincter may be affecting continence, or that the method of identification used in published surveys is not accurate. As with delivery, assessments done immediately surgery will always show significant seepage which may be misinterpreted as incontinence. Six months is the minimum duration of follow-up needed to obtain reliable risk numbers. Mixing urine and stool has been found to have a predictable effect on anal sphincter control, as does diarrhea, in patients having uretero-sigmoidostomy after urinary bladder resection [936]. Patients with rectal cancer form a special group in whom cancer issues often distort the continence disturbance that may result from rectal resection [997] or radiotherapy [998].

4.8. Specific neurological and other diseases

Several specific diseases have anecdotally been associated with AI in case series, and mechanisms to explain the associations have been investigated [999]. Examples are diabetes [938], stroke [1000-1001], multiple sclerosis, Parkinson’s disease, systemic sclerosis, myotonic dystrophy, amyloidosis, spinal cord injury, imperative anus, Hirschsprung’s disease, retarded or interrupted toilet training, procen tie, and any illness causing diarrhoea (HIV, IBD, radiation, infection). Many of these conditions directly affect patient mobility and ability to perform daily living activities or they cause diarrhoea or faecal impaction.
4.8.1 Constipation

Constipation may alternate with diarrhoea in irritable bowel syndrome making defaecation chaotic and often very urgent. Often retained feces leads to anal seepage that cannot be held. In the New Zealand survey [902], the 2 of 3 rule for categorising an individual as incontinent excluded constipated patients, which was also assessed in their survey, the positive rate fell from 13.2% to just over 9%. This further demonstrates the frequent co-existence of constipation and AI, similar to the frequent coexistence of urinary incontinence and AI.

Because of a paucity of clinical trials that specifically address risk factors and prevention of AI, the strongest available data to identify risk come from cohorts that collected data on potential risk factors prior to the onset of incontinence. Prospectively collected risk assessments for FI have occurred in three nursing home cohorts. Porell combined UI and FI into a single outcome variable and found many positive associations in a cohort of 60,000 nursing home residents in Massachusetts [1002]. Age, African American race, cognitive and ADL impairments predicted the outcome, although specific relative risks for incidence are not presented. Chassange followed 234 previously non-FI residents in France for 10 months, during which 20% had FI episodes, but only 7.5% developed long lasting FI [1003]. The others had acute episodes due to diarrhoea or impaction. The factors associated with the development of long lasting FI were urinary incontinence (UI) (2.9, 1.8-4.6), decreased mobility (1.8, 1.1-3.0), and cognitive defects: either as seen in an MMSE score <15 (2.5,1.4-4.4) of history of dementia (2.1, 1.2-3.5). Neither gender nor age were risk factors. Nelson reported, in a cohort of 18,000 nursing home residents in Wisconsin, a subgroup of 3,850 continent of both urine and faeces in 1992 and were assessed one year later [1004]. 15% developed FI. Positive associations were seen for ADL loss (3.4, 2.4-4.5), trunk restraints (2.5, 1.7-3.6), dementia (1.7, 1.4-2.0), African American race (2.1, 1.3-3.4) and age (1.02, 1.0-1.0). UI was not investigated as a risk factor because it was felt to be a co-morbid condition. In a broadly based cross sectional survey, it was apparent that factors that affect an individual’s general health or physical capabilities, independent of age and gender, place that individual at greatest risk for AI [918], though all four are significantly associated with AI [901]. Among obstetrical patients age has also been a consistent association, with less consistent associations noted for chronic bronchitis (OR =6.5, 1.1-38), symptoms of pelvic prolapse (5.0, 3.0-8.7) and obesity (3.0, 1.0-3.4) [1003]. Defecatory dysfunction has also been assessed in pre-partum women [1006-1008], found to be prevalent and which has led to an important preventive strategy for post partum AI described below.

5. PREVENTION

This discussion is by necessity descriptive, so preventive measures are only relevant insofar as they provide insight into aetiology of incontinence. By far the most frequently applied preventive measure is CD, discussed above. Its lack of effectiveness in preventing anal incontinence provides a valuable insight into the relationship of pregnancy and AI – that the focus may need to be more on the pregnancy rather than the delivery and how it effects defaecation afterwards. A decision analysis study suggests specific obstetrical indication for elective CD that may be cost effective [1009]. Another study related to birth trauma randomized mothers to immediate post-partum anal ultrasound with repair of occult defects in the sphincter and continence assessed in follow-up, demonstrating an improved outcome with this intervention [1010]. Intervention pre partum with pelvic floor exercises has been assessed in a number of randomized trials [1011-1012] for the purpose of diminishing post partum AI. One Cochrane review found this strategy effective [1011]. Sixteen studies were included in the analysis in which 6,181 women participated. Those without prior urinary incontinence were randomized to either pelvic floor training or standard care. At 12 months postpartum the intervention group were half as likely to have AI (RR= 0.52; 0.31-0.87). A subsequent report has not shown this benefit, and has yet to be included in the Cochrane review [1012]. The AHRQ recently published a monograph on prevention of incontinence, though the strategies listed for AI were therapies for existing AI, such as pelvic floor exercises and retraining, rather than established mechanisms for prevention [1013].

6. SUMMARY POINTS

- Anal and urinary incontinence commonly coexist, particularly in the elderly and in nursing home residents (LE 1).
- The prevalence of anal incontinence increases with age, but is present in all age groups in both genders varying from 1.5% in children to more than 50% in nursing home residents (LE 1).
- AI is almost as common in men as in women (LE 2).
- More analyses comparing AI after CS and VD have been published.
- Studies reporting a protective effect of CS have been published.
- Obesity is perhaps the most modifiable risk factor for AI (LE 2) but the data associating obesity with AI are inconsistent.
• Intrapartum pelvic floor education can decrease the risk of subsequent development of AI postpartum (LE 1)

• As populations age, co-morbid disease becomes a significant component of fecal incontinence risk. Surgery, neurological diseases, and stroke are examples.

• Cognitive and ADL impairment are associated with faecal incontinence.

• More population based prevalence surveys have been published.

• Systematic reviews of prevalence, including the role of age and gender, CD and decision analyses for the use of CD in macrosomia have been published, providing necessary integration of data with quality assessment of existing literature.

7. FUTURE NEEDS

• Risk factors for AI in each age group are still poorly defined

• Prevention research, much less policy, are therefore still a great distance away.

• Randomised trials are needed of AI (and UI) in average risk women comparing VD and CD with minimal cross over and sufficient follow-up to adequately assess FI and UI.

X. WHY DO PREVALENCE ESTIMATES DIFFER?

The discussion here relates to UI only, as data and literature for FI and POP are very scarce. However, many of the principal arguments will be relevant to these conditions as well.

1. GENERAL PROBLEMS IN SURVEY RESEARCH

The well documented variation in prevalence estimates is thought to result at least in part from several confounders common to survey and epidemiological research. Herzog and Fultz,[1014] in a review of the prevalence and incidence of UI in community-dwelling populations, proposed that past investigations were plagued by sampling and non-response issues, by self selection and attrition, by definitional, conceptual, and measurement issues. Comprehensive reviews about measurements and methodological aspects of investigating UI are provided. It is clear that there are large methodological challenges to rigorous research in this field. In general, the quality of recent large studies has undoubtedly improved, but the scientific community must continue to deal with methodological challenges in order to achieve progress.

2. DIFFERENT DEFINITIONS AND MEASUREMENT

A major problem in research on UI has been the use of different definitions and measurements, and this might contribute to the wide range of reported prevalence estimates. The former ICS definition of UI – as a condition in which involuntary loss of urine is a social or hygienic problem and is objectively demonstrable - included objective demonstration of urine loss as one critical component. This aspect limited the ICS definition for community based epidemiological investigations, because objective demonstration of UI is difficult to achieve outside of the clinical setting, and studies which were able to include this aspect in their assessment might have produced different prevalences. In addition, a social or hygienic aspect of the definition was problematic in epidemiological studies because it added a subjective aspect to an objectively defined condition and therefore confounded the investigation of prevalence, incidence, and risk factors. In a previous report we argued for reconsideration of the definition of UI, and we emphasised that the core of the definition should be "any involuntary loss of urine". In accordance with this view, ICS changed its definition in 2002 to UI being "the complaint of any involuntary leakage of urine".

The new definition makes epidemiological research easier. But three consequences should be addressed:

1. Epidemiological studies should not be based on this definition alone, and all studies should include a minimal additional data set, standard confounders, and questions specific to the aim of the study. This is discussed in the Section on Recommendations for further research.

2. The number of persons fulfilling the definition will increase. This should not be interpreted as an increase in the number potential of patients.

3. Public awareness, case finding of health care personnel, and help seeking behaviour may be affected by a new and more extensive definition.

Studies have used different severity levels and time frames for defining UI. A further factor complicating the conceptualisation and measurement of UI in epidemiological studies lies in the nature of the condition. UI is a chronic condition (or set of conditions) that often starts slowly and comes and goes for a considerable time period before it become fully established. If people get used to their UI or notice it less, this can interfere with valid assessment.
Ideally self-report measures are validated by clinical evaluations. However, clinical and even urodynamic investigations should be regarded as other measures, not necessarily as gold standards, because it is known to be difficult to demonstrate all urinary symptoms in the clinical setting.

Low response rates may further bias prevalence estimates. Known differences between responders and non-responders can be compensated during the analysis. The major problems is unknown differences in response rates and other characteristics. Incontinent women may not answer (or deny UI) because of embarrassment or related handicaps. But incontinent women may also find the subject particularly relevant and therefore respond to a greater extent than continent women. At present, we do not know much about how these factors may affect the comparison between incontinent and continent women.

One paper explored the problem of underreporting incontinence and how it can be altered with the use of an introduction to the incontinence questions and probing [178]. Another paper explored the issue of selection bias in mailed surveys. The first wave had a higher prevalence of incontinence than follow-up mailings, and thus individuals with UI tended to respond on the first wave. In an English mailed survey on incontinence and other urinary symptoms, a sample of non-responders were traced, and those eligible were asked questions from the survey [1015]. Compared with the responders, the non-responders overall showed little differences in reporting of urinary symptoms. However, non-responders >70 tended to be of poorer general health, and they reported certain urinary symptoms more frequently.

3. SUMMARY POINTS:
- The lack of epidemiological data from populations underrepresented in research limits the world wide application of the present information.
- Many investigations are plagued by sampling and non response issues, by self selection and attrition. Many early studies were obtained by sampling patients seeking care.
- A major problem is the use of different definitions of incontinence. The new ICS definition makes epidemiological research easier.
- There are large methodological challenges to research in the field of UI. Unless the scientific community deals with these issues, progress will be difficult to make.

XI. HELP SEEKING BEHAVIOUR

1. URINARY INCONTINENCE

A majority of people with UI have not sought help [540]. Reasons given by people for not seeking help include: not regarding incontinence as abnormal or serious, considering incontinence to be a normal part of ageing, having low expectations of treatment and thinking they should cope on their own. Some studies also confirm the notion that embarrassment may be an important reason for not seeking help. There is an association between help seeking and condition-specific factors like duration, frequency and amount, and people’s perceptions of the impact of incontinence but other more personal characteristics like individual health care behaviour and attitudes may also play a role.

In a Norwegian study 4.4 % of all women >20 years old in a community consulted their general practitioner for UI during a 3 year period [1016]. Mentioning the symptoms to a physician may not be enough. There are reports of doctors not responding, either by ignoring the statement of symptoms or by providing a dismissive explanation, and people interpreting a lack of response from the doctor as an indication that no treatment is available. In a study of management of incontinence in general practice, 30% of the women who had told their doctor about their symptoms perceived that they were offered no help. It is probable that many primary health care providers lack confidence in managing UI, and that this contributes to under treatment in those seeking help.

Only a small proportion of incontinent community-residing women have had surgery, medication, or exercise regimens. In addition to seeking help from the formal health care system, common responses to symptoms of illness are self-management and self-treatment behaviour. The major method of actively managing UI among community residents is the use of absorbent products.

It is obvious that millions of men and women suffer from their UI, and that for many of them good treatment options are available. However, for many persons with very mild or occasional UI it is probably adequate not to seek help from the health care system. Others are satisfied with just information and understanding about the causes and in many cases self care may be quite appropriate. A Danish study has shown that simple information and advice was adequate "treatment" for 23% of the women attending an open access incontinence clinic [1017]. A Swedish study found that among 136 women with UI, 36% wanted clinical evaluation, and only 24% subsequently started treatment [651].

Both epidemiological and qualitative research in this field should be encouraged in order to understand
cultural, religious, and personal factors for help seeking behaviour world wide. Specifically, other than condition-specific factors should be further explored, e.g. persons’ health care behaviour, perceptions and attitudes.

2. FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE

There are indications of underreporting also of FI and patients’ reluctance to report symptoms or to seek treatment. It has been shown that women are more willing to report FI than men. For POP we have no information.

3. SUMMARY POINTS:

- Recent publications confirm that a majority of people with FI, UI, and POP have not sought help.
- Only a small proportion of urinary incontinent community-residing people have had surgery, medication, or exercise regimens.
- Increasing severity, increasing duration, and urgency/mixed type of UI are related to consulting a health care provider.
- Associations other than condition-specific factors should be further explored in future research, e.g. persons’ health care behaviour, perceptions and attitudes.
- Health care personnel should be encouraged to approach persons at risk for FI, UI and POP. People with such symptoms should be assessed so services and treatment can be offered and targeted. The patient’s view of management, even denial, should be respected.

XII. EPIDEMIOLOGY AND CLINICAL WORK: FROM RESPONDENT TO PATIENT

We have emphasised some major and important differences between epidemiology and clinical work. These differences may have several implications. A selection process is most often accomplished first by self-selection (help seeking), then a referral system, which provides specialist physicians to a patient population with higher prevalence of disease, more severe disease, and often skewed type distribution, thus obtaining test results with fewer false positives, better diagnostic accuracy, and more efficient use of resources. However, such intended and purposeful selection bias has its drawbacks. There is growing evidence that this selection process introduces bias into research and hampers our ability to generalise hospital based research back to general or primary care populations. Furthermore, it may result in recommendations and guidelines for diagnosis or therapy derived from tertiary care centres that are inappropriate at the primary care level. Often guidelines, review articles or teaching material do not take into account the varying prevalence and variation in the clinical picture between community and hospital. They may also emphasise use of tests or equipment that are not appropriate or relevant for primary health care, thus leading to over utilisation of referrals. Data from hospitals or specialist level may also overestimate level of burden, costs and number of persons in need of treatment if such data are used for extrapolation back to community level. Therefore it is important that this Consultation uses different algorithms for initial and specialised care (see other relevant chapters).

One study provides substantial empirical evidence to support the existence of selection bias for UI [125]. The analyses were based on three populations of incontinent women: Community level (epidemiological survey), primary care level (prospective study), and secondary care level (university hospital, prospective study). The general practice patients were older and the hospital patients younger than those in the community. From community via general practice to hospital, there was an increase in duration, frequency of leakage, amount of leakage, severity and perceived impact of incontinence. Help-seeking at the primary care level was associated with increasing age and severity, and with urgency symptoms and impact. Referral from general practice to hospital was only associated with lower age and urgency symptoms.

Under the subtitle Severity and Impact we have given examples of how the prevalence estimates for women change dramatically when bothersomeness and severity are considered. Taken together with selection bias, this emphasises caution when epidemiological data are used in a clinical context. It concerns “level of care” in several ways; there is a large transitional zone from healthy to diseased, there is a danger of medicalisation, and there is a danger of treating patients at a higher level than necessary. Risk factors, predictors and correlates discovered in epidemiological studies are probabilistic of nature and may not be decisive in the clinical assessment of an individual patient. In addition, the attributable risk due to some known risk factors may be statistically but not clinically significant.

1. WORLDWIDE ESTIMATES OF LOWER URINARY TRACT SYMPTOMS

In order to effectively plan health care resources it is necessary to estimate the prevalence and incidence of illnesses to know to what extent resources require
to be allocated to a specific illness health care condition. This chapter has dealt with three major global problems, urinary and faecal incontinence as well as pelvic organ prolapse, that affect women and men throughout the world. Irwin and coworkers [539] have published data estimating the current and future worldwide prevalence of lower urinary tract symptoms.

The objective of the study was to estimate the current and future number of people with LUTS, including overactive bladder (OAB) and Urinary Incontinence (UI) utilising the current ICS definitions. Age- and gender-specific prevalence rates from the EPIC study [417] were applied to the worldwide over 20 year old population (4.2 billion) with males and females stratified into five-year age groups (20-24 to 80+). Projected population estimates for all worldwide regions were based on the United States Census Bureau International Database (IDB).

Estimates were presented for 2008, 2013 and 2018 and are summarised in Tables 21 and 22. Table 21 summarises the estimated number of individuals with certain LUTS symptoms by year and sex in the world population and Table 22 describes the estimated number of individuals of LUTS and OAB over 10 years across the world regions.

Estimates and projections featured in this analysis were based on prevalence rates of LUTS described in the EPIC study – based primarily on a European population. The prevalence rates featured in the EPIC study are similar to other prevalence rates of LUTS that were found in others studies across other countries [284,537]

The projections in this report assume the prevalence rates of LUTS will remain throughout the year 2018 for all age and sex groups.
Prevalence of LUTS will also increase as other factors related to LUTS, such as obesity, increases. The estimated number for present and future years are not true numbers but are based on a projected population configured by the International Database (IDB). The IDB’s estimates and projections are drawn by Census Bureau demographers and are based on reviewed censuses, surveys, and vital statistics provided by National Statistics Offices. Data on international migration and refugee movements, public health efforts, socio-political circumstances, and historical events such as natural disasters and conflict are all considered when the IDB calculates the estimates and projections.

It is anticipated that with the overall aging of the population the prevalence of LUTS will also increase. It has been shown that LUTS are burdensome to individuals and the likely increase in the number of individuals experiencing LUTS has implications on healthcare resources and overall health burden. This analysis is an estimate of the number of individuals with LUTS based on a conservative prevalence rate, and so the future number of those with certain LUTS may surpass those of this report.

2. SUMMARY POINTS:

- The spectrum of severity of anal and urinary incontinence, as well as pelvic organ prolapse, and the symptom profile of patients referred to specialist centres do not necessarily reflect the spectrum of disease seen in the community.

- The selection and referral process may introduce bias into research and hamper the ability to generalise hospital-based research back to primary care populations.

- One should be very careful with calculating numbers of patients in need of therapy based on epidemiological data.

1. URINARY INCONTINENCE

It is recommended that more sustained research on measurement of UI should be performed including, its types and severity to move the research ahead. Longitudinal study designs are needed to estimate incidence of UI and describe the course of the condition and its different forms and to investigate its risk factors and possible protective factors.

There is still little knowledge with regard to prevalence, incidence, and other epidemiological data in developing countries. A recent review on the global prevalence of urgency urinary incontinence clearly showed that prevalence rates are largely unknown for many countries in the world [1019]. It is recommended that fundamental research regarding prevalence, incidence and other epidemiological data in

STROBE (Strengthening of the Reporting of OBservational studies in Epidemiology) statement was introduced [1018]. It is a checklist of items that should be addressed in articles reporting on the three main study designs of analytical epidemiology: cohort, case-control, and cross sectional studies. The use of this checklist is highly recommended.

13. RECOMMENDATIONS FOR FURTHER RESEARCH

Much biomedical research is observational and the reporting of such research is often inadequate which hampers the assessment of its strengths and weaknesses and of a study’s generalisability. The
developing countries should be encouraged, and tailored to the cultural, economic and social environment of the population under study.

Crude prevalence studies (descriptive epidemiology) from USA and Europe are abundant, and further studies should be done only with recommended and validated questionnaires or in order to combine data from the prevalence study with studies of co-factors and predictors (analytical epidemiology). Control for confounders, stratification, and multivariate techniques should be increasingly used because of the need for more advanced epidemiological analyses of risk factors and comorbidity. Strength of associations should be determined by relative risks and odds ratios, and confidence limits should be given. We have still very little knowledge of the absolute and relative importance of several risk factors, and almost no information about the attributable risk of the factors in society.

Some potential risk and protective factors deserve more attention. For example, the role of pregnancy and childbirth in the development of UI must be studied in a fashion that links population-based methods to clinical assessment of pregnancy, delivery and the birth trauma and follows women over many years. Such a design is necessary because the effect of pregnancy and childbirth may become clear only years later when the woman is older and because the woman will not be able to report the exact nature of the tear or episiotomy, etc. There should be more emphasis on the associations between UI and specific diseases like stroke, diabetes, psychiatric disease and genital prolapse. Genetic components should be investigated.

Primary prevention is the main goal in the management of human disease. An important strategy would thus be to identify the individuals at risk, and then take measures to reduce the risk among those individuals or in certain risk groups. A predictive modelling system based on risk factors identified in population studies has been put forward [1020]. Primary prevention studies should be encouraged, but the epidemiological basis for choosing appropriate interventions is weak.

In surveys based on questionnaires or interviews symptoms can be registered. There are convincing data suggesting that the different types may reflect quite different pathologies and risk factors. Differentiating the types in future research might therefore prove very fruitful. Methodological work has still to be done in this area, but typical type descriptions should be included in new studies. Likewise, studies of risk factors should include important and known confounders such as age, parity, and weight.

Variations in definitions and measurement issues are fundamental and lead to problems with assessing the findings in epidemiological studies. We need to improve epidemiological studies by including variables that better characterise UI, so that more advanced and informative analyses may be conducted. It is therefore recommended that all epidemiological studies include a minimum data set (Table 24), including elements of screening question, frequency measure, quantity of urine loss, duration, type, and severity. In addition, it is recommended that validated measures of bother/quality of life and urinary symptoms other than UI should be included. We here also refer to the chapter from the committee on symptom and quality of life assessment.

2. FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE

In these areas there is a need for more epidemiological research in all areas; prevalence, incidence, and risk factors. Many of the fundamental methodological issues relevant to UI discussed above are highly relevant to the fields of FI and POP.

The committee emphasises that uniform definitions of FI and POP should be used in studies, and there should be a move towards a standardisation of measurement instruments in community surveys that can be used worldwide. Developing definitions is a scientific process requiring careful conceptualisation of the condition in light of its many clinical presentations and underlying mechanisms. This will require a multi-method approach and consideration of issues such as reliability and validity.

I. INTRODUCTION

The previous edition of this report in the 5th edition of *Incontinence* (2013, pp109-178) covered several topics of current interest including updates on: interstitial cells; detrusor and urethral muscle contractile activation; the structure and function of the urothelium; the physiology of the ano-rectum; and translational topics that included identification of novel targets for bladder dysfunction and the role of biomarkers to help understand more of the pathophysiology of the overactive bladder and detrusor overactivity. This edition aims to update the reader on several of these rapidly-evolving areas, but also introduce some new topics that are important areas for research to understand pathophysiological processes in the lower urinary tract and lower gastro-intestinal tract.

The committee has worked closely with Committee 3 (Neural Biology) as several topics have relevance to them both. This Committee considered new advances in our understanding of excitation-coupling in bladder wall smooth muscle, including the hitherto less-studied trigone, *muscularis mucosa* and perivascular myocytes. Interstitial cells continue to be an area of great activity and their phenotypic influence over other cells has been reconsidered and updated. The urothelium was reconsidered with regard to its barrier and transport functions, whilst its role in transducing sensations, in particular to the nervous system, is considered by Committee 3. In addition, there have been great advances in understanding the (patho)physiology of the ano-rectum and these are also reflected here. The functional interaction of the ano-rectum with the lower urinary tract (LUT) is very close and the cellular mechanisms that control the ano-rectum are equally relevant to LUT function.

Two new areas have been included. Firstly, the skeletal muscle physiology of the pelvic floor muscles and the external urethral sphincter. Derangements in the function of these muscles underlie a number of LUT pathologies but the pathophysiological processes that cause them have been given very little attention in fundamental research. Committee 3 of the previous consultation considered the neural control of these muscles and the aim of this report was to expand on this knowledge and form a more complete understanding of their (patho)physiology. Secondly a new area has been introduced regarding the physiology of the foetal and neonatal bladder, as well as its development in childhood. In particular the development of detrusor smooth muscle function is described, including consideration of the changes that occur in the presence of congenital anomalies of the lower urinary tract. The functional physiology of this topic is very sparsely pursued although the consequences for children with congenital anomalies are profound.

With respect to translational sciences, the identification of new drug targets for management of LUT disorders has again been given prominence, and novel targets are always being identified. Furthermore, a more holistic approach to such disorders has been taken, as they are generally associated with changes to more than one part of the tract, or indeed due to interaction between different cells in a particular tissue. Examples are provided whereby certain agents and treatments may have complex actions on various cells and tissues of the LUT that together may have a beneficial function.

Overall great advances are being made to understand the fundamental basis of LUT disorders. However, there remains a great deal to be discovered as to how different cells and tissues influence each other’s function and how this may impact on the genesis of LUT disorders and offer more targeted therapies.

II. EXCITATION-CONTRACTION COUPLING IN BLADDER SMOOTH MUSCLE

1. DETRUSOR SMOOTH MUSCLE DURING THE STORAGE PHASE

1.1. Relevance of Spontaneous Activity

During the storage phase, intravesical pressure rises remarkably little, thus detrusor smooth muscle (DSM) is often considered to be quiescent or relaxed. Non-voiding contractions were thought as a sign of an
overactive bladder or as artificial due to non-physiological ‘fast’ filling cystometry. However, it is now more widely accepted that the DSM in normal bladders is spontaneously contractile to maintain a shape with a minimum surface area. This property allows micturition contractions to be generated efficiently upon parasympathetic nerve excitation, irrespective of the intravesical urine volume [1].

In bladder of humans [2,3] and laboratory animals [4,5] in vivo, non-voiding contractile activity, termed ‘micromotions’, develops as localized events that are associated with small rises in intravesical pressure. In rat and guinea pig bladder, non-voiding contractions increase in amplitude and frequency with increases in intravesical volume, suggesting that non-voiding activity may stimulate afferent nerves conveying a sense of bladder fullness [4,5].

In the isolated whole bladder of the guinea pig and pig, the corresponding activity is seen as ‘non-propagating’ autonomous activity [6,7]. A recent study applying multi-electrode arrays to isolated whole guinea pig bladder demonstrated that spontaneous electrical waves on the bladder surface propagate preferentially in the axially adjacent direction for only a limited distance [8], indicating that autonomous activity arises from spontaneous electrical events.

Spontaneous phasic contractions are recorded in DSM strips taken from various species including human, [9,10]. The mechanisms underlying these spontaneous contractions include the firing of spontaneous action potentials that can be detected as surface electrical waves in whole bladder preparations and associated intracellular Ca2+ transients (Figure 1 [11]).

Increases in the amplitude, spread and/or changes in the pattern of spontaneous activity, e.g. tetanic contractions, are observed in human overactive bladders with detrusor overactivity [1] or in animal models [12]. A recent study demonstrated that spontaneous ‘transient’ contractions of detrusor smooth muscle have a much larger influence than their baseline tone on afferent nerve activity during storage phases [13]. Thus, it is reasonable to assume that increased spontaneous contractility causes urinary urgency reported during a sense of bladder fullness [4,5]. In the isolated whole bladder of the guinea pig and pig, the corresponding activity is seen as ‘non-propagating’ autonomous activity [6,7].

A recent study applying multi-electrode arrays to isolated whole guinea pig bladder demonstrated that spontaneous electrical waves on the bladder surface propagate preferentially in the axially adjacent direction for only a limited distance [8], indicating that autonomous activity arises from spontaneous electrical events.

Spontaneous phasic contractions are recorded in DSM strips taken from various species including human, [9,10]. The mechanisms underlying these spontaneous contractions include the firing of spontaneous action potentials that can be detected as surface electrical waves in whole bladder preparations and associated intracellular Ca2+ transients (Figure 1 [11]).

Increases in the amplitude, spread and/or changes in the pattern of spontaneous activity, e.g. tetanic contractions, are observed in human overactive bladders with detrusor overactivity [1] or in animal models [12]. A recent study demonstrated that spontaneous ‘transient’ contractions of detrusor smooth muscle have a much larger influence than their baseline tone on afferent nerve activity during storage phases [13]. Thus, it is reasonable to assume that increased spontaneous contractility causes urinary urgency reported in patients with overactive bladder. Therefore, understanding the mechanisms regulating the spontaneous excitability of DSM, that plays a critical role in maintaining bladder storage function, is fundamental to establish the basis and therapeutic targets of overactive bladder.

While ‘non-voiding’ activity in whole bladders has been considered to reflect spontaneous contractile activity of DSM, evidence is accumulating that the ‘mucosa’ (or muscularis mucosa, see below) is also spontaneously contractile. Because of the close apposition of the ‘mucosa’ with the urothelium and suburothelial afferent nerves, its spontaneous activity may have a larger impact on afferent nerve activity. Therefore, the origin of spontaneous ‘non-voiding’ activity in whole bladders is an important area for future study.

1.2. Origin of Spontaneous Activity

Autonomous activity in isolated whole bladders or spontaneous phasic contractions in muscle strips are not diminished by tetrodotoxin (TTX) nor atropine, indicating that they do not originate from parasympathetic nerve excitation [6,9]. Since the discovery of interstitial cells in the bladder expressing Kit-receptor tyrosine kinase [14], a specific marker for interstitial cells of Cajal (ICC) that act as electrical pacemaker cells in the gastrointestinal tract [15], Kit-positive interstitial cells have been a favorite candidate as pacemaker cells driving detrusor spontaneous activity. This analogy is supported by several ‘indirect’ pieces of evidence: 1) isolated single interstitial cells are capable of generating spontaneous ‘nifedipine’-resistant Ca2+ transients; 2) detrusor interstitial cells are preferentially located along the boundary of detrusor muscle bundles where spontaneous detrusor Ca2+ transients originate; 3) the number of interstitial cells increases in animal models of overactive bladder or in patients with overactive bladder, 4) imatinib mesylate (Glivec), an inhibitor of Kit-receptor tyrosine kinase suppresses detrusor spontaneous contractile activity as well as their action potentials [10,16]. However, no evidence of electrical coupling of interstitial cells with DSM has been demonstrated. Rather, Ca2+ transients recorded from interstitial cells in situ occur independently of Ca2+ transients in adjacent DSM cells [17]. The acute inhibitory action of imatinib is most likely attributable to its non-specific action on both L-type VDCCs and Ca2+ release from intracellular stores rather than inhibition of Kit signaling [18]. Consistently, Glivec exerts no acute effects on spontaneous slow waves in the gastrointestinal tract [19]. Moreover, the distribution of Kit-positive interstitial cells and spontaneous contractile/electrical activity are little affected in bladders taken from W/Wv mice that have partial loss of gastrointestinal ICC and associated dysregulation of its motility [20]. Curiously, a later study using double labelling of Kit-positive cells and PDGFRα-positive cells (described later) failed to resolve Kit immunoreactivity in the murine bladder using verified antibodies that labelled Kit immunoreactivity in ICC of the colon [21].

Electrophysiological investigations have demonstrated that single DSM cells are capable of generating spontaneous action potentials that are very similar to those recorded in ‘multicellular’ syncytium of the intact tissue preparations [22,23]. Moreover, isolated DSM cells taken from human bladders with idiopathic detrusor overactivity exhibit aberrant spontaneous activity [9]. Therefore, the origin of spontaneous activity in detrusor is most likely to be the DSM cells themselves, so that their altered properties would contribute to several pathological conditions.
1.3. Voltage-Dependent Ca\(^{2+}\) Channels

L-type voltage dependent Ca\(^{2+}\) channels Spontaneous action potentials in DSM result from the opening of L-type voltage dependent Ca\(^{2+}\) channels (LVDCCs, [17,22]). Ca\(^{2+}\) influx during action potential discharge appears to be amplified by triggering Ca\(^{2+}\)-induced Ca\(^{2+}\) release (CICR) via ryanodine receptor Ca\(^{2+}\) channels in the sarcoplasmic reticulum (Figure 1A). Thus, individual action potentials are associated with spontaneous Ca\(^{2+}\) transients resulting in spontaneous phasic contractions [17]. Ca\(^{2+}\) sensitisation by constitutively active Rho kinase (described later) may augment the ‘Ca\(^{2+}\)-dependent’ spontaneous phasic contractions. Bursting action potentials are associated with larger Ca\(^{2+}\) transients and corresponding ‘summed’ phasic contractions (Figure 1B). Since the resting membrane potential of DSM in situ ranges between -50 mV and -40 mV which is very close to the activation threshold of LVDCCs, the generation and/or frequency of action potentials is highly sensitive to the membrane potential [24,25].

![Figure 1. Correlation between spontaneous electrical, intracellular [Ca\(^{2+}\)] and mechanical activity in detrusor smooth muscle. (DSM) A: Ca2+ influx via L-type voltage-dependent Ca2+ channels (LVDCC) during the action potential (black trace) is amplified by Ca2+-induced Ca2+-release (CICR) to induce a Ca2+ transient (blue trace) followed by phasic contraction (red trace). The unit for the Ca2+ trace is a fluorescence ratio, R, when illuminated sequentially at 340 and then at 380 nm in a rapid turnover, R340/380. Constitutively active ROCK may augment spontaneous phasic contractions by Ca2+-sensitisation. B: Compared to individually generated action potentials, bursting action potentials trigger larger Ca2+ transients and phasic contractions.](image-url)

T-type voltage dependent Ca\(^{2+}\) channels. The functional role of T-type voltage dependent Ca\(^{2+}\) channels (TVDCCs) in the urinary and male genital tracts, including the bladder, is well summarized in a recent review article [26]. TVDCC currents that can be clearly distinguished from LVDCC currents have been recorded from DSM cells of human and guinea pig bladders [27,28]. In the gastrointestinal tract, TVDCCs appear to contribute to the upstroke of pacemaker potentials generated by ICC, and thus contribute to the pacemaker mechanism [15]. In DSM of the guinea-pig bladder, Ni\(^{2+}\) (30 μM), a blocker for small conductance Ca\(^{2+}\)-activated potassium (SK) channels, Ca\(^{2+}\) influx through TVDCCs may preferentially access SK channels to stabilise detrusor excitability. In isolated human DSM cells, Ni\(^{2+}\) (100μM) blocked iberiotoxin-sensitive spontaneous transient outward currents (large conductance Ca\(^{2+}\)-activated potassium (BK)-STOCs), suggesting the functional coupling of TVCCs with BK channels. Interestingly, Ca\(^{2+}\) [28]. A higher concentration of Ni\(^{2+}\) (100μM) converted individual action potentials into bursts, and thus increased the amplitude but reduced the frequency of spontaneous phasic contractions. Since the effects of Ni\(^{2+}\) (100μM) on action potentials are very similar to those of apamin, a blocker for small conductance Ca\(^{2+}\)-activated potassium (SK) channels, Ca\(^{2+}\) influx through TVDCCs may preferentially access SK channels to stabilise detrusor excitability.
influx through TVDCCs but not LVDCCs is an essential trigger for the activation of a Ca²⁺-activated Cl⁻ current (CACL) in isolated interstitial cells of the guinea-pig prostate [30]. Functional coupling of TVDCCs with Ca²⁺-activated channels thus varies amongst species, as well as different lower urinary tract tissues.

In DSM cells from bladders with detrusor overactivity, the current density of TVDCCs increases, while LVDC density is reduced [31] and supports the observation of increased action potential generation in these cells [32]. Since the window current for TVDCCs lies around the resting membrane potential, the upregulation of TVDCCs would cause membrane depolarization and/or Ca²⁺ influx, which would increase detrusor contractility by activating LVDCCs or CICR. However, the net outcome of TVDCCs upregulation in terms of detrusor contractility would be determined by the balance between Ca²⁺ influx though TVDCCs and the subsequent activation of Ca²⁺-activated K⁺ channels.

1.4. Ca²⁺-Activated Chloride Channels
Ca²⁺-activated Cl⁻ channels (CACL) function as predominant 'pacemaker' currents in interstitial cells of various smooth muscle tissues, including ICC in the gastrointestinal tract or interstitial cells in the urethra [15,33]. In pig detrusor smooth muscle cells, endothelin-1 induces an inward current that is inhibited by niflumic acid or DIDS, blockers for CACL current, but not by nifedipine [34]. In the rat bladder, immunoreactivity against Anoctamin-1 (Ano1) CACLs, co-locates in vimentin-positive interstitial cells. Although it was not stated, Ano1 immunoreactivity appears to be also expressed in DSM bundles [35]. In the same study, niflumic acid or 5-Nitro-2-(3-phenylpropylamino)-benzoic acid reduced the amplitude and frequency of spontaneous phasic contractions, suggesting that Ano1 CACLs may play a role in generating spontaneous phasic activity. An increased expression and function of CACLs in detrusor myocytes isolated from obstructed rat bladder may contribute to greater bladder excitability [36]. It should be noted that spontaneous action potentials in DSM are not blocked by CPA, caffeine or ryanodine [25,37], agents that do prevent spontaneous activity in the urethra arising from spontaneous Ca²⁺ release and subsequent opening of CACLs [38]. Transgenic Ano1 knockout mice display uncoordinated Ca²⁺ transients in their ICC, no electrical slow waves as well as non-rhythmic, uncoordinated spontaneous contractions in their small intestine [39]. Future studies taking an advantage of Ano1 knockout mice should reveal the functional relevance of Ano1 Ca²⁺-activated Cl⁻ channels in developing spontaneous activity in DSM.

1.5. TRP Channels
The role of stretch-activated Ca²⁺ permeable TRPV₄ channels in the urothelium in sensing bladder fullness is well established [40]. TRPV₄ channels are also expressed in DSM and may play a role in regulating DSM contractility upon bladder filling [40]. GSK1016790A, a potent TRPV₄ channel agonist, enhanced spontaneous phasic contractions in detrusor muscle strips associated with a rise in the basal tension of the mouse and rat bladders [41,42]. GSK1016790A enhanced spontaneous phasic contractions and also caused a sustained contraction that are suppressed by nifedipine. This suggests that the membrane depolarisation and subsequent activation of LVDC, rather than the Ca²⁺ influx through TRPV₄ itself, plays a dominant role in the generation of these contractions [41]. The enhanced spontaneous contractile activity upon bladder filling would facilitate afferent discharge, and the sustained contractions may effectively prevent excessive bladder wall distension.

A recent study demonstrated that TRPV₄-positive mice showed markedly higher voiding frequencies [43]. Since the activation of TRPV₄ in the urothelium would cause urothelial release of ATP to trigger a micturition reflex, the higher voiding frequency of TRPV₄⁻ mice is rather unexpected. Interestingly, these mice also consistently developed higher frequency non-voiding contractions [33,43]. The higher incidence of non-voiding contractions may be attributed to increased DSM excitability during the storage phase. Thus TRPV₄ may also have an inhibitory role in DSM contractility in addition to having an excitatory function in results which demonstrated functional coupling between TRPV₄ and BK channels in DSM of the guinea-pig bladder [44].

Recently, TRPM₄, Ca²⁺-activated monovalent cation channels, have been shown to be expressed in DSM of human, rat and guinea-pig bladders and play a role in regulating its excitability and contractility [45,56]. Thus, 9-phenanthrol, a TRPM₄ channel inhibitor, decreased transient inward cation currents and voltage step-induced whole cell currents, as well as attenuated spontaneous phasic contractions.

1.6. Potassium Channels
K⁺ channels contribute to action potential repolarization as well as the resting membrane potential, and thus play a critical role in stabilizing DSM excitability of human and laboratory animals. The role of different types of K⁺ channels in regulating detrusor excitability is summarized in a recent review article [47].

In all species studied so far, including human, large conductance Ca²⁺- and voltage-dependent K⁺ (BK) channels play a predominant role in stabilising DSM excitability [48]. Since BK channels contribute to action potential repolarisation, pharmacological blockade of BK channels enhances the amplitude and duration of spontaneous action potentials (Figure 2A,
As expected, the blockade of BK channels greatly enhanced spontaneous phasic contractions [50]. In DSM of the guinea-pig [25] but not human or mouse [24,49], BK channels also appeared to contribute to the generation of an action potential ‘after-hyperpolarization’. Ca\(^{2+}\) influx through LVDCCs upon action potential firing has been shown to facilitate the opening of BK channels. Subsequent Ca\(^{2+}\) release from sarcoplasmic reticulum via CICR also contributed to the activation of BK but not SK channels [51]. Thus, the inhibition of CICR with CPA or ryanodine results in the enhancement of spontaneous action potentials and associated phasic contractions. Consistently, deletion of pore-forming subunits of BK channels in mouse bladder resulted in an overactive phenotype [52].

Of interest, NS11021, a BK channel opener, that suppresses spontaneous phasic contractions, reduced the frequency of spontaneous action potentials without changing the resting membrane potential [53]. Thus the opening of a small number of BK channels that is not associated with a membrane hyperpolarization may be sufficient to block the generation as well as propagation of action potentials. Considering the amplitude of the after-hyperpolarisation (approximately 10 mV), the physiological activation of BK channels during action potential firing appears to be highly efficient.

Small conductance Ca\(^{2+}\)-activated K\(^+\) (SK) channels play an important role in determining the pattern of action potential firing, while contributing little to the action potential configuration. Thus, the blockade of SK channels converted individual action potentials into bursts, resulting in increased amplitude of spontaneous contractions (Figure 2B, [24,25]). Recently, PDGFRα-positive cells (see below) in the bladder, that also predominantly express SK3 protein, may well stabilise detrusor excitability [54,55]. However, changes to the pattern but not frequency of action potential firing is an unlikely result from a simple deletion of a hyperpolarizing input from non-DSM cells. Suppressing SK3 channel expression in mouse bladder was associated with an increase in DSM spontaneous phasic contractions \textit{in vitro}, and bladder over-activity \textit{in vivo} [56]. An essential role of SK2 channel expression in regulating DSM contractility has also been demonstrated using mice lacking SK2 gene expression [57].

SK channel openers, e.g. NS309, SKA31, suppress spontaneous phasic contractions in a manner sensitive to apamin [58,59]. In isolated DSM cells with resting membrane potentials of about -25mV, these openers caused small apamin-sensitive hyperpolarization.

\textbf{Figure 2. Role of K+ channels in regulating spontaneous action potentials in detrusor smooth muscle (DSM).} A: BK channels predominately contribute to action potential (AP) repolarisation to limit the amplitude and duration of the AP. They also generate an after-hyperpolarisation; reduced by BK channel blockade with iberiotoxin (IbTX, red trace, guinea-pig DSM). B: Increased SK channel opening (with NS309, blue trace) hyperpolarises the cell and slows AP generation. C: Kv7 channel blockade (with XE991, red trace) depolarises the cell and accelerates AP firing.
sation. In DSM bundle preparations where physiological membarne potentials, i.e. -50-40 mV, is maintained, SK channel openers prevent spontaneous action potentials with or without membarne hyperpolarizations [60]. Of interest, SK channel openers dramatically prolong the duration of after-hyperpolarization without increasing their amplitude in a manner sensitive to apamin (Figure 2B). This action of SK channel openers may preferentially suppress tetanic contractions seen in pathological bladders by dispersing bursting action potentials.

Because of their slow inactivation and low-voltage activation thresholds, Kv7 channels are considered to contribute to the resting membarne potential. Kv7 activators, e.g. flupirtine, retigabine or ICA-069673, block spontaneous transient depolarisations (or action potentials) in isolated guinea-pig DSM cells, associated also with membarne hyperpolarisation. In contrast, XE991 (10 μM), a Kv7 blocker, depolarises the membarne to trigger the generation of spontaneous transient depolarisations [61-63]. Figure 2C Consistently, Kv7 activators suppress spontaneous phasic contractions in a manner sensitive to Kv7 inhibitors. In DSM bundle preparations of the guinea-pig bladder, XE991 also depolarised the membarne and dramatically increased action potential frequency (Figure 2C) [60]. However, flupirtine slowed or prevented spontaneous action potentials without hyperpolarizing the membarne. In mouse DSM, TEA (10 mM) further enhanced the amplitude and duration of iberitotoxin-treated action potentials and also suppressed their after-hyperpolarizations in mouse detrusor smooth muscle [49]. In single DSM of the mouse bladder, slowly-inactivating Kv currents that were blocked by TEA, but not 4-AP, were recorded although the molecular expression of Kv7 was not examined [64].

2. INHIBITORY MECHANISMS

In addition to the intrinsic relaxing mechanisms of K⁺ channels on DSM, several other mechanisms may be involved in stabilising DSM excitability/contractility during the storage phase.

2.1. β- Adrenoceptors

It is widely quoted that noradrenaline released from sympathetic nerves acts on β- adrenoceptors in DSM to directly suppress its contractility during the storage phase [65]. However, this is unlikely as sympathetic nerve fibres predominantly innervate the blood vessels in the bladder wall not DSM in most species, including human [66,67]. This view is consistent with the finding that nerve-evoked relaxation of DSM strips is hardly detected in the presence of α,β-methylene ATP and atropine, while nitrergic relaxations are detected in trigonal and urethral muscle strips [68]. On the other hand, sympathetic, α-adrenergic constrictions of submucosal arterioles or venules can be readily detected in the rat bladder [69,70]. Thus, the predominant effect of the sympathetic innervation of the DSM is inhibition of the parasympathetic pathways at spinal and ganglion levels [71].

Nevertheless, exogenously-applied β3 adrenoceptor agonists effectively suppress spontaneous phasic contractions of DSM. In isolated DSM, β3 adrenoceptor agonists and PDF4 inhibitors that increase intracellular cAMP levels hyperpolarise the membarne by opening BK channels to relax DSM [72,73]. However, in DSM bundle preparations of the guinea-pig bladder, BRL37344 (10 μM), a β3 adrenoceptor agonist, or rolipram (10nM), a PDF4 inhibitor, slowed or prevented action potential firing without hyperpolarizing the membarne [60]. Although a higher concentration of rolipram (100nM) was capable of hyperpolarizing DSM membarne, IbTX, a BK blocker, prevented the rolipram-induced blockade of action potentials but not the hyperpolarization. Since cAMP appears to be capable of reducing DSM contractility by mechanisms other than BK channel opening [74], the relevance of BK channel-induced hyperpolarisation to cAMP-dependent relaxation of DSM is of interest.

2.2. Parathyroid Hormone-Related Protein

Parathyroid hormone-related protein (PTHrP) released from DSM upon stretch may act as an endogenous DSM relaxant during bladder filling [75]. A recent study in the rat bladder demonstrated that PTHrP potently suppressed spontaneous phasic contractions, while exerting only a modest inhibitory effect on carbachol-induced contractions [76]. PTH1R, a PTHrP receptor, predominantly locates in the muscular layers of the bladder wall (Figure 3A, [77,78]) and the concurrent expression of PTHrP in DSM indicated that PTHrP may function as a relaxing factor in an autocrine or paracrine fashion. Bath-applied PTHrP largely suppresses spontaneous contractions, while little affecting CCh-induced contractions, indicating that PTHrP appears important for normal bladder function as well as a therapeutic target for overactive bladder. Endogenous and exogenously administered PTHrP may not disturb neurally-mediated detrusor contractions during the voiding phase, while effectively suppressing spontaneous contractions that could stimulate afferent nerve firing (Figure 3B). In contrast, downregulation of PTHrP-mediated stabilisation of DSM contractility may result in overactive bladder or reduced bladder capacity. Indeed, specimens taken from patients who have undergone bladder augmentation invariably show negative PTH1R staining in their DSM [77]. Because the detrusor has a tenfold higher sensitivity to PTHrP compared to the muscularis mucosae, and that they are separated by layers of connective tissue, PTHrP may function as autocrine relaxant of DSM without suppressing mucosa contractility [78].

In other smooth muscles, PTHrP acts via the adenylyl cyclase-cyclic AMP-PKA pathway. However, the involvement of this pathway in detrusor relaxation has not been established. Further studies will be needed to explore the mechanism of PTHrP-induced suppression of spontaneous DSM contractions.
2.3. **PDGFR-α /SK3 Positive Cells**

Interstitial cells that are labelled specifically with antibodies against platelet-derived growth factor receptor-α (PDGFRα-positive cells) functionally express SK3 channels and thus may stabilise DSM excitability by hyperpolarising them [54,55]. PDGFRα-positive cells have also been identified in the detrusor layer and lamina propria of human and guinea pig bladders [79]. Of interest, PDGFRα-positive cells are a subpopulation of vimentin-positive cells and in human and guinea pig bladders a significant proportion co-expresses Kit immunoreactivity. PDGFRα-positive cells have a close apposition with varicose nerve processes within the DSM and lamina propria, and respond to purines by generating apamin-sensitive hyperpolarization [80, suggesting that PDGFRα/SK3 positive cells may also be involved during purinergic inhibition of detrusor excitability. To date, no evidence of electrical coupling between PDGFR-α/SK3-positive cells and neighbouring DSM cells has been demonstrated.

![Image of PDGFR-α /SK3 Positive Cells](image)

**Figure 3. Expression PTHrP-R and function of PTHrP in detrusor smooth muscle (DSM) and muscularis mucosae (MM).** A: Guinea-pig bladder; both DSM and MM express PTHrP receptor immunoreactivity, with weaker expression in the urothelium. Phalloidin label (green) for F-actin in cells: Hoechst label (blue) for nuclei (DNA). B: Bath-applied PTHrP (10 nM, abolishes spontaneous phasic contractions (upper trace), whilst leaving nerve-evoked contractions (single or repetitive stimulation) largely unaffected.

2.4. **TRPV4-BK Coupling**

The activation of TRPV4 with GSK, a TRPV4 agonist, enhances DSM contractility in mouse and rat bladders [41,42]. Thus, TRPV4 expressed in DSM may be considered to have an excitatory effect on DSM excitability/contractility upon bladder filling. In guinea-pig DSM, GSK (1 nM) evoked a sustained contraction associated with a cessation of spontaneous phasic contractions in a manner sensitive to HC-067047, a TRPV4 antagonist [44]. Cessation of spontaneous contractions induced by GSK is reversed or prevented by iberiotoxin or paxilline, BK channel blockers, but not apamin, a SK blocker. GSK abolished spontaneous Ca²⁺ transients, increased basal Ca²⁺ levels and also prevented spontaneous action potential discharge associated with DSM membrane hyperpolarisation (Figure 4A). Iberiotoxin restored spontaneous Ca²⁺ transients and action potentials, and reversed the hyperpolarization. Thus, Ca²⁺ influx through TRPV4 appears to activate BK channels to suppress spontaneous contractions by inhibiting...
EXCITATION-CONTRACTION COUPLING IN BLADDER SMOOTH MUSCLE

LVDCCs (Figure 4B). Since TRPV<sub>4</sub> is a stretch-activated channel, such functional coupling of TRPV<sub>4</sub> with BK channels may ideally function as a self-limiting mechanism for bladder contractility during its storage phase. Of interest, unlike mouse bladder, where the urothelium has a much stronger expression of TRPV<sub>4</sub> than DSM, in the guinea-pig bladder TRPV<sub>4</sub> expression is stronger in DSM compared to urothelium (Figure 4C).

Figure 4. Functional coupling of TRPV<sub>4</sub> with BK in DSM A: GSK, a TRPV<sub>4</sub> agonist, caused a cessation of spontaneous Ca<sup>2+</sup> transients (upper traces from three cells) and action potentials (lower panel). This was followed by a rise of the resting Ca<sup>2+</sup> concentration and membrane hyperpolarisation. Iberiotoxin (IbTX, 100 nM), a BK channel blocker, restored spontaneous Ca<sup>2+</sup> transients and action potentials and also reversed the hyperpolarization. B: A schematic drawing of the proposed relationship between TRPV<sub>4</sub> and K<sup>+</sub>/Ca<sup>2+</sup> channels is shown below, whereby upon bladder wall distension, Ca<sup>2+</sup> influx via stretch-activated TRPV<sub>4</sub> channels activates BK channels to inhibit L-type Ca<sup>2+</sup> channel activity. C: Guinea-pig bladder wall, both DSM and muscularis mucosae (MM) express a strong TRPV<sub>4</sub> immunoreactivity (right panel). A phalloidin label for F-actin is shown in the left panel.

3. DETRUSOR SMOOTH MUSCLE DURING VOIDING PHASE

3.1. Ca<sup>2+</sup>-Dependent Cholinergic Transmission

DSM receives a very high density of parasymptathetic (cholinergic) innervation forming ‘true’ autonomic neuromuscular junctions [67]. Single DSM cells have multiple neuromuscular junctions where their membrane forms very close appositions with a number of nerve varicosities. In normal human DSM, excitatory neuromuscular transmission is exclusively mediated by acetylcholine, while a significant non-cholinergic component is evident during nerve-evoked DSM contraction in other species [9]. Despite a greater density of M<sub>2</sub> muscarinic receptors than M<sub>3</sub> muscarinic receptors in DSM, neurally-released acetylcholine predominantly acts on M<sub>3</sub> muscarinic receptors accounting for over 95% of the cholinergic contraction [81,82]. This suggests that M<sub>3</sub> muscarinic receptors may be clustered within the neuromuscular junctions. The relative contribution of M<sub>3</sub> and M<sub>2</sub> receptors to the carbachol (CCh)-induced contraction appears not to be altered in obstructed human bladders [83].

M3 receptors couple to G<sub>q/11</sub> guanine nucleotide binding proteins that stimulate phosphoinositide hydrolysis by phospholipase C (PLC). Thus, a contribution of inositol 1,4,5-trisphosphate (InsP<sub>3</sub>)-mediated Ca<sup>2+</sup> release from the sarcoplasmic reticulum (SR) to cholinergic-mediated DSM contractions has been suggested. However, it has been suggested that M3 muscarinic receptor-mediated contraction of human
bladder is largely mediated by Ca\textsuperscript{2+} influx through LVDCCs and activation of a Rho-associated kinase (ROCK), while PLC and protein kinase C (PKC) activation are little involved [84] (Figure 5A). The rise of the intracellular Ca\textsuperscript{2+} concentrations upon Ca\textsuperscript{2+} influx through VDCCs will be amplified by Ca\textsuperscript{2+}-induced Ca\textsuperscript{2+} release (CICR) from the SR and activate Ca\textsuperscript{2+}/calmodulin dependent activation of myosin light chain kinase (MLCK) resulting in myosin regulatory light chain phosphorylation to initiate DSM contractions. In guinea-pig detrusor, cholinergic nerve stimulation increases the frequency of action potential firing and induces oscillatory Ca\textsuperscript{2+} transients associated with contractions [37], suggesting the importance of Ca\textsuperscript{2+} influx through LVDCCs in cholinergic contractions. In mouse detrusor when photolysis of caged InsP\textsubscript{3} can promote Ca\textsuperscript{2+} release from the SR, neurally-released ACh triggers bursting action potentials and corresponding Ca\textsuperscript{2+} transients [85]. Moreover, nerve-evoked contractions are greatly suppressed by the blockade of LVDCCs but upon blockade of InsP\textsubscript{3} production or SR Ca\textsuperscript{2+} handling there is little effect, suggesting that InsP\textsubscript{3}-mediated Ca\textsuperscript{2+} release does not participate in cholinergic nerve-mediated contraction.

In human detrusor, neurally-released ACh evokes an inhibitory junction potential (IJP) that is followed by action potential discharge (Figure 5B) [24]). Blockade of SK but not BK channels abolishes the IJP and unmasks an excitatory junction potential (EJP) which triggers multiple action potentials, suggesting that SK channels function as a self-limiting mechanism to prevent an excessive increase of intracellular Ca\textsuperscript{2+} and hence limit the contraction of DSM. Ionic conductances underlying the EJPs have not been identified, but it is reasonable to assume that CACL or Ca\textsuperscript{2+}-activated TRPM4 may be involved (Figure 5B). A recent

**Figure 5. Cholinergic transmission in human detrusor smooth muscle (DSM).** A: Junctional and ‘extrajunctional’ transmission. Receptors that activate depolarisation-induced Ca\textsuperscript{2+} influx and PKC-dependent Ca\textsuperscript{2+} sensitisation by nerve mediated stimulation (left). Bath-applied muscarinic agonists (right) act preferentially on ‘extrajunctional’ M3 receptors to activate ROCK the signalling pathway as well as depolarisation-induced Ca\textsuperscript{2+} influx. B: Left traces: nerve (cholinergic) stimulation evokes an inhibitory junction potential (IJP: black trace) followed by action potential firing. Lower panel: After blockade of SK channels, the IJP is converted to an excitatory junction potential (EJP) to trigger more rapidly an action potential (blue trace). Lower traces: After nifedipine treatment nerve stimulation evokes a small IJP (black trace) that is followed by a slow depolarisation. After blockade of SK channels, an IJP is unmasked (blue trace). M3 receptor stimulation appears concurrently to activate SK channels and Ca\textsuperscript{2+}-activated inward currents. Schematic diagram of the inter-relationship between L-type Ca\textsuperscript{2+} channels (LVDCC), SK channels and muscarinic receptor activation.
study using isolated human DSM demonstrated that muscarinic receptor stimulation results in the suppression of BK channel-dependent transients outward currents and membrane depolarization by modulating intracellular Ca\textsuperscript{2+}, but not by directly inhibiting BK channels [86]. Therefore, BK channels that play a predominant role in stabilising DSM excitability may be suppressed during cholinergic transmission, while SK channels may have a counteracting action.

3.2. Ca\textsuperscript{2+}-Sensitisation in Cholinergic Transmission

In addition to the Ca\textsuperscript{2+}-dependent contractile pathway, the stimulation of muscarinic receptors is thought to recruit ROCK- and PKC-dependent Ca\textsuperscript{2+} sensitization of the DSM contraction mechanism [87]. A study using transgenic mice expressing calmodulin sensor MLCK in smooth muscle demonstrated that activation of DSM muscarinic receptors by neurally-released ACh leads to phosphorylation of the 17 kDa PKC-potentiated protein phosphatase 1 inhibitor (CPI-17) to enhance Ca\textsuperscript{2+} sensitivity, but not the myosin-targeting subunit of MLCP (MYPT1). This may suggest that ROCK-mediated Ca\textsuperscript{2+} sensitization is not involved in cholinergic neuromuscular transmission [88]. The involvement of the ROCK signalling pathway in muscarinic DSM contraction has been demonstrated using only high concentrations of bath-applied muscarinic agonists, thus signalling pathways underlying neurally-released transmitters and bath-applied agonists could well be different. In murine gastric fundus, cholinergic motor neurotransmission activates PKC-dependent CPI-17 phosphorylation, while bath-applied carbachol recruits additional ROCK-dependent MYPT1 phosphorylation [89]. Thus, carbachol, as a muscarinic agonist, was proposed to activate 'non-junctional' muscarinic receptors, indicating that focalized (or synaptic-like) neurotransmission, rather than diffuse 'volume' neurotransmission operates in this tissue. Likewise, neurally-released ACh in DSM may access only 'junctional' M3 receptors, while bath-applied muscarinic agonists may preferentially act on 'extra-junctional' M3 receptors (Figure 5A). ROCK inhibitors do suppress spontaneous phasic contractions [90] or high-potassium-induced contractions in guinea-pig DSM [91]. Therefore, constitutively active ROCK may contribute to basal MYPT1 phosphorylation to enhance Ca\textsuperscript{2+}/calmodulin dependent contractility. In rabbit DSM, activator of PKC with phorbol12,13-dibutyrate induces contraction which involves both PKC and ROCK signalling pathways [92]. CPI-17 is phosphorylated directly by PKC and indirectly via PKC-dependent activation of ROCK, but ROCK mediated-MYPT1 phosphorylation is not involved. A constitutively active isoform of ROCK that apperas to be different form that activated by PKC may contribute to the high basal MYPT1 phosphorylation in DSM.

Increased expression of RhoA and ROCK and enhancement of CCh-induced tonic contraction that is sensitive to ROCK inhibitors have been reported in obstructed [93] and ischaemic [94] rat bladders. In addition, bladder outlet obstruction enhances the ROCK pathway, increasing CCh-induced Ca\textsuperscript{2+} sensitization of permeabilized guinea pig DSM, while diminishing the contribution of the PKC pathway [95]. This suggests that the ROCK pathway plays a larger role in regulating the contractility of pathological DSM.

DSM from diet-induced obese mice displays an overactive bladder phenotype and develops greater contractions irrespective of the stimuli (e.g. with CCh, α, β-methylene ATP or KCl) which are fully reversed by an LVDCC blocker [96] even in the absence of an up-regulation of Ca\textsuperscript{2+}-channel (Cav1.2) protein expression. Chronic but not acute metformin treatment improves their insulin sensitivity and normalizes the in vitro bladder hypercontractility as well as their cystometric dysfunction. PKC protein expression is higher in DSM from obese mice and reversed upon treatment with an LVDCC blocker or metformin. Thus it appears that insulin resistance and the enhanced Ca\textsuperscript{2+} influx though LVDCC and PKC upregulation are causes of detrusor overactivity by mechanisms yet to be identified. KCl-induced contractions are augmented in DSM taken from hypercholesterolemic rats, but their spontaneous and CCh-induced contractions are not altered [97]. Although the relative contribution of M3/M2 receptors to these CCh-induced contractions are not changed, LVDCCs blockade results in a much larger inhibition of M3-mediated contractions in hypercholesterolemic DSM, whereas ROCK-dependent components are not altered. Therefore, changes in DSM contractility in hypercholesterolemia may also be attributed to altered properties of LVDCCs. Of interest, a study using adiponectin-sense-transgenic (Adip-Sen) mice demonstrated that their DSM exhibit a larger Ca\textsuperscript{2+} dependency of CCh-induced contractions, attributed to an increased expression of the Ca\textsuperscript{2+}-dependent isoform of PKC, PKCα resulting in Ca\textsuperscript{2+} sensitization [98]. Since adiponectin is an endogenous antidiabetic factor that is reduced in individuals with obesity, this finding is apparently contradictory to the observation in metabolic syndrome model animals.

3.3. Purinergic Transmission

Non-cholinergic DSM contractions are mediated by ATP, co-released with ACh from parasympathetic nerves, acting on P2X purinoceptors. In guinea-pig, neurally-released ATP evokes excitatory junction potentials (EJPs) which trigger action potentials and associated Ca\textsuperscript{2+} transients to contract DSM [37]). Purinergic contractions appear to result from Ca\textsuperscript{2+} influx through LVDCCs that is amplified by CICR. A study using transgenic mice expressing calmodulin sensor MLCK in smooth muscles demonstrated that purinergic transmission has a larger contribution to the initial contractile phase during nerve-evoked contractions, while cholinergic transmission is dominantly involved in the sustained phase [88]. Purinergic transmission induces Ca\textsuperscript{2+}/calmodulin dependent activation of
MLCK resulting in myosin RLC phosphorylation without causing CPI-17 phosphorylation, suggesting that purinergic contraction is exclusively Ca\textsuperscript{2+} dependent.

Unlike normal human bladder in which neurally-mediated DSM contractions exclusively rely on the release of ACh, atropine-resistant components can be seen under pathological conditions [98]. Furthermore, a recent study has demonstrated that normal paediatric DSM also exhibits a purinergic contraction that decreases with postnatal development [100]. An in vitro contractile study has also demonstrated that exposure of DSM strips to cycles of hypoxia–glucopenia and reoxygenation increases the atropine resistant component of EFS-induced contractions, while not increasing the cholinergic component [101]. The augmentation of purinergic transmission may be attributed to increases in the expression of P2X1 receptor.

The mucosa of guinea-pig and pig bladders contracts spontaneously or in response to electrical field stimulation or bath-applied agonists such as CCh, purines or neurokinins [106-108]. In the guinea pig bladder, the muscularis mucosa is a thin layer located between the urothelium and detrusor, displays immunoreactivity to α-smooth muscle actin, and is thus considered a source of spontaneous contractions [109]. In the human urinary bladder, the muscularis mucosa forms a discontinuous layer that is clearly distinct from the detrusor, and is well recognised as an anatomical landmark for bladder cancer staging. In the bladder of rat, rabbit, cat and dogs, the muscularis mucosa is not morphologically evident, perhaps explaining the lack of mucosa contractile activity in these species.

Since the bladder mucosa develops a much larger contraction per unit cross-sectional area than DSM [108], specialised contractile elements such as myofibroblasts or the microvasculature have been suggested to contribute to mucosa contractile function. A recent study examined the contractility of ‘isolated’ muscularis mucosa strips in which the urothelium and suburothelial blood vessels had been removed (Figure 6, [78]). The muscle force generated by ‘isolated’ muscularis mucosa per sectional area was approximately eight times larger compared to that of detrusor. Moreover, the non- muscularis mucosa area of the mucosa did not exhibit any spontaneous contractions. Thus, the muscularis mucosae appears to be the main contractile element in the mucosa, but the specialised contractile machinery that generates such a large cross-sectional force compared to the detrusor is not yet established.
The mucosa shares a number of common properties with detrusor smooth muscle, but also displays some differences. For example, BK and SK channels play a less prominent role in regulating mucosa spontaneous contractions [100]. Capsaicin enhances spontaneous contractions in the detrusor, while suppressing those of the mucosa [109] or ‘isolated’ muscularis mucosae [79].

Despite the presence of muscularis mucosae in the bladder of several species including human, its physiological role is not well understood. An early report implied that muscularis mucosae bundles are associated with suburothelial blood vessels in the human bladder. In the guinea-pig bladder, immunohistochemical analysis of whole mount mucosa demonstrated that the muscularis mucosae is preferentially colocalised along the long axis of suburothelial blood vessels, while some is sparserly distributed in non-vascular areas (Figure 6, [77]). Such a morphological relationship between muscularis mucosae and suburothelial blood vessels may indicate that spontaneous contractions of the muscularis mucosae prevent the vessels from stretching upon bladder wall distension. Contraction of muscularis mucosae may also effectively maintain the folding of the urothelium. In addition, muscularis mucosae may cause larger mechanical stimuli to suburothelial sensory nerves than DSM, and thus may have an important role in sensing bladder fullness in normal and pathological bladders (Figure 6). Even though mice and rats are the most common species used for investigating bladder function their lack of a muscularis mucosae and a non-contractile muscosa, limits their use as a model of human bladder.

4.2. Suburothelial Microvasculature

Ischaemic and reperfusion damage to the cells in the bladder wall has been considered as a major cause of lower urinary tract symptoms associated with ageing and metabolic syndrome [110-112]. Previous
studies have focused on the insufficient blood supply to the bladder due to the occlusion of the iliac artery associated with atherosclerosis, using animal models that have undergone local endothelial injury to induce chronic bladder ischaemia [113-114]. The iliac artery, particularly at its bifurcation, is indeed the site where atherosclerosis preferentially develops upon endothelial dysfunction [115]. Vasorelaxants such as α-adrenoceptor antagonists, β3-adrenoceptor agonists and PDE5 inhibitors, improve bladder storage function without improving the narrowed luminal diameters of the feeding arteries [110]. This suggests that their therapeutic effects can be attributed to their actions on the contractile and/or morphological properties of the microvasculature within the bladder wall. The bladder microvasculature may also be the origin of bladder dysfunction seen in systemic vascular dysfunction models [116,117]. However, current information on the functional characteristics of the bladder microvasculature is limited.

Blood vessels in the bladder wall are characterised by their tortuous arrangement to efficiently accommodate the considerable spatial changes associated with the cyclic stretching and relaxation of the bladder wall during the micturition cycle [118]. Thus, they are capable of maintaining their diameters so that the resistance against blood flow is not increased during the filling phase. Besides this structural characteristic, suburothelial venules in the bladder of rat [67,70] and mouse [119] develop spontaneous phasic constrictions so that the venules may actively facilitate venular drainage. In the rat bladder, venular constrictions predominately arise through contractions of circumferentially-arranged venular smooth muscle cells, while stellate-shaped pericytes also exhibit spontaneous Ca2+ transients and contractions. In the mouse bladder, the contractile mural cells generating spontaneous Ca2+ transients are stellate-shaped pericytes, while spindle-shaped smooth muscle cells are distributed only in the proximal, larger venules.

The mechanisms underlying spontaneous venular constrictions are action potentials arising from the

---

**Figure 7. Spontaneous contractions and Ca2+ transients in suburothelial venules.**

**A:** Spontaneous depolarisations (upper trace) from a venular pericyte and synchronous Ca2+ transients (lower traces) from three associated cells from a network of cells. The pericyte network from where the Ca2+ transients are shown below. ∆Ft/F0 as used in the calibration bars for the Ca2+ transients is a positive function of the intracellular [Ca2+].

**B:** Blockade of L-type voltage-dependent Ca2+ channels (LVDCC) with nicardipine suppresses Ca2+ transients and disrupts synchrony.
opening of LVDCCs (Figure 7A, [67,119]). Blockade of LVDCCs suppresses venule spontaneous Ca\(^{2+}\) transients and also disrupts their synchrony with the contractile mural cells, indicating they play a critical role in maintaining multicellular coupling (Figure 7B). After the blockade of LVDCCs, mural cells are capable of generating asynchronous spontaneous Ca\(^{2+}\) transients resulting from InsP\(_3\)-induced Ca\(^{2+}\) release from the SR, suggesting that the SR plays a primary role in generating venular spontaneous activity. Subsequent opening of Ca\(^{2+}\)-activated chloride channels results in depolarisation triggering the opening of LVDCCs and associated Ca\(^{2+}\) influx to cause venular constrictions, (Figure 7A). Spontaneous constrictions of the suburothelial venules are accelerated by neurally-released noradrenaline upon the activation of \(\alpha\)-adrenoceptors [70]. After \(\alpha\)-adrenoceptor blockade, sympathetic nerve stimulation inhibits spontaneous constrictions that may involve endothelial NO production.

Unlike venules, suburothelial arterioles are quiescent at rest. Noradrenaline released from sympathetic nerves predominantly acts on \(\alpha_1A\)-adrenoceptors to constrict arterioles [69]. Consistently, varicose nerve bundles immunoreactive for tyrosine hydroxylase, a. marker of sympathetic nerves, are distributed along the side of suburothelial arterioles [120]. This pharmacological profile of suburothelial arterioles may partly explain the improvement of bladder microcirculation and storage function with \(\alpha\)-adrenoceptor antagonists in overactive bladder animal models [121,122].

5. TRIGONE

5.1. Spontaneous Activity

Because of its structural connection to the intravesical portion of the ureter, the trigone can play a role in regulating the opening and/or closure of the ureteral orifices. The main mechanism to prevent vesicoureteral reflux is the oblique angle of the insertion of the ureter through the bladder wall, providing a compression valve as the bladder fills. However, periodic trigone contractions may support opening of ureteral orifices to facilitate filling and may also assist compression during contraction. Spontaneous phasic contractions are present in 71% and 89% of trigone strips from pigs and humans, respectively, compared to 20% of detrusor [9]. The detailed mechanisms underlying the spontaneous contractility were studied in the superficial trigone of the guinea pig bladder, in which the majority of muscle strips generated spontaneous phasic contractions [123]. Smooth muscle cells isolated from the trigon exhibited either discrete or, less often, fused Ca\(^{2+}\) transients that were abolished by either a LVDCC blocker or Ca\(^{2+}\) free solution, but not by thapsigargin, an inhibitor of SR Ca\(^{2+}\) uptake, or FCCP, a mitochondrial uncoupler. Thus, spontaneous Ca\(^{2+}\) transients result from Ca\(^{2+}\) influx through LVDCCs, while intracellular Ca\(^{2+}\) stores are not fundamentally involved. Spontaneous contractions in trigone strips are also abolished by LVDCC blocker or Ca\(^{2+}\) free solution, but not the T-type Ca\(^{2+}\) channel blocker, NiCl\(_2\). Trigonal smooth muscle fire bursting action potentials, although their sensitivity to LVDCC blockers has not been tested [124], suggesting that as in the case of DSM electro-mechanical coupling may be crucial in developing spontaneous contractions. Consistently, in the pig trigone, cromakalim suppresses spontaneous contractions, presumably by opening K\(_{ATP}\) channels to hyperpolarise the membrane [125]. Since niflumic acid, a CACL blocker, attenuates trigonal Ca\(^{2+}\) transients and muscle contractions, these CACls may activate LVDCCs by depolarising the membrane. Unlike DSM in which BK and SK channels play major roles in stabilising muscle excitability, the blockade of BK or SK channels little affect spontaneous the Ca\(^{2+}\) transients in trigonal smooth muscle cells. Obviously, extensive electrophysiological investigations are required to understand the regulatory mechanisms of trigonal smooth muscle excitability.

Immunolabeling of gap junctions (Cx43) was approximately 5 times greater in the trigone than in detrusor smooth muscle [123]. 18-ß-glycyrrhetinic acid, a gap junction blocker, reduces the amplitude but increases their frequency of the spontaneous contractions in the trigone, suggesting that intercellular communication may play a role in developing such contractions. Spontaneous electrical activity in the trigone is generated independently from that in the detrusor, indicating that the trigonal syncytium is not continuous with detrusor [126]. Interestingly, electrical activity in the trigone is unchanged during the filling and voiding phases, while the electrical activity in the detrusor is dramatically increased during voiding. More recently, spatiotemporal mapping techniques have also demonstrated that propagating patches of contraction travelled mainly along the anterior and lateral surface of the bladder and did not traverse the trigone [127].

5.2. Neuromuscular Transmission.

Neurally-evoked contractions of the superficial human trigone are predominately mediated by \(\alpha\)-adrenergic, in contrast to detrusor, and cholinergic nerves [128]. Trigonal smooth muscle vigorously contracts upon \(\alpha\)-adrenergic receptor stimulation but also responds to ACh. After the blockade of \(\alpha\)-adrenergic and cholinergic transmission, the trigone exhibits residual non-adrenergic, non-cholinergic (NANC) contractions as well as relaxations.
In the guinea pig superficial trigone, phenylephrine augmented carbachol-induced contractions (4-fold of control) without a corresponding increase in intracellular Ca\(^{2+}\) concentration ([Ca\(^{2+}\)]) [129]. Phenylephrine generated a greater contraction for a given rise of [Ca\(^{2+}\)] compared to KCl-induced contractions, suggesting that \(\alpha\)-adrenergic activation also recruits Ca\(^{2+}\)-sensitisation mechanisms. The PKC inhibitor GF 109203X and the ROCK inhibitor Y-27632 reduced the phenylephrine contractions by 60 and 40 %, respectively, without altering the Ca\(^{2+}\) transients. Thus, the synergistic effects of muscarinic and adrenergic receptor activation on trigonal contractility appear to result from an \(\alpha\)-adrenergic evoked Ca\(^{2+}\)-sensitisation mechanism. Similarly, phenylephrine-induced contractions in rat trigonal smooth muscle are suppressed by ROCK inhibitors [130]. ROCK inhibitors also reduced the basal tone and \(\alpha,\beta\)-mATP-induced contractions, although they only marginally affected KCl-induced contractions. Thus, constitutively active ROCK that facilitates Ca\(^{2+}\)-dependent contractions may contribute to the contractile function of trigonal smooth muscle. In comparison to the trigone of young rats, the trigone of old animals display a significant decrease in the contractions evoked by electrical stimulation, high potassium and bethanechol. This suggests that this may be attributable to a decline in depolarisation-induced contractions of the trigone, most likely upon the opening of LVDCCs [131]. The relative contribution of electro- and pharmaco-mechanical coupling as well as MLCP-based Ca\(^{2+}\)-sensitisation to trigonal contractile function remains to be established. In the pig bladder trigone, the presence of an intact urothelium depresses the contractile responses to carbachol or histamine, but not phenylephrine. Phenylephrine-induced contractions of intact urothelium strips are diminished by carbachol or histamine in a manner sensitive to atropine or mepyramine, respectively [132], suggesting that muscarinic or H1 receptor activation in the urothelium may release ‘unidentified’ relaxing factors.

NOS-immunoreactive nerve fibres distribute within the muscle bundles of pig trigone [133] Electrical field stimulation of pig trigonal muscle strips induces relaxations, which are inhibited by NG-nitro-L-arginine, a nitric oxide (NO) synthase inhibitor, suggesting a functional nitricergic innervation to trigone. Trigonal relaxation induced by low frequency stimulation was associated with increased formation of cGMP and abolished by ODQ. Neurally-released NO therefore relaxes trigonal smooth muscle by stimulating soluble guanylate cyclase to produce cGMP [134,135]. Intracellular signalling pathways involved in the nitricergic relaxation of the trigone remains largely unknown. High frequency nerve stimulation triggers NO-independent relaxation that is not impaired by ODQ or blockers of BK, SK or K\(_{ATP}\) channels. Capsaicin, chymotrypsin, a VIP receptor inhibitor or \(\beta\)-adrenoceptor antagonists also fail to inhibit the NO-independent relaxation, thus the transmitter or mechanism of this relaxation remains to be identified.

### III. CELL PHYSIOLOGY OF INTERSTITIAL CELLS IN THE URINARY BLADDER

#### 1. INTERSTITIAL CELLS IN SMOOTH MUSCLE TISSUES

Interstitial cells (IC) refer to a class of non-muscle cells found in the interstitium of smooth muscle tissues such as the gastrointestinal tract and the urinary tract. In the gut, these cells, first described by the Spanish neuroanatomist Ramon y Cajal and known as Intestinal Cells of Cajal (ICC) act as pacemakers driving peristaltic activity of the smooth muscle and contributing to the transmission of signals from enteric nerves to smooth muscle. In the lower urinary tract (LUT) similar non-muscle cells are present in the bladder and urethra and are typically described in the literature as Cajal-like cells, ICC-like cells, myofibroblasts, ICC, IC or other related terms such as telocytes.

Several review articles have summarised what is known of the localisation and morphology of LUT IC from electron microscopy, histology, immunofluorescence and multiphoton/confocal microscopy and isolated cell studies [136-142]. The purpose of the present chapter is not to review all of the early literature but to provide an updated review of what we know of the cellular physiology of bladder IC. Importantly, studies of LUT IC in disease have been reviewed and essential gaps in our knowledge are highlighted.

#### 2. LOCATION OF BLADDER INTERSTITIAL CELLS

IC have been studied in the bladder for almost two decades and many independent groups have described a number of classes or subtypes based on their location. IC in the lamina propria (IC-LP, Figure 8) form a network between the urothelium and the detrusor muscularis [14, 143-145] and have been further classified as upper IC-LP and deep IC-LP [146]. Perivascular IC are found surrounding the microvessels in the lamina propria and may belong to the pericyte family [119,120,147-149] (Figure 9). Within the detrusor layer, intramuscular IC (IC-IM) lie on the edge of smooth muscle bundles, running in parallel with the bundle axis and a further subtype forms small networks in the interbundle spaces (IC-IM). Serosal IC have also been reported in guinea-pig bladder [150].

While the above describes IC subtypes based on their location, several biomarkers are used to identify IC in tissue specimens, freshly isolated cell suspensions or cell cultures. The receptor tyrosine kinase KIT, encoded by the proto-oncogene c-kit is an established...
marker of ICC in the gastrointestinal tract and many studies report KIT-positive IC in the urinary bladder [14,145,147,151-153]. The intermediate filament vimentin, is expressed by many IC, and KIT-positive IC represent a sub-population of vimentin-positive IC. Like the gut, the bladder also contains KIT-negative IC and it seems that the majority of these are vimentin-positive [144-146,154]. Whilst antibody specificity and species differences of KIT epitopes may explain KIT-negative IC, it is more likely that KIT-negative cells are a specific IC subtype and bladder IC are a heterogeneous group of cells with a spectrum of phenotypes ranging from fibroblastic to myoid. Expression of KIT has been suggested to be age-related with higher expression in neonatal bladders than young adult (see section on ageing below).

Platelet-derived growth factor receptor alpha (PDGFRα), another receptor tyrosine kinase, is expressed by a significant proportion of human, guinea-pig and mouse bladder IC providing another biomarker for identification [53,57]. In mouse bladder, PDGFRα-IC are KIT-negative whereas in guinea-pig and human bladder, some IC are positive for both KIT and PDGFRα while others are only PDGFRα-positive [154]. NTPDase, a member of the ectonucleotidase family has also been demonstrated as a marker of murine bladder IC, colocalising with KIT, vimentin, Ano1 and Cx43 [155]. IC-LP and detrusor IC that are also N-cadherin-positive have also been reported in human bladder, which strongly resemble KIT-positive or vimentin-positive IC in other studies [141]. Finally, CD34 is expressed by some IC in human bladder which were KIT-negative, providing a further means of classification [154].

IC associated with bladder microvessels have been identified with KIT, PDGFRα and vimentin (see also section II.4.2). Like other IC, perivascular IC have a defined ultrastructural phenotype which is distinctive from vascular smooth muscle and other non-muscle cells e.g. fibroblasts, mast cells and myofibroblasts. Interestingly, they make close associations with vascular smooth muscle cells with end-foot like connections and have been proposed to be involved in the local regulation of vascular perfusion of the bladder.

Figure 8. Interstitial cells of the lamina propria. A: Haematoxylin & eosin stained section of guinea-pig bladder showing the mucosal layer which includes the urothelium, lamina propria and muscularis mucosae. Networks of interstitial cells are present in the lamina propria. B: Confocal image of vimentin-positive (green) interstitial cells in a whole-mount sheet of rat bladder mucosa (nuclei are counterstained with DAPI (blue)). C: Recording of Ca2+-signalling activity in four neighbouring interstitial cells in the guinea-pig lamina propria. Electrical field stimulation (EFS) of nerves (2 Hz) synchronized the events in the four cells demonstrating functional innervation. (figure courtesy of Bronagh M McDonnell, Susannah MY Gray and Karen D McCloskey)
3. BLADDER IC RECEPTORS

The physiological properties of bladder IC have been studied with patch-clamp electrophysiology, live-cell Ca²⁺-imaging with epifluorescence or confocal microscopy and modulator release assays. Perhaps unsurprisingly, bladder IC express many of the receptors and ion channels that are found in urothelial cells, intramural nerves and smooth muscle cells and there is compelling evidence that they are closely involved in processes underpinning filling, voiding and sensing of fullness.

3.1. Muscarinic Receptors

Muscarinic receptors M2 are the dominantly expressed subtype on detrusor smooth muscle compared with M3 in a 3:1 distribution. Nevertheless, M3 are apparently more important than M2 in the modulation of bladder contraction. Detrusor IC functionally express M3 receptors; activation by acetylcholine or its stable analogue carbamylcholine (carbachol) in isolated cells evoked large Ca²⁺-transients which showed some sensitivity to M2 antagonists but were blocked by M3 antagonists [156]. In cultured murine detrusor IC, cholinergic agonists evoked transient inward currents which were sensitive to the pan-cholinergic antagonist atropine, and the M3-selective antagonist, 4-DAMP [157,158]; furthermore; M2 and M3 receptors were demonstrated to be expressed on rat bladder KIT positive-IC with immunofluorescence.

Figure 9. Cell physiology of perivascular interstitial cells. A: Confocal image of KIT-positive interstitial cell of the lamina propria (IC-LP) and perivascular interstitial cell in the guinea-pig bladder (nuclei counterstained with DAPI (blue)). B: Recording of Ca²⁺-signalling activity in a perivascular interstitial cell and an adjacent vascular smooth muscle cell in the guinea-pig bladder. Electrical field stimulation of nerves (0.5 Hz) increased the frequency of events in the perivascular interstitial cell and evoked a response in the vascular smooth muscle cell, demonstrating functional innervation. (figure courtesy of Susannah MY Gray and Karen D McCloskey)
Carbachol evoked membrane depolarisation and increased the frequency of spontaneous transient depolarizations in cultured mouse detrusor IC [157]. This was consistent with an ex vivo study of guinea-pig bladder tissue where exogenous application of carbachol evoked Ca\(^{2+}\)-transients [156]. Furthermore, in a later study, stimulation of intramural nerves in similar preparations with electrical field stimulation (EFS) elicited atropine-sensitive Ca\(^{2+}\)-transients, showing that bladder IC were functionally innervated by cholinergic nerves [160].

Freshly dispersed guinea-pig IC-LP are reportedly insensitive to cholinergic agonists although purinergic receptors were expressed on the same cells [158]. The lack of physiological response may be a consequence of the particular cell isolation technique used as guinea-pig IC-LP in situ responded to EFS by firing atropine-sensitive Ca\(^{2+}\)-transients [148].

### 3.2. Purinergic Receptors

ATP is an important neurotransmitter in the bladder, along with acetylcholine. In mouse bladder, contractile responses to EFS are almost 50% atropine-sensitive and 50% PPADS or suramin-sensitive (indicating acetylcholine or ATP respectively as a neurotransmitter). ATP is also a co-transmitter with acetylcholine in rat, guinea-pig, rabbit and sheep however, the situation is rather different in normal human bladder where the EFS response is almost exclusively cholinergic. Purinergic receptors are expressed on human bladder smooth muscle cells, thus either ATP is not co-released with acetylcholine or the purine is completely degraded in the neuromuscular space so that it does not activate the detrusor cell. It has been reported that an ATP-sensitive component of EFS emerges in disease conditions, such as overactive or obstructed bladders (see section II.3.3 above). In the normal bladder, non-neuronal sources of ATP release, including urothelium could activate smooth muscle cells or IC to potentially contribute to mechanisms of sensory transduction or relaxation during filling. Consistent with this notion, cultured human and freshly-dispersed guinea-pig IC-LP respond to ATP and the P2X\(_{10}\) agonist, α,β-methylene ATP with Ca\(^{2+}\)-signals [147,158] and which were sensitive to the P2X receptor antagonist, TNT-ATP [161]. Moreover, immunofluorescence shows protein expression of P2X\(_1\), P2X\(_2\) and to a lesser extent, P2X\(_3\) on IC-LP.

Studies with animal tissue demonstrate that IC-LP from guinea-pig and rat bladder generate Ca\(^{2+}\)-signals, transient inward currents and transient depolarizations in response to exogenous ATP [41,158,162]. In tissue preparations, IC-LP respond to EFS by generating Ca\(^{2+}\)-signals which were sensitive to the pan-purinergic receptor antagonist, suramin [160]. Murine detrusor PDGFRα-positive IC express P2Y\(_1\), receptors which when stimulated by ATP, activate small-conductance Ca\(^{2+}\)-activated-K\(^+\) (SK) channels leading to hyperpolarisation [54]. Activation of SK channels in these same cells by UTP (a P2Y\(_2\) and P2Y\(_4\) agonist) has also been reported along with mRNA expression of several P2Y subtypes, including P2Y\(_{2}\), P2Y\(_4\), P2Y\(_6\), P2Y\(_{12}\), P2Y\(_{13}\), P2Y\(_{14}\), in addition to P2Y\(_1\) [78].

In an electrophysiological study of cultured KIT-positive IC from mouse detrusor, nifedipine-sensitive spontaneous electrical activity has been reported [157], providing confirmation of the essential role of L-type Ca\(^{2+}\)-channels [163] in this activity. ATP also depolarised these cells [157] and increased the frequency of spontaneous transient depolarisation firing, demonstrating that release of ATP from neuronal or non-neuronal sources can impact on their electrical excitability.

### 4. BLADDER IC ION CHANNELS

#### 4.1. Potassium Channels

A number of K\(^+\)-channels are functionally expressed on bladder IC through patch-clamp studies. As discussed above, SK channels are present on murine detrusor PDGFRα-positive IC [54] where large-conductance Ca\(^{2+}\)-activated-K\(^+\) (BK) are apparently absent. The SK3 channel isoform gene was dominantly expressed compared with SK1, SK2 and SK4. In contrast, guinea-pig detrusor IC, have dominant BK currents with kinetics distinctively different from BK currents in neighbouring smooth muscle cells but with little evidence for SK channels [164] (Figure 10). Guinea-pig detrusor IC, in addition to BK channels, also express a number of voltage-dependent K\(^+\) channels including the Kv7 family, encoded by KCNQ genes. The Kv7 channels are involved in regulation of the IC resting membrane potential and providing a control mechanism to prevent over-excitability. Inhibition of Kv7 channels resulted in increased duration of spontaneous Ca\(^{2+}\)-events, membrane depolarization and increased spontaneous contractions and baseline tone suggesting that IC regulation of contractility may involve Kv7 mediated hyperpolarisation.
4.2. Calcium Channels
Bladder IC have been reported to express both L-type (CaV1) and T-type (CaV3) Ca²⁺ channels. Guinea-pig detrusor IC have classical nifedipine-sensitive inward Ca²⁺ currents which would provide a depolarising mechanism for the membrane potential. Rat bladder IC were shown, with immunohistochemistry and PCR, to express CaV3.1 (α1G), CaV3.2 (α1H) and CaV3.3 (α1I) channels [165]. This is consistent with an electrophysiological study of L-type currents in guinea-pig bladder detrusor IC which also reported a nifedipine and Ni²⁺-insensitive inward Ca²⁺ current which may be CaV3.1 or CaV3.3 rather than CaV3.2, which is less-sensitive to Ni²⁺ inhibition [163]. In contrast, PDGFRα-positive IC from mouse bladder reportedly do not have inward Ca²⁺ currents [54], highlighting species or cell type differences in physiological properties.

4.3. Hyperpolarisation-Activated Cyclic nucleotide-Dependent (HCN) Channels
Some early papers speculated whether detrusor IC could act as pacemakers, driving the activity of neighbouring smooth muscle cells. This hypothesis, triggered by the known role of gut ICC as pacemakers of smooth muscle activity and peristalsis, seemed unlikely unless a candidate pacemaker current could be identified. More recent work has demonstrated the presence of currents mediated by HCN channels, (Iₜ). Gene [166] and protein expression of HCN channels in human and rat IC-LP and detrusor IC by immunofluorescence [167,168] was confirmed with patch-clamp studies. The electrophysiological studies described a slowly-activating but non-inactivating current, also activated by hyperpolarisation, and was sensitive to the pan-HCN inhibitor, ZD7288 [166-168]. ZD7288 reduced baseline Ca²⁺ in isolated IC and diminished spontaneous contractions in strips from rats with detrusor overactivity [166]. This work adds support to the notion of detrusor IC having pacemaker type functions, however, the mechanism linking IC to smooth muscle has not yet been elucidated.

4.4. Chloride Channels
Calcium-activated chloride channels ICl(Ca) are important in guinea-pig IC-LP, providing depolarization when activated by ATP and underpinning spontaneous transient depolarisations [158]. Also an attractive candidate for pacemaking in detrusor IC, there is currently no electrophysiological evidence in support of ICl(Ca) in these cells although gene expression of
intracellular Ca\textsuperscript{2+}

Anoctamin-1 (Ano-1), and protein expression of Ano-1 in juvenile rat mucosa and detrusor vimentin-positive-IC has been reported [169]. Application of channel inhibitors to detrusor strips diminished spontaneous activity however one should be mindful of the additional effects of these inhibitors as activators of BK channels and inhibitors of L-type Ca\textsuperscript{2+} channels. which would also bring about similar effects.

4.5. Other Signalling Pathways

One of the first studies to show IC in the bladder demonstrated that the cellular targets of nitric oxide signalling with cGMP immunohistochemistry were non-muscle cells with the multi-branched morphology of ICC [143]. This work was corroborated by a number of other studies reviewed by McCloskey [140,170]. More recently, nitric oxide-guanylyl cyclase has been reported to be present in murine detrusor PDGFRα-positive IC [171]. Of interest, in contrast to the urethra where NO-GC is expressed in smooth muscle cells and its activity leads to relaxation, bladder NO-GC does not contribute to a NO-induced relaxation and currently has an unknown role. Phosphodiesterase type-2 (PDE2) expression on IC-LP and detrusor IC of guinea-pig bladder has also been reported [172]. Phosphodiesterases terminate NO-cGMP signalling by hydrolysing cGMP to 5′-GMP and are used clinically to treat erectile dysfunction and bladder storage disorders. Furthermore PDE5 inhibition has been described in IC-LP indicating the expression of PDE5 receptors on these cells [173].

Bladder IC may release modulator substances under certain conditions. For example, in a cultured model of pig IC-LP, stretch evoked the release of ATP [161], similar to what is already known of urothelial cells. In addition to ATP, bladder IC also release prostaglandins, an important modulator of bladder contractility [151]. An investigation of the source of prostaglandins in rabbit bladder revealed that KIT-positive/Vimentin-positive IC expressed cyclooxygenases 1 and 2 (COX1 and COX2). Prostaglandins, products of COX were shown in the same study to modulate bladder spontaneous contractions whereas COX inhibitors diminished contractility.  This suggested that one role of bladder IC was to modulate spontaneous activity by release of prostaglandins. Vimentin-positive guinea-pig IC-LP and detrusor IC subtypes express both prostaglandin E receptor type-2 (EP2) and COX1, also highlighting the potential importance of prostaglandin pathways in these cells [174].

IC in gut and the lower urinary tract share features of intracellular Ca\textsuperscript{2+} signalling, which is both spontaneous in nature and in response to stimulation by agonists or neurotransmitter substances. Cultured human IC-LP exhibit spontaneous intracellular Ca\textsuperscript{2+} transients, representing 55% of the cells observed with the frequency of events and the percentage of active cells enhanced by ATP [161]. IC-LP from guinea-pig bladder also exhibit spontaneous Ca\textsuperscript{2+}-events; a feature of around 50% of cells [158]. These cells also respond to ATP, UTP and a reduced extracellular pH by generating Ca\textsuperscript{2+}-transients [162]. Freshly dispersed guinea-pig detrusor IC exhibit spontaneous Ca\textsuperscript{2+}-transients and in response to cholinergic stimulation [14,156].

Intracellular Ca\textsuperscript{2+}-signalling has also been measured from IC whilst within a multicellular tissue preparation [17]. In guinea-pig preparations it was shown that these signalling events were unlikely to be pacemaking to adjacent smooth muscle bundles, due to their significantly lower frequency and asynchronous appearance with respect to Ca\textsuperscript{2+} transients in detrusor myocytes.. Spontaneous Ca\textsuperscript{2+}-events were not temporally synchronised; events sometimes transmitted between adjacent cells but more often, IC-LP fired individually with no corresponding event in adjacent cells. Of interest, stimulation of intramural nerves (cholinergic or purinergic) within the preparations through electrical field stimulation (EFS) synchronised IC-LP activity. A similar scenario was encountered with IC-IM, where adjacent IC-IM were rarely synchronised with each other or with neighbouring smooth muscle cells, but EFS synchronised all cellular activity. Perivascular IC also displayed spontaneous Ca\textsuperscript{2+}-signalling which was not synchronised with that of neighbouring vascular smooth muscle cells; activity of these cell types was also synchronised with EFS. Overall, there is no demonstrable signalling via Ca\textsuperscript{2+} transients between ICs in different layers of the bladder wall and adjacent cells. However, there is good evidence for functional innervation to the three types of ICs discussed above. This latter phenomenon corroborates earlier morphological and ultrastructural studies of nerve-IC interactions [14,145,175].

6. BLADDER INTERSTITIAL CELLS IN DISEASE/DYSFUNCTION OF THE BLADDER

6.1. Spinal Cord Injury

About five weeks after spinal cord injury in rats (full transection at T9/10) there is a striking reduction of vimentin-positive-ICs, five weeks after injury, apparently due to apoptosis and cell death. These bladders had a decompensated, hypoactive phenotype and the lack of IC was commensurate with areas of patchy denervation [176]. This was in agreement with a similar model, six weeks post-SCI, in which there was a significant reduction in KIT-positive IC [177]. This latter study also reported an increase of KIT-positive IC in a model of suprasacral spinal cord transection at S1-3. These observations demonstrate the reliance
of bladder IC number on cellular homeostasis for maintenance and potentially requiring neuronally-released factors, such as stem cell factor.

6.2. Diabetes

The distribution and number of KIT-positive/Cx43-positive IC in human bladder from diabetic patients is decreased in both the lamina propria and detrusor [178]. In a rat model of diabetic cystopathy (treated with streptozotocin, STZ) detrusor IC number is also reduced [41]. Of importance, HCN channel expression in detrusor IC was also reduced, as well as a loss of caveolin-3 which colocalises with HCN – caveolin-3 is a component of the membrane caveolae signalling complex that transduce extracellular signals to intracellular pathways. The consequences of this on bladder spontaneous activity was indicated by reduced sensitivity of diabetic bladder strips to forskolin (which increases cAMP concentrations and activates HCN channels), compared with normal animals. Consistent with a reduced number and activity of ICs in bladders from diabetic subjects, application of the KIT/PDGFRα inhibitor, imatinib mesylate (Glivec) to STZ-induced diabetic rat bladders produced a concentration-dependent decrease of carbachol-induced phasic contractile activity [179]. This was interpreted as an inhibition of KIT-positive ICs deceased contractile activity. However an alternative explanation may be that Glivec decreased the L-type Ca²⁺-current required for the action potential upstroke and contraction in detrusor smooth muscle cells as reported previously [180].

6.3. Bladder Outlet Obstruction

The partial bladder outlet obstruction or pBOO model is widely used as an experimental model of obstruction analogous to benign prostate hypertrophy. The changes to bladder structure and function that result are well understood with respect to smooth muscle and innervation and several groups have studied the fate of IC in this model. As part of a larger study of P2X1 location and function in rats subjected to pBOO, a significant increase in the intensity of P2X1 staining in KIT-positive IC was found [153]. This was consistent with a larger peak amplitude of inward current in pBOO IC when activated by the P2X1 agonist α,β-methylene ATP [153]. In the same model, gene expression of HCN1 was increased compared with normal, and a higher current density of Iₘ, sensitive to ZD7288, was found in patch clamp studies [166].

In addition to changes in receptors and ion channel number and function, there is corroborating evidence that the number of ICs themselves increase after pBOO. The number of IC-LP and detrusor increased in guinea-pig pBOO bladders with an upregulation of IC muscarinic receptor M3 expression [150,181-182]. KIT-positive IC number is also increased in rat bladders with pBOO [183].

6.4. Other Overactive Bladder Studies

Increased P2X2 and P2X5 receptor expression in detrusor IC has been measured in tissue from female rats with bladder overactivity, as assessed by cystometrograms [184]. However, mouse PDGFRα-positive cells do not respond to the P2X agonist α,β-methylene ATP suggesting that functional P2X receptors are not present on these cells, at least in normal mouse bladder [78]. Again, this apparent discrepancy may be accounted for in the differences in purinergic physiology in normal and diseased human and rodent bladders. The number of KIT-positive IC from normal and neurogenic paediatric human bladders was compared; the latter from a group of patients with myelomeningocele, the most common cause of neurogenic bladder in children. No difference in the number of KIT-positive IC was found between the two groups [185].

6.5. Ageing and Development

Bladder dysfunction is highly prevalent in the elderly population and there is a consensus that symptoms progress with ageing. Several groups have studied contractility and smooth muscle function in ageing models and others have focussed on IC numbers in neonatal, juvenile, adult and ageing bladders. No differences in the number or location of KIT-positive or vimentin-positive IC-LP and detrusor IC were measured in juvenile and adult pig bladder specimens [10]. However, it was noted in this study that juvenile bladder preparations had enhanced spontaneous contractions which were sensitive to Glivec, whereas activity in adult bladders was relatively insensitive. With IC from neonatal rat bladders KIT-positive and vimentin-positive cells in the mucosa and detrusor were observed [146]. Administration of Glivec to newborn rats for seven days resulted in injury to detrusor IC but the IC-LP were relatively intact. The detrusor IC lesion may explain the lower contraction frequency and an altered response to muscarinic agonists observed in bladder strips. KIT or PDGFRα may therefore be important in the maturation of IC in the detrusor with these cells having physiological roles in the generation of spontaneous and carbachol contractions.

The next few years should see our knowledge of IC in ageing and development models increase as this is a significant gap in our knowledge. The selection of relevant animal models to represent co-morbidities e.g. pBOO, obesity, metabolic syndrome and diabetes should be combined with ageing. In the present review, the papers cited were not designed to elucidate gender differences in IC in either normal or diseased bladders. Current and future studies need to incorporate gender balance into their design so that knowledge is translational to improving the life of women and men with LUTS.
7. SUMMARY OF BLADDER IC PHYSIOLOGY

This section has reviewed the current state of the art of the cellular physiology of bladder IC, an area that has progressed over the last three years. A profile of the receptor, ion channel and Ca^{2+} signalling physiological profile for IC in the mucosa and detrusor layers is emerging (Figure 11). It is clear that bladder IC have the relevant mechanisms to participate in the bladder functions of filling and voiding in addition to sensory transduction and are regulated by intramural nerves. The discovery of pacemaking type currents adds support to the hypothesis that bladder IC might regulate smooth muscle activity by giving depolarizing input. While it seems unlikely that they directly pace the detrusor smooth muscle, they may provide intermittent depolarisation. Conversely, bladder IC also have mechanisms of hyperpolarisation through a number of K^+ channels, some of which are regulated by ATP and which would provide a brake mechanism to prevent bladder overexcitability, an essential function during filling. Finally, the role of perivascular IC in providing local control of bladder vascular perfusion is an exciting area that may help understand and address the issues relating to bladder ischaemia that are common to many pathophysologies.

Figure 11. Summary of morphology and physiology of interstitial cells in the bladder wall. Schematic diagram illustrating interstitial cells in the layers of the bladder wall. The ion channels, receptors and signalling proteins described in the article are listed for lamina propria IC and detrusor IC. (figure courtesy of Bronagh M McDonnell and Karen D McCloskey)
IV. TRANSPORT FUNCTIONS OF THE UROTHELJUM

1. INTRODUCTION

The urothelium is the epithelial lining of the renal pelvis, the ureters, the urinary bladder and outflow tract. It lies at the interface between the urinary space and underlying tissues and plays a critical role as a permeability barrier to ion, solute and water flux, as well as pathogens. Whereas once considered a simple high resistance barrier, the urothelium is recognised as having the potential to modify the composition of stored urine [186,187] as well as function as an integral part of a sensory web in which it receives, amplifies, and transmits information about the external milieu to the underlying nervous and muscular systems [188]. Therefore, the urothelium is a dynamic tissue that not only responds to changes in its local environment but can also relay this information to other tissues in the bladder. This section of Chapter 2 will be primarily concerned with transport and permeability functions of the urothelium, the sensory functions will be considered in the following chapter.

2. THE STRUCTURE OF THE UROTHELJUM

The urothelium, mainly a transitional epithelium of endodermal origin, typically comprises large umbrella (superficial) cells, intermediate cells and a layer of basal cells. Originally, the urothelium was considered as pseudostratified as studies reported that thin cytoplasmic extensions connected the various cell layers to the basement membrane [189]. However, subsequent studies demonstrated that the urothelium is stratified and the cytoplasmic extensions are rarely observed in the intermediate cell layer [190].

2.1. Basal and Intermediate Cell Layers

Basal cells are germinal in nature with a diameter of 5–10µm, and form a single layer that contacts the basement membrane. Although several studies have indicated the existence of progenitor cells within the basal cell layer, their exact topology and identity as well as their role in key processes such as tissue regeneration and repair have not been fully clarified [191]. Although the turnover rate of the urothelium is estimated to be 3–6 months [192] it shows enormous regenerative capability when it is damaged and can restore itself within days of significant damage [193,194]. In a recent study, it was demonstrated that a small subset of basal cells of embryonic origin, characterised by expression of keratin 14, function as stem cell and can participate both in natural and injury-induced bladder regeneration by giving rise to all urothelial cell layers [191].

Intermediate cells are single nucleated, pyriform in shape with a diameter of 10–25µm. They lie on the top of the underlying basal cells and can be one to several cell layers thick [195]. They are connected to one another and the underlying umbrella cells by desmosomes and possibly by gap junctions [190,196]. The number of intermediate cell strata differs in various species. In rodents, the intermediate cells are one to two layers thick and in humans up to five layers have been observed [188]. The state of bladder fullness dictates the thickness of this layer with cells appearing in fewer numbers in distended compared to empty bladders. It is believed that the change in the thickness of the intermediate cell layer is achieved by cells sliding past one another during bladder filling. It is unclear whether this “sliding” will result in reversible breakage of cell-cell contacts [188].

The intermediate cell layer is partially differentiated and these cells can express uropilakins (UPS) and discoidal/fusiform-shaped vesicles [188,197]. It has been proposed that the intermediate cells closest to the umbrella cell layer can rapidly differentiate into umbrella cells when the cell barrier is disrupted as a result of senescence, bacterial infection, or experimental manipulation [197-199]. The exact triggers that promotes the rapid differentiation of intermediate cells is unknown, but may include exposure of uncovered intermediate cells to growth factors or other mediators in urine, or loss of cell-cell contacts between intermediate cells and the overlying basolateral surface of umbrella cells [188].

2.2. Umbrella Cell Layer

The permeability barrier function of the urothelium is primarily associated with the superficial umbrella cells which form a single layer of highly differentiated and polarised cells. Umbrella cells have an extremely slow turnover rate with a cell cycle time of 40 weeks in some species [192], which additionally contributes to the impenetrable integrity of the urothelium. The morphology and shape of the umbrella cells is dependent on the filling state of the bladder. In empty bladders these cells are roughly cuboidal and become highly stretched and are squamous in morphology when the bladder is filled [195,200]. The apical side of umbrella cells is scalloped, comprising of plaques (also known as the asymmetrical unit membrane or AUM) and intervening hinge regions. The membrane associated with hinge and plaque regions is similar to myelin; rich in cholesterol, phosphatidylcholine, phosphatidylethanolamine and cerebroside [188,201]. The polygonal-shaped plaques are ~0.5µm in diameter, 12 nm in thickness and are made up of one to five subunits each. The major constituents of the subunits are a family of uroplakins (UP), which include UP Ia, UP Ib, UP II, UP IIIa [188,195]. UP Ia is a urothelial receptor that binds uropathogenic Escherichia coli, which is responsible for more than 90% of urinary tract infections [202]. The hinge areas comprise at least one unique protein, which is called urohingin [203] and it is speculated that due to the
crystalline nature of the plaque regions, receptors and ion channels are localised to the hinge areas [188]. The surface of the umbrella cells is covered by a multi-charged anionic glycosaminoglycan (GAG) layer, which may be important in bacterial anti-adherence and prevention of urotheelial damage by large macromolecules. The role of the GAG layer as a barrier to micromolecules is still controversial and there is no definite evidence that the GAG layer acts as the primary barrier between urine and underlying tissues [188].

An additional feature of umbrella cells is the presence of discoidal or fusiform-shaped vesicles (DFV). These vesicles and their associated cytokeratin filaments are responsible for delivery of UPs and other proteins to the apical surface of the cells. It is hypothesised that during bladder filling the umbrella cells recruit these vesicles to fuse with their apical membranes, thereby increasing the overall surface area [204,205]. On voiding, the extra surface membrane is believed to be endocytosed. This replenishes the population of cytoplasmic vesicles, followed by a refolding of the umbrella cell membrane and mucosal surface in preparation for the next filling cycle [204,205].

### 3. THE BARRIER FUNCTION OF THE UROTHELIUM

The permeability properties of an epithelium define the movement of water and solutes/ions across the membrane, and the regulation of this movement is vital for homeostasis. Epithelial “tightness” is commonly assessed by measurement of transepithelial electrical resistance (TER), with epithelia displaying a TER >500 Ω.cm² classified as “tight”. Measuring the permeability of different epithelial tissues has revealed that the urothelium is the least permeable epithelium with a TER of 10,000 to >75,000 Ωcm², making it the tightest and most impermeable epithelial barrier [206].

It has been generally assumed that urine held in the bladder is identical to that excreted by the kidneys. However, recent studies have shown that the composition of urine can change during its passage from renal pelvis to the bladder [186,187,207]. Since the bladder is exposed to very large concentration gradients of ions, pH and solutes, it is not surprising that pathways for transport of Na⁺, K⁺, Cl⁻, urea, creatinine and water exist in the urothelium [188]. These pathways, coupled with the large surface area of the urothelium and the long storage times of urine, indicate that depending on the physiological status of the organism, the urothelium may play a vital role in ion, solute and water homeostasis.

The urothelium has two permeation pathways. The paracellular pathway, consisting of intercellular space and tight junctions (TJs) and the transcellular pathway, consisting of the apical and basolateral plasma membranes of the umbrella cells (Figure 12, [206,208]).

### 3.1. The Paracellular Pathway

Paracellular transport is passive, consisting of diffusion and osmosis with no directional discrimination [208]. The zone of attachment between adjacent urothelial cells forms a junctional complex composed of TJs and adherence junctions (AJs), both of which form continuous belts, and desmosomes (Figure 13). Desmosomes form individual circular plaques that are arranged in a row just below the AJs and together with AJs, play an important role in cell-cell adhesion.

**Figure 12.** Paracellular and transcellular pathways of the urothelium. The paracellular pathway, consists of intercellular space with tight junctions (TJs) acting as the gatekeepers. The transcellular pathway, represents the route across the cell consisting of the apical and basolateral plasma membranes of the umbrella cells. The apical plasma membrane is represented with urothelial plaques and the glycosaminoglycan (GAG) layer. DFV, discoidal fusiform vesicles; N, nucleus; TJ, tight junctions; GAG, glycosaminoglycan layer.
However, TJs are the main regulators of paracellular transport.

Tight junctions (TJs), which encircle the apical end of the lateral surface of adjacent umbrella cells, prevent the unregulated flux of ions, organic solutes and water across the paracellular space by forming close apposition of anastomising filamentous strands between the plasma membranes of neighbouring cells (Figure 13). Epithelia with high resistance were observed to have TJs with more strands than low-resistance epithelia and there is an exponential relationship between the number of TJ strands and passive resistance [208]. It is believed that TJs undergo structural and functional reorganisation to preserve barrier integrity during filling and voiding cycles [209]. The TJs consist of peripherally associated scaffolding proteins, cytoplasmic signalling proteins and transmembrane proteins. Scaffolding proteins such as zonula occludens-1 (ZO-1), link the tight junction associated transmembrane proteins to the prejunctional actin cytoskeleton and may also be important in transducing regulatory signals that control the paracellular barrier [210]. The transmembrane proteins of the TJs include occludins and claudins, the coxsackie/adenovirus-associated receptor, the junctional adhesion molecules and tricellulin [208]. Occludins and claudins form continuous branching fibrils of transmembrane particles that completely encircle the apical aspect of the lateral surface of each cell and are responsible for creating a complex barrier with ion and size selectivity [210].

The claudins are 20-25kDa proteins with four transmembrane domains, two extracellular loops and a short -COOH intracellular tail with a PDZ-binding motif that promotes interactions with other proteins, such as ZO-1 (Figure 13, [211]). The specific claudin isoforms associated with the urothelium are now being investigated. The amino acid composition of the extracellular loop of these different isoforms control paracellular permeability by forming anion/cation selective, or occluding pores [209,212-214]. There are currently at least 27 claudin isoforms which are capable of heterophilic or homophilic adhesion between cells [208]. Claudin-4, -8, -12 and possibly -13 have been found in the urothelium of rat, mouse and rabbit bladders [210,215] and claudin-3, -4, -5 and -7 have been found in the human urinary tract [216]. These interspecies differences in expression of claudin isoforms could explain the reason for TER and permeability variances between different species. Claudins are also expressed in the basolateral plasma membrane of superficial, intermediate and basal urothelial cells, but their exact role, organisation and regulation is not fully understood [208].

Figure 13 The zone of attachment between adjacent urothelial cells. A: This zone forms a junctional complex composed of tight junctions (TJ) and adherence junctions (AJ), both of which form continuous belts, and desmosomes (Ds). B: Enlargement of the structure of a tight junction (TJ) between umbrella cells. TJs are made up of three members of transmembrane proteins: junctional adhesion molecules (JAMs), claudins and occludin.

Occludins span the membrane four times and undergo homophilic adhesion between cells (Figure 12, [208]). They were the first transmembrane proteins described and it was assumed they were the key component of TJs until it was demonstrated that occludin knock-out mice had structurally and functionally normal junctions [217,218]. ZO-1 and occludins are also found in the basolateral surface of the umbrella cells and the plasma membranes of intermedi-
ate and basal cells [210]. The presence of ZO-1, occludin and claudins at cell borders could help cell adhesion, especially during wound healing.

Bladder filling stimulates an expansion of the urothelium and umbrella cell TJ ring, a process which is rapidly reversed upon voiding. One mechanism that can contribute to the filling induced TJ ring expansion is the insertion of newly synthesized or recycled membrane proteins via exocytosis at the TJs [209]. Indeed, studies in other cell systems have demonstrated that the membrane components of TJs are highly dynamic, even at steady state [219]. It is assumed that as exocytosis controls TJ expansion during filling, endocytosis plays an important role during voiding [209]. An increase of ion permeability across the umbrella cell TJ was also reported during bladder filling which was assumed to be independent of the low capacity, nonselective leak pathway. This increased permeability may alter the function of sensory neurons or muscle cells by altering their ionic milieu and may be an important communication pathway between the urothelial cells and the underlying tissues [209]. Disruption of TJs has been associated with various bladder conditions such as outlet obstruction, spinal cord injury, bacterial cystitis, all of which are characterised by alterations of the urothelium and umbrella cell junctional complex [188].

3.2. The Transcellular Pathway

The total transepithelial resistance is due to parallel arrangement of paracellular and transcellular resistances. The paracellular resistance can be >100,000 Ωcm², whilst the transcellular resistance can vary from 10,000 to >100,000 Ω·cm² [220]. The main transcellular permeability barriers are the apical and basolateral plasma membranes of umbrella cells [208]. The apical plasma membrane in various species has a resistance of up to 150,000 Ωcm² which is much higher than that of the basolateral plasma membrane, with a resistance of only 1,500 Ωcm² [221]. The variability of the transcellular resistance is due to differences of the apical membrane permeability and not the basolateral membrane [220]. It is believed that although uroplakins, which are the major proteins of the apical plasma membrane, may be important in preventing transcellular absorption of water and solutes from the urine, they are not solely responsible for the transcellular barrier function [222]. Uroplakin post-translational modification, which results in functional plaque formation on the apical side of the umbrella cells, as well membrane lipid composition and profile are important factors in regulating the transcellular barrier function [206]. The specific fatty acid membrane composition can alter the lipid profile of the apical plasma membrane, inducing changes in the interparticle and uroplakin distance, which ultimately affects the permeability barrier function as well as the pathway of endocytosed urinary fluid [206]. Transcellular transport can be passive or active, is directional and energy dependent and is facilitated by transporters and channels.

4. WATER AND ELECTROLYTE TRANSPORT ACROSS THE UROTHELIUM

4.1. Water Transport in the Urothelium

The mechanism by which water passes through biological membranes was a matter of debate until the discovery of a large family of transmembrane channel proteins called aquaporins (AQPs) [223]. AQPs are a class of membrane water channels whose primary function is to facilitate the passive transport of water across the plasma membrane in response to osmotic gradients that are created by active transport of solutes. There are currently 13 AQPs (0-12) identified in mammalian tissue. A subset of AQPs is the aquaglyceroporins: AQPs which also facilitate passive transport of glycerol and possibly other small solutes such as urea, glycerol, H₂O₂ and CO₂. AQPs regulate transepithelial water movement in various tissues, e.g. kidney, and some subtypes are regulated by circulating vasopressin. Recent studies have confirmed the presence in the urothelium of AQP-3, -4, -7 and -9 in human tissue [224], AQP-1, -2 and -3 in rats [225] and AQP-1, -3, -9 and -11 in pigs (Figure 14). This suggests that AQPs may play a regulatory role in urothelial cell volume and osmolarity and also determine the final composition of urine. Indeed this hypothesis is further supported by the expression of AQP1 and AQP3 in the urothelium of the American black bear. This mammal typically hibernates for 4-5 months and does not eat, drink, urinate or defecate during this time. However, it is known to produce and reabsorb urine in equal amounts daily [226,227].

The cellular localisation of AQPs in urothelial cells is an interesting indicator of their functionality. In rats, AQP2 and AQP 3 are found on the basolateral, but not apical, membrane of umbrella cells, as well as the plasma membrane of intermediate and basal cells [225]. The AQPs which are expressed on the apical membrane of umbrella cells may be responsible for the initial water influx and subsequent egress through basolateral AQPs to the intermediate and basal cells. This would allow water to be transported from the bladder lumen, through the urothelial cell layers towards the interstitial space and circulation [188].

The exact function of AQPs in the urothelium is still unclear; however, several roles have been proposed. One possibility is that the AQPs are responsible for regulation of cell tonicity and volume of urothelial cells. Changes to the extracellular osmolarity of urothelial cells is a form of stress which also results in release of transmitters such as ATP, acetylcholine, nitric oxide etc. Release of these transmitters has significant effects on afferent nerves in the mucosa, as well as direct effects on the spontaneous contractile activity of the bladder wall [228,229]. However, the exact role of AQPs in mediating the sensory and con-
tractile functions of the bladder wall, and the mechanisms by which their expression and function in the urothelium is regulated remains unclear.

4.2. Solute Transport in the Urothelium

In addition to water, solutes such as urea and creatinine are constantly re-absorbed from the urine (or secreted depending on the local environment) and the net transport of these solutes is regulated by the hydration status [208]. Although possible simple diffusion of urea down its concentration gradient could be considered, the magnitude of the quantity of flux, and its rapidity of movement indicate that transport is facilitated or active in nature [230,231]. There are two subfamilies of urea transporters: UT-A and UT-B [232]. UT-A, is located apically, whereas UT-B is primarily located on the basolateral surface of umbrella cells and the membrane of intermediate and basal cells [188]. This provides a system whereby urea is absorbed apically by UT-A and is then transported through the umbrella cell and exits on the basolateral side via UT-B, allowing for modulation of cell volume and osmolality [233].

4.3. Ion Transport in the Urothelium

Several pathways for ion transport have been described in the urothelium. The apical plasma membrane of urothelium contains Na⁺, K⁺ and Ca²⁺ channels, as well as other cation-sensitive channels, whilst the basolateral plasma membrane expresses Cl⁻ channels, Na⁺/H⁺ and Cl⁻/HCO₃⁻ exchangers, ATPase-dependent pumps as well as Na⁺ and K⁺ channels [208].

The best understood pathway is mediated by the amiloride-sensitive Na⁺ channel (ENaC), which is expressed on the apical membrane of umbrella cells. ENaC facilitates transurethelial Na⁺ flux along with Na⁺/K⁺-ATPase dependent active transport on the basolateral membrane to provide the net electrochemical gradient that promotes Na⁺ absorption. When the bladder is empty and the urothelium is not stretched, Na⁺ absorption through ENaC channels is

the primary contributor to transepithelial potential difference of nearly -30mV [234,235]. However, when the urothelium is stretched, amiloride sensitive current significantly increases which is likely the result of increased apical membrane exocytosis of ENaC-containing DFVs [235]. Na⁺ entering the cell through ENaC channels then exits across the basolateral membrane via Na⁺/K⁺-ATPase. As Na⁺ is extruded from the basolateral membrane, the Na⁺/K⁺-ATPase brings K⁺ into the cell, which then exits the cell across the basolateral membrane through K⁺ selective channels. This outward movement of K⁺ across the basolateral membrane generates a membrane potential of -55 mV [220]. ENaC is also proposed to play a role in mediating ATP release from the urothelium as well as having a mechanosensory role in modulating stretch-induced exocytosis at the apical membrane of the umbrella cells [188].

Urothelial stretch can also stimulate K⁺ and Cl⁻ secretion. Secretion of Cl⁻ from urothelial cells has been demonstrated in experimental conditions, but the channel responsible for Cl⁻ transport is not yet identified. Although pathways for Cl⁻ entry across the basolateral membrane of umbrella cells, including Cl⁻ channels and Cl⁻/HCO₃⁻ exchanger have been proposed [235], the apical pathway for Cl⁻ secretion has not yet been described. The pathways for K⁺ transport include an apically expressed non-selective cation channel (NSCC) which is mechanosensitive and can also transport Ca²⁺ across the apical surface of umbrella cells [235]. Other K⁺ channels in the urothelium include Kir 1.1 (inwardly rectifying K⁺ channel), which has recently been found to be expressed on the apical membrane of umbrella cells [236]. The exact function of this channel is unknown, but it could be important in regulating cell volume or transmembrane electrical potential (3). Additional K⁺ channels that have been identified in the urothelium include: heparin-binding EGF-modulated inwardly rectifying channel, Kir 2.1; large-conductance Ca²⁺-activated K⁺ channels (BK); small/intermediate-conductance Ca²⁺-activated K⁺ channels (SK/IK); and ATP-sensitive K⁺-channels (KATP) [237]. These channels have been shown to either modulate K⁺ transport or K⁺ secretion across the urothelial cells [188].

Other ion channels with a potential sensory role have also been described in the urothelium [238]. These include non-selective transient receptor potential (TRP) channels, which are permeable to Ca²⁺, Mg²⁺ and Na⁺ [239] and purinergic receptors (P2X), a further family of non-selective cation channels.

5. SUMMARY

The urothelium represents an effective blood-urine barrier that prevents, or at least regulates, reabsorption of toxic metabolites and pathogens from urine. Various specialised features such as surface glycans, membrane lipids and tight junction proteins make the urothelium one of the tightest barriers. These specialised features of the urothelium allow the urinary tract to accommodate large changes in urine volume, as well as present an effective barrier against urinary tract infections and allow communication between the urothelium and the underlying tissues of the urinary tract. Beyond the role of forming an effective barrier, the presence of AQPs, solute and ion transporters in the urothelium indicates that there are potential pathways for altering the composition of urine, making this tissue an active component of water, salt and solute homeostasis. The specialised features of this tissue must also be considered in the development and application of drugs, especially those given intravesically, for targeted delivery.

V. THE PATHOLOGY OF FUNCTIONAL DISORDERS OF THE LOWER URINARY TRACT IN PERINATAL SUBJECTS AND CHILDREN.

1. INTRODUCTION

The physiology of lower urinary tract tissues from adults with normal and pathological conditions has been the subject of considerable study. However, the same is not true of foetal tissues and those from children or neonatal animals. This is in spite of the fact that several developmental conditions have continuing and profoundly detrimental effects on lower urinary tract function long after the original condition has been surgically managed. Moreover, therapeutic management of less debilitating conditions in children is also hampered by an incomplete knowledge of normal tissue physiology. The purpose of this section is to review current data regarding the cell and tissue physiology of lower urinary tract animal and human tissues, in particular from the bladder, spanning the period from foetal development to childhood and how this relates to normal and abnormal function within the lower urinary tract.

2. DEVELOPMENT OF THE LOWER URINARY TRACT

The urinary organs, kidneys, ureters, the bladder and the urethra, develop early in gestation - after the third week. The kidneys and ureters develop from fused outgrowths of intermediate mesoderm immediately under ectoderm originally from fifth cervical to the third thoracic segments to form a pronephric duct. This grows caudally to open into the cloaca (below) and when the original region atrophies is then called the mesonephric (Wolffian) duct. Ureteric buds from the Wolffian duct grow into nearby mesenchyme to...
initiate kidney development – further consideration will not be given here, but see [240,241].

The bladder and urethra derive ultimately from the cloaca, which offers a single orifice in the developing embryo from the hindgut. Soon after, a urogenital membrane (urorectal septum) grows caudally to divide the cloaca into ventral (urogenital sinus) and dorsal (rectum) compartments. The urorectal septum itself consists of two fused mesodermal structures; an upper, frontal fold of Tourneux, and two lateral folds of Rathke, which complete the division between the urogenital sinus and rectum and form the perineum. Malformation of these structures can lead to fistulas between the rectum and either the urethra of bladder. The pelvic organs are supported by connective tissue and the perineal musculature, which form from the mesoderm surrounding the new rectum.

The bladder develops from the anterior part of the urogenital sinus and has a functional outflow in early foetal life through the allantois and thence to the umbilicus. The allantois itself develops as a diverticulum from the yolk sac and has a key role in the formation of umbilical vessels. It is eventually obliterated during development and forms a fibrous cord, the urachus, still connected to the umbilicus. The posterior portion of the urogenital sinus develops into the whole female urethra and the pre-prostatic, prostatic and membranous urethra in males.

During such development, the Wolffian ducts distal to the ureteric buds opens into the urogenital sinus near to where the bladder neck will form. This process brings the ureteric bud with it until the ureters themselves separate from the Wolffian ducts and incorporate themselves into a more anterior part of the urogenital sinus that will form the bladder dome. The triangular region bounded by these insertions forms the bladder trigone. Thus the trigone has a mesodermal origin whilst the remainder of the bladder is endodermal in origin. However, the trigone is subsequently covered by endodermal epithelial (urothelial) cells and so has a mixed cellular origin [242,243]. After about developmental week 12 the urothelial cells are overlain by mesenchyme that itself differentiates into: i) a lamina propria adjacent to urothelium composed of connective tissue, that also contains fibroblasts, nerves and blood vessels, and ii) detrusor smooth muscle [244]. Urothelium is necessary to induce mesenchyme to differentiate. Differentiation of mesenchyme into detrusor smooth muscle requires the presence of urothelium via the diffusion of a signalling molecule [244,245]. Subsequent studies have demonstrated the importance of the Sonic Hedgehog pathway in this process [246,247].

The urethra forms itself from the lower part of the urogenital sinus (UGS). In males the prostate and membranous urethra arise from the pelvic part of the UGS while the spongy urethra comes from the phallic part (urethral plate). In females the whole urethra and part of the vagina arise from the pelvic part of the UGS while the phallic part (urethral plate) forms the vestibule and the labia minora.

3. THE FUNCTIONAL PROPERTIES OF FOETAL DRETUSOR SMOOTH MUSCLE.

At the end of the first trimester the bladder has a reservoir capability with discrete inner and outer longitudinal muscle layers and a circular central layer, along with a discernable trigone area [248]. Increased muscle development occurs until term, when there is also an increase of bladder capacity and discrete micturition episodes [249]. From the first trimester onward bladder compliance increases in keeping with its increasing importance as a urine storage organ, observations matched by a decrease of passive stiffness during development [250]. Measurements in both humans and animal models results show this is not just from increased muscularisation but also from a reduction of resting smooth muscle tone [251,252] as well as from changes to connective tissue whereby collagen content changes from predominantly type-III to an increasing proportion of type-I [253-255].

In humans, urinary bladder innervation is advanced by week 13 when organogenesis is about complete. Parasympathetic innervation and the density of cholinergic receptors increases up to term, but throughout there is a sparse noradrenergic innervation, in contrast to more dense supplies to the ureter and urethra [256-258]. Similar developmental histories are found with bovine and sheep development [259,260]. In addition a nitric oxide supply to the bladder, as evidenced by nitric oxide (NO) synthase immunoreactivity, develops over a similar time-frame [261], the functional significance of which requires evaluation.

These structural changes are accompanied by development of functional properties of tissue in the bladder wall. Comparison of intracellular signalling pathways associated with Ca2+ regulation show that these are fully functional early in development [262]. Cells isolated from foetal sheep bladders in the 2nd and 3rd trimester, at term or from young adults show that the resting intracellular Ca2+ concentration is the same in all groups, as were increases of intracellular Ca2+ in response to muscarinic receptor agonists, membrane depolarisation and caffeine to release Ca2+ from intracellular stores. Responses to a purinergic (P2X,) receptor agonist (ABMA) were somewhat lower in foetal cells, as was a reduced potency to carbachol, suggesting some post-natal function changes did occur. However, it can be concluded that the membrane and intracellular pathways for contractile development are fully developed in foetal detrusor cells (Figure 15). Such cellular changes are mirrored by development of contractile detrusor responses. Between the second and third trimester contractions to muscle depolarisation with high-K superfusate increases, using bovine and sheep preparations, consistent with increased muscularisation. However, contractions to
muscarinic and purinergic agonists increase even more suggesting there is a development also of the intracellular signalling pathways to these agents (250,263) and consistent with the above observations of isolated cells. Later in development – from the onset of the third trimester until term – nerve-mediated contractions progressively develop suggesting an increase of functional innervation to detrusor (250,263). Nerve-mediated relaxation has also been observed in the latter stages of development and shown to be mediated by NO-dependent pathways, due to its abolition by agents that limit the activity of NO-synthase of intracellular cGMP pathways (250,264). The significance of this contractile modality has yet to be identified and the extent to which it persists in the bladder after term. Electrically-induced relaxation was present only in the foetal bladder and was suggested as a mechanism to protect the upper tract from excessive increase of bladder pressure [265]. This progressive development, firstly of muscle intracellular signalling systems and then of functional innervation is consistent with the maturation of voiding responses from small, brief contractions in the second trimester to more maintained and effective voiding contractions in the third [266-269]. Radio-telemetry of cystometric recordings in foetal sheep bladders show that in the later stages of development low compliance filling is interspersed with voiding and non-voiding contractions occur [269].

Figure 15: Intracellular Ca2+ transients to contractile agonists in foetal sheep detrusor cells. A: response to 1 µM ABMA. B: response to a high-K solution. C: response to 1 µM carbachol. D: comparison of change of intracellular [Ca2+] with carbachol in detrusor myocytes from; mid-second trimester (2), mid-third trimester (3), term (T) foetuses and adult bladders (A).
4. THE FUNCTIONAL PROPERTIES OF DETRUSOR FROM POSTNATAL DEVELOPING BLADDERS

At birth the functional development of the bladder continues, until in humans a broadly adult phenotype is established at about 50 months. Over this time-scale the ratio of detrusor muscle to connective tissue increases [270,271], as does the density of functional innervation, the latter inferred from comparing the force developed by nerve-mediated and agonist-induced contractions [271]. However, in postnatal detrusor from both humans and pigs the intracellular signalling pathways, surface membrane receptor agonists and ion channels are similar to the adult phenotype [271,272] and is consistent with a similar picture in late-term foetal detrusor myocytes [262]. An exception is the low potency to muscarinic receptor agonists, observed in foetal tissue and persisting in the postnatal human and pig detrusor bladder [271,272].

Figure 16 shows a significant positive relationship between force generated by a contractile agonist (carbachol) and the smooth muscle:connective tissue ratio from human detrusor samples collected from normal bladders of children with between 1 and 48 months of age. An interpretation of the data is that an increase of bladder contractile performance is due to the increase of smooth muscle in the detrusor layer and not due to a development of myocyte contractile function.

The decrease of connective tissue content in post-natal development is mirrored by a reduction of passive muscle stiffness [271]. This implies that bladder compliance also increases during post-natal development and is consistent with an increase of maximum (expected) bladder capacity up to adolescence with no change of the increase of detrusor pressure during the filling period [273,274].

A further feature of human postnatal developing detrusor was significant atropine resistance of nerve-mediated contractions in tissue from stable bladders, in contrast to the adult phenotype. Although it diminished with time it still persisted up to postnatal 50 months. In adult tissue atropine resistance has been attributed to reduced breakdown of released ATP by ectoATPases in the neuromuscular junction [275], but it is not known if this is the case in the postnatal bladder. Overall, the reduced potency of muscarinic receptor agonists and atropine resistance in postnatal human detrusor muscle may contribute to the variable effectiveness of anticholinergic agents to treat enuresis and overactive bladder in children [276,277].

An additional feature of postnatal bladders is the generation of large amplitude spontaneous contractions, in contrast to higher frequency, smaller contractions in adult bladder and also reminiscent of large spontaneous contractions in the overactive bladder [278]. These large, neonatal contractions disappear with the development of supraspinal mechanisms to control bladder function [279]. These contractions are resistant to neurotoxins, such as TTX and therefore are unlikely to be nerve-mediated, and originate from the sub-urothelium layer adjacent to detrusor. A proposed mechanism is that acetylcholine and ATP released from the urothelium by external forces such as mechanical stress either diffuse to the muscle layer or use interstitial cells to mediate the response. The latter mechanism has credence as gap junction blockers inhibit neonatal spontaneous contractions, and it is observed that interstitial cells in the suburothelium form a functional electrical syncitium connected by gap junctions formed of connexin43 proteins [280].

4.1. Collagen and its Contribution to Biomechanical Properties of the Bladder Wall

Collagen is an important constituent of the extracellular matrix and its physical properties are important for two reasons. Firstly it contributes to the passive stress-strain characteristics of tissues, including those of the lower urinary tract. When the bladder wall is stretched during filling the increase of wall stress (tension), and hence intravesical pressure, will be greater if the tissue comprising the bladder wall is stiffer. Secondly, force generated by actively contracting muscles will be transmitted through the tissue mass by imparting strain on the extracellular matrix and hence the biomechanical properties of the latter will determine force transmission throughout the muscle mass. Fibrillar collagen is a key component of extracellular matrix and provides structural integrity.
Collagen type-I and type-III are important constituents of lower urinary tract tissues and tissue are often composites of these types in varying proportions [281] - these will be considered here.

Collagen molecule of types –I, -II, -III, -V and –XI form fibrils and is a triple helix protein with length and diameter about 300 and 1.6 nm respectively. These molecules complex to form a fibril with diameter about 100 nm, which themselves coalesce to form fibres with diameters in the micron range [282-284]. Type-I collagen is a trimer of two a1- and one a2-chains, whilst type-III is composed of three a1-chains. Generally type-I collagen is more non-elastic than type-III: it imparts resistance to tensile forces, whilst type-III collagen provides more flexibility [285,286]. Values of the elastic modulus of type-I collagen varies widely in the literature typically between 1 and 10 GPa [287,288], but sometimes lower [289]. However, these values are several orders of magnitude greater than shear forces [288] and emphasises the load-bearing properties that it has. Type-III collagen lacks 3-hydroxproline in its molecular structure and may be a reason why it cannot form thick fibrils as can type-I [290]. There are less reliable measurements for the elastic modulus of type-III collagen but from measurements in mixed type–I/-III strands it may be estimated that the elastic modulus is about one-half of type-I collagen [291].

For completeness, collagen type-IV is the key structural protein on basement membranes that act as a substrate for other protein, such as integrins, to form a stable supporting structure. However, they do not impact on the overall stress-strain properties of lower urinary tract tissues.

5. LOWER URINARY TRACT CONGENITAL ANOMALIES

At about the time of completion of organogenesis many congenital problems of the urinary tract and genitalia will start to become manifest. This section will deal with anomalies that generate bladder dysfunctions that occur not just during foetal development but persist throughout childhood and into adult life, and which may cause co-morbid conditions such as renal failure [292]. Whilst the detection of such anomalies and surgical management has greatly improved, their consequences on lower urinary tract function are poorly understood. Several conditions will be described, those that have a more direct influence on bladder function considered in greater detail. Further clinical information on the pathogenesis

- Posterior urethral valves occurs only in boys but is the commonest congenital anomaly occurring in as many as 1:5000 live births [293]. It causes bladder outflow obstruction and up to one third of patients will develop end stage renal failure [294]. Similar, but less common, conditions that also cause bladder outlet obstruction are anterior urothral valves and syringocoele.

  - The bladder extrophy-epispadias-cloacal extrophy complex. Separation of the cloaca into the urogenital sinus (US) and hindgut occurs at a time when the anterior abdominal wall develops. Rupture of the cloacal membrane before its caudal descent (above) causes several externalisation of organs in the umbilical wall: bladder extrophy if US and hindgut have separated, or if not cloacal extrophy if not to expose bladder and hindgut. There is poor bladder contractile function as it does not develop in a closed space to allow intravesical pressures to fully develop [295,296]. Epispadas is incomplete urethral tubularisation but allows the bladder to form normally. Epispadas is common, but the extrophies are less common than PUV (1 in several tens of thousands [297]).

  - prune belly syndrome: characterised by poor development of the abdominal muscle, undescended testicles and urinary tract problems, such as dilatation of the ureters and hydronephrosis [298]. It is rare, occurring in about 1:40 000 live births

  - Relatively unusual conditions such as foetal megacystis - an unusually large bladder for the appropriate trimester [299] – and bladder diverticulum - often presenting as bladder outflow obstruction [300].

  - Spina bifida occurs in which vertebral arches of the spinal columns are incomplete or absent. A meningocele is a cyst formed of dura and arachnoid membranes protruding through the defect and of ten externalising. The cyst is called a myelomingocele if it contains cord tissue. Neurological damage often results in a neurogenic bladder (and bowel) with poor bladder wall compliance and high bladder pressures from increased outflow resistance [301].

5.1. Pathophysiology of Detrusor Function with Foetal Bladder Outflow Obstruction

Many of the above congenital lower urinary tract problems are associated with bladder outflow obstruction (BOO) and this has been attributed as a key aetiological factor in life-long poor urinary tract function in a very high proportion of these patients. Because posterior urethral valves (PUV) is the most common congenital cause of BOO much attention has been directed to its long-term consequences. Vesicoureteral reflux is extremely common at diagnosis of PUV [302], is often associated with hydronephrosis [303] and has a poor prognosis for renal failure that may develop at any stage in childhood or adult life [304,305], however further consideration is beyond the scope of this review. Changes to bladder function are also common and urodynamic observations include: decreased bladder capacity, low compliance,
detrusor overactivity with a hypocontractile phenotype, a significant post-void residual, and day/night incontinence [302]. The implied causal link between these bladder dysfunctions and upper tract problems motivate studies to understand their cellular and tissue origins. Moreover, the time of valve ablation may affect the extent of bladder dysfunction in later life [306], so that it is important to characterise the exact antenatal natural history of bladder dysfunction associated with BOO. The foetal sheep has proved to be a good model to study the effect of BOO [307-311] by partial occlusion of the urethra and complete occlusion of the urachus (Figure 17). Sheep have second and third trimesters between 45-90 and 90-143 days respectively and obstruction is generally undertaken at 45-75 days, with bladders retrieved for characterisation between several days afterwards until full term.

Obstruction early in the second trimester results in cystic renal lesions [307,312] and in one foetus the appearance of prune-belly syndrome [307]. Obstruction for periods between only five days in utero to term is associated with bladder hypertrophy - increased weight - and increased capacity - when compared to sham-operated controls [310,313-316]. With shorter periods of obstruction wall thickness also increases, but with longer periods this decreases along with a reduced detrusor/extracellular matrix ratio [314,316].

A greater compliance during filling is also measured after 30 days obstruction [315,316], associated with reduced passive elasticity of isolated preparations [316]. These changes are accompanied by increased extracellular matrix and reduced matrix metalloproteinase (matrix collagenase) activity [317,318]. Of interest, earlier studies with human bladder from obstructed foetuses showed increased elastin content, but no relative increase of collagen [319,320]. However, there is greatly increased cell turnover that accompanies bladder wall remodelling in foetal obstruction, as observed by greater labelling for proliferating cell nuclear antigen in the detrusor layer, if not in the urothelium or lamina propria (PCNA, [316]). Apoptosis is increased, accompanied by increased caspase-3 and BAX expression and decreased Bcl-2, the latter promoting cell survival [316].

A functionally decompensated contractile state of obstructed foetal bladders is indicated by reduced responses to contractile agonists, such as muscarinic

**Figure 17. The effect of outflow tract obstruction on the foetal bladder. Left: Dissected urinary tracts of foetal sheep (105 days gestation) after a sham-operation or partial outflow tract obstruction 15-days previously. Right: sections through the detrusor layer of the bladder wall of a sham-operated or obstructed foetal bladder – Masson’s Trichrome stain (light blue, extracellular matrix; purple, muscle). The Table below lists changes to the bladder dimensions and ex vivo functional characteristics. (Figure with the courtesy of Peter Cuckow, Nikish Thiruchlevam and Christopher Fry)
receptor agonists, and nerve-mediated stimulation [314,316]. Furthermore, nerve-mediated contractions are reduced to a greater extent than agonist-induced responses [315,316] indicating a relative denervation as well as a hypecontractile state of the detrusor. This is corroborated by reduced expression in obstructed bladders of neuronal tissue-markers such as S100 protein and protein gene product-9.5 [315]. Of interest is a nerve-mediated nitregic relaxation in foetal bladders that is absent in adult tissue. Such a pathway is absent in detrusor from obstructed foetal bladders [314,316]; it remains to be ascertained if this contributes to the decreased filling compliance of these bladders.

Two factors may thus contribute to the hypecontractile state of obstructed foetal bladders: replacement of detrusor muscle with extracellular matrix and reduction of postganglionic parasympathetic fibres to detrusor. A final possibility is impairment of excitation-contraction coupling in detrusor myocytes. With isolated myocytes from obstructed or sham-operated bladders, intracellular Ca\(^{2+}\) transients to membrane depolarisation (raised KCl) or caffeine (release Ca\(^{2+}\) from intracellular stores) were similar, but those to muscarinic or purinergic agonists were diminished [321]. This suggests that the membrane and intracellular machinery for Ca\(^{2+}\) is not significantly altered in obstructed bladders, but receptor coupling may be diminished.

Thirty days of obstruction, i.e. from mid-2nd to early 3rd trimesters is sufficient to produce a decompensated, hypecontractile, low compliance bladder (Figure 17). Of interest would be to know if a compensated phenotype develops initially and when this changes to a decompensated state. This was addressed by measuring morphological and functional changes after only nine days of obstruction [322,323] by either i) ligation only of the urachus or ii) urachus ligation and partial urethral obstruction. Similar results in both intervention groups reinforced the importance of the urachus in bladder drainage at midgestation. Overall, this period of obstruction represented a cusp from compensation to decompensation.

Figure 18. The effect of brief (9-days) obstruction on the initiation of re-modelling in the foetal bladder. Left: sham-operation; right: obstruction. (Figure with the courtesy of Marie-Klaire Farrugia, Adrian Woolf and Christopher Fry)

Morphological investigations of bladder wall samples have been carried out from newborn humans with exstrophy and from sheep with an exstrophy phenotype surgically induced in 70-80 day old foetuses [326-328]. In both cases a decrease of the collagen-to-smooth muscle ratio was recorded: in human samples the increased collagen was due to an increase of type-III, whilst type-I and type-IV contents were unchanged; in sheep samples the collagen I/III ratio was unchanged. A reduction of myelinated and smaller nerve fibres has also been recorded in newborn human exstrophy samples [329]. The exstrophy-epispadias complex results in part from several genetic changes that incudes altered expression of P63 protein that leads to poor development of the urothelium. Ulceration and inflammation of the mucosa also occurs in the sheep exstrophy model [330]. However, in contrast to foetal bladder outflow models there has been little description of structural changes that occur and no systematic characterisation of the functional properties of bladder tissues.

Different models of myelomeningocele (MMC) have been developed, including: in foetal sheep surgical exposure of the spinal cord to the amniotic space at 75 days and animal examined at term [331]; oral gavage of retinoic acid to pregnant rats (embryonic day 12, term day 22 [332]). With the surgical-intervention animals a typical neuropathic bladder phenotype presented, some with dilated, thin bladders and others with a contracted, thick-walled bladder. At the microscopic level this was mirrored in a narrow urothelium, and a thin muscle layer with fibrosis between muscle bundles, or a thickened urothelium and muscle layer with no excessive fibrosis. Normal ganglion and nerve development was observed [331,333]. Retinoic acid-induced MMC was studied in days 16-20 foetuses. There was no increase of connective tissue between muscle bundles – in contrast to that seem in
human tissue [334] – and progressive denervation to the muscle bundles [332]. Functionally, nerve-mediated responses were absent and contractures to raised-KCl solutions and to carbachol were attenuated. This model demonstrates a denervated and hypcontractile phenotype.

5.3. Postnatal Detrusor Function from Children with Congenital Abnormalities

Very little work has been carried out on the morphological and functional characteristics of detrusor from children born with congenital anomalies. Longitudinal urodynamic follow-up studies after valve ablation show detrusor overactivity, high compliance significant residual volume and ‘myogenic failure’ in some patients [335-337]. However, it should be noted the term ‘myogenic failure’ refers to an overdistended bladder and does not imply any actual demonstration of reduced muscle contractile function.

Measurements have been made of in vitro contractile function and morphology of detrusor samples from neonates and children up to 1-year old after surgical correction for congenital anomalies such as PUV, bladder exstrophy and MMC. Compared to data from bladders of similarly aged children with no such anomalies and stable bladders, contractile responses to muscarinic agonists and nerve-mediated stimulation were significantly lower in all groups with anomalies (Figure 19A). However, the reduction of the responses by the two modes of stimulation were not significantly different. This suggests that there was no evidence for functional denervation in the detrusor of samples from congenital anomaly bladders. This is consistent with observations of normal nerve profiles in exstrophy bladders after surgical reconstruction [338]. Of interest atropine resistance in these samples was also present, as observed with tissue from neonates with stable bladders.

Figure 19. Contractile and biomechanical properties of neonatal bladder with congenital anomalies. A: upper; contractile responses of detrusor to carbachol and the smooth muscle (SM)/connective tissue (CT) ratio in samples from children with normal bladders (control), exstrophy (exstr), posterior urethral valves (PUV) and myelomingocele (neuropath). Lower; cross-sections of the detrusor layer of samples from a normal bladder and one with bladder exstrophy – van Gieson stain; muscle, orange; connective tissue, red. B: passive tension response to a muscle sample during a rapid stretch for 60 seconds. The steady-state tension, E, is plotted below for samples from control and exstrophy bladders. Data are mean±SD, *p<0.05. (Figure by courtesy of Navroop Johal and Christopher Fry)

The reduction of contractile responses was mirrored by a greater proportion of extracellular matrix in the groups of anomalies, which suggests that the reduction of contractile responses was due, at least in part,
to replacement of muscle with connective tissue (Figure 19B). A reduction of smooth content of tissue from human exstrophy bladders has been recorded previously [339] where it was also shown that the smooth muscle content increased after reconstruction along with improved bladder function.

A remaining question is if loss of contractile function also results from failure of detrusor muscle itself to generate force. This is not a likely contributor in isolated detrusor myocytes intracellular Ca$^{2+}$ responses to muscarinic agonists were similar in those from children with stable bladders and congenital anomalies. This corroborated by finding similar densities of muscarinic receptors in detrusor from normal and exstrophy paediatric bladders [340]

Overall, there is no evidence that contractile bladder dysfunction in neonates with congenital anomalies is caused by reduced contractility of the detrusor muscle itself, or its excitatory innervation. Of more significance is the loss of muscle tissue and its replacement by connective tissue. Strategies to improve bladder function after surgical correction of these different anomalies should concentrate on reversing the decline of the smooth muscle / connective tissue ratio.

**VI. THE MUSCULATURE OF THE PELVIC FLOOR AND EXTERNAL URETHRAL RHABDOSPINC TER**

Skeletal muscle components in the pelvic floor and around the urethra provide important roles in providing continence mechanisms as well as some visceral organ support. The previous edition of the consultation [341] provided a detailed account of the neural control of these structures. This report will concentrate on the properties of the muscles themselves with brief resumés of neural control including any advances that may have been made in the intervening period and where there is direct relevance to understanding the muscle physiology.

**1. THE PELVIC FLOOR MUSCLES**

The pelvic floor is situated at the base of the pelvis, supports pelvic visceral organs [342] and, as the urethra and ano-rectum penetrate it, may provide a continence mechanism. Furthermore, although not considered here, it is important to support movement and posture, in concert with the musculature of the abdomen and lower back; normal sexual function; and in reciprocal function with the diaphragm breathing. The innermost layer is comprised of the the coccygeus muscles and the the levator ani. The levator ani itself has three components (Figure 20A): the puborectalis; pubococcygeus and iliococcygeus muscles; the last two referred to also as the pubocaudalis and iliocaudalis muscles in many animals.

The ventral portion of this structure has a superficial cover of deep and superficial perineal muscles, the latter fixed to the ischial tuberosities and a midline tendinous perineal body that itself acts as an insertion point for several pelvic floor muscles. Fibres in these muscles run at 90° to the ventral-dorsal orientation of the pelvic diaphragm and help support the pelvic floor and fix the perineal body in the centre. Most superficial in the male are the bulbospongiosus and ischio-cavernous muscles to anchor and stabilise the penis, or the vestibular bulb in females, and the former also contributes to emptying the urethra at the end of micturition (Figure 20B). In addition, skeletal muscle fibres also comprise the anal and urethral rhabdosphincters that play key roles in continence. To complete the pelvic floor the obturator internus and the piriformis muscles exit the bowl-shaped pelvic floor and attach to the top of the femur and concerned with moving the hip. The previous edition of the consultation [341] discussed importantly the female pelvic floor [343] and here the male counterpart will also be described.
1.1. The Levator Ani Musculature

It is well recognised that the levator ani are important for support of the pelvic organ. In women this is corroborated by the orientation of muscle fibres, at least in the pubococygeus and iliococygeus muscles: an ability to close penetrating tubular structures such as the vagina, rectum and possibly urethra is also indicated for the puborectalis muscle [344]. Much of the literature concerned with the function of the 'levator ani', in particular the role of androgens, also includes a consideration of the bulbospongiosus muscle. For completeness both will be considered here, although extrapolation of data obtained from the superficial perineal muscles to the deeper layers requires full evaluation.

The levator ani musculature has insertions to bone, as do most other skeletal muscles. Forces from the contraction of muscle fibres and transmitted to a type-IV collagen endomysium, which is turn connects to an epimysium rich in type-I collagen. Leaflets of epimysium aggregate to an intramuscular and extramuscular tendon. Skeletal muscle tendons require some elastin to recover their original length after a contraction [345], aided somewhat by the elasticity of muscle fibres themselves and also the mesh-like structure of collagen fibres [346]. However, levator ani fasciae are relatively rich in elastin [347], common to other skeletal muscles that insert not just to bone but also to soft tissues. In the case of levator ani this is with the urethral and anal rhabdosphincters and such an elastic junction may reduce damage after a strong muscular contraction of the levator ani. Furthermore, elastin fibres coexist with smooth muscle cells in such skeletal muscle / soft tissue interface and is true of levator ani muscles [347]. These smooth muscle cells do not form muscle bundles but are randomly orientated and so are not likely to form a separate contractile element. Rather they may form a viscous buffer in the connective tissue interface, as many smooth muscle cells in such an environment contract when passively stretched, as would happen in a skeletal muscle contraction [348]. Their individual electrical and mechanical properties have not been characterised.

Muscle fibre types are characterised as (Figure 21):

Type I: Slow twitch, high oxidative capacity, non-fatigable, moderate diameter, red

Type IIA: Fast twitch, very high oxidative capacity, non-fatigable, small diameter, red

Type IIB: Fast twitch, low oxidative capacity, fatigable, large diameter, white

Figure 20. Diagrams of the pelvic floor musculature from above (A) and below (B). A: view from above to show the coccygeus (C), pubococygeus (PC) and iliococygeus (IC) muscles. The piriformis (pir m) and obturator internus (ob m) muscles are also shown. B: view from below with the levator ani muscles in the centre and overlain by the deep transverse perineal muscle. The superficial transverse perineal muscle attaches to the perineal body. p.i.t., pelvic iscial tuberosities. Overlain (in orange) is the bulbospongiousus muscle.
The content of the O2 acceptor myoglobin is indicated by the red (high) or white (low) colour and further indicates high oxidative capacity. In rats the muscle fibre type is mainly Type-IIB, but small fibre diameter, and suggests that this would not provide much continuous pelvic floor support [349]. In dogs and sheep the majority of fibres were Type-II, but with no further histochemical differentiation, however the lack of fatigue with tetanic stimulation would also suggest type-IIA [350]. By contrast, in human muscle samples from women with or without genitourinary prolapse and/or urinary incontinence, about two-thirds of fibres were Type-I, with the remainder mainly Type-IIB [351]. There was no difference between samples from women with or without these pathologies, nor a dependence on age or parity. There was a similar observation in levator ani samples from men undergoing radical prostatectomy of cystectomy, with about 67% of Type-I fibres and the remainder now mainly Type-IIA [352]. Of interest in squirrel monkeys the Type-I/II is somewhat intermediate with about 43% if Type-I fibres in the pubococcygeus muscle [353]. Thus, with quadrupeds the need for continuous support for visceral organs will be less, as would be the consequent requirement for maintained contraction of levator ani muscles. With a bipedal stance humans will have a greater requirement for visceral organ support and so require a more non-fatigable muscle component to the pelvic floor. In the squirrel monkey study [353] changes to muscle histology that might be detrimental to function (e.g. fibrosis, increased muscle diameter) were associated with ageing, but not with parity or the presence of pelvic organ prolapse.

There is a paucity of work on the contractile or electrophysiological properties of levator ani muscles. Thus, although the fundamental principles of skeletal muscle contraction may be carried over to understand levator ani muscle function it should be remembered that the muscle fibre type differences, outlined above, will impact on aspects such contractile speed and sustainability. In vitro experiments with dog and sheep samples show fused, maintained and repeatable tetanic contractions at 20 Hz stimulation [350] and not different from other type-IIA muscles. In rat tissue resting and action potential characteristics [354] are also similar to those in other slow muscle types [355]. However, the muscle mechanics, biomechanical and electrophysiological properties of these muscles have not been systematically characterised. Therefore, the factors that influence excitation-contraction coupling and how they may change in pathological conditions cannot be properly evaluated.

In the absence of much direct physiological characterisation of the contractile properties of levator ani muscles, anatomical studies of human cadaveric specimens give some pointers. Comparative measurement of pubococcygeus, illeococcygeus and coccygeus: muscle fibre length; sarcomere length; and cross-sectional area of muscle within a muscle bundle after correction for collagen content have been made [356,357]. Data were interpreted as muscles with longer fibre length had a greater overall length of shortening, sarcomere length would indicate where on the length-tension curve the muscle was placed at.

Key facts:
- The different colours of muscle fibres reflects labelling of different myosin ATPase isoforms
- Motoneuron diameter. Larger diameters reflects greater action potential conduction velocity and rate of muscle activation
- Motor unit: the basic functional contractile unit of a skeletal muscle – a motoneurone and the individual muscle fibres it innervates.
rest, muscle cross-sectional area an estimate of contractile strength. Fibre length was greatest in pubococcygeus and least in coccygeus, whereas sarcomere length and cross-sectional area were similar. The greater length of pubococcygeus fibres was interpreted as an ability of this muscle to contract despite large changes of abdominal pressure. Surprisingly the sarcomere lengths were very short (about 2 µm) compared to those of other skeletal muscles such as latissimus dorsi (mixed type-I/II [358,359]) or psoas (predominantly type-IIA fibres) muscle [360,361] and implies that the ability of the muscle to contract would not be impaired by considerable lengthening. Estimates of absolute tension developed by these muscles was however, small compared to those above and alone they could not contract sufficiently to offer pelvic floor support with substantial changes of abdominal pressure.

1.2. Innervation of Levator Ani Muscles in Females and Males

In the females of humans, cats, dogs, monkeys and rats the muscles of the levator ani are innervated by the nerve of the same name (LA nerve) that emerges from S3-S5 segments: there is no evidence of a significant contribution from the pudendal nerve [362,363]. The course of the nerve is differs between subjects; in slightly less than half of dissected cadavers the nerve to the levator ani had an external position along the inferior surface of the LA muscle after passing through the coccygeus muscle. In the remainder, the nerve passed over the superior surfaces of the coccygeus and iliococcygeus muscles [364]. It is important to appreciate the course of the LA nerve and its variability to: reduce damage during surgical procedures; to appreciate that the LA and pudendal nerves at the ischial spine are only about 0.5 cm from each other [365], so that pudendal nerve block would probably impact on the LA nerve as well. Also it is important to understand that damage to the nerve in childbirth may predispose to a greater incidence of later pelvic organ prolapse (POP), due to the significant relationships between levels of levator ani damage, parity and POP [366,367]; although a small study of bilateral denervation of the levator ani in squirrel monkeys did not increase POP [368]. Large and small diameter motor neurones are present in the LA nerve that may correspond to α-motor neurones and γ-fibres that innervate muscle spindles that are observed in the levator ani [363,369]. This presumes that monosynaptic stretch reflexes can be evoked in these muscles. Motor neurones processes also project to terminations of muscle spindle and Golgi tendon organs afferents [370], but also to Onuf’s nucleus and imply a coordination levator ani and urethral rhabdosphincter musculature. As with motor neurones two populations of afferent nerves are identified, the larger ones possibly conveying proprioceptive information, whilst the smaller ones convey nociceptive sensations.

Reflex control of pelvic floor musculature during micturition is poorly studied. In female rabbits the PC muscle is active during filling, whilst it is quiet during micturition [371]. In a study with male rats PC EMG activity increased during micturition [372]. It is noteworthy that the rabbit, as in humans, exhibits a complete inhibition of sphincter activity during micturition, whilst in the rat there are high frequency increases of sphincter activity that gives a more dyssynergic voiding pattern. However, it highlights the potential difficulty to inter-species comparisons and also that pubococcygeus and iliococcygeus muscles have other functions also, such as controlling tail activity and influencing effectiveness of copulation in rats [373].

Less work is available in males. The pubococcygeus muscle in male rats is innervated by the somato-motor branch of the pelvic nerve that carries both sensory and motor nerves and with motor neurone cell bodies in the lumbosacral boundary [372,373]. Micturition and raised bladder pressure were associated with an increase of, and possibly activated, pubococcygeus activity. Muscle activity produced reflex inhibition of detrusor function so that voiding was intermittent and oscillations of bladder pressure were superimposed on the raised baseline. The muscle is also attached to the urethral rhabdosphincter thus exerting a control over sphincter competence.

2. ANDROGENS AND ‘LEVATOR ANI’ FUNCTION.

The contractile properties of levator ani/ bulbospongiosum muscles are susceptible to exposure to androgens. This is of interest to investigate potential steroid hormone-muscle interactions and neuromuscular development, as well as gain insight into the potential side-effects on pelvic floor function of androgen therapy for other conditions. Castration of male rats had no effect on muscle action potentials; however, there was a loss of total muscle weight and prolongation of contraction time indicating a change to contractile machinery [354]. Moreover, castration is associated with a loss of muscle nicotinic receptors and acetylcholinesterase activity, reversed by testosterone treatment [374,375]. Transmitter release from motor neurones to levator ani muscles is regulated by Ca\textsuperscript{2+} influx at the nerve terminal via P/Q-type (Ca\textsubscript{2,1}) as well as N-type (Ca\textsubscript{2,2}) Ca\textsuperscript{2+} channels. Castration induced functional loss of Ca\textsubscript{2,2} ameliorated by testosterone treatment [376]. However, the frequency and amplitude of miniature-end-plate potentials, representing random transmitter release from the motor synapse are increased by castration and reversed by testosterone administration [375,377]. Thus androgens could act to prevent quantal losses of transmitter during an absence of motor nerve depolarisation, so that with large Ca\textsuperscript{2+} influxes through Ca\textsubscript{2,2} channels on arrival of the action potential transmitter release is maintained [376].
Androgens, but not estrogens, also affect levator ani function immediately post partum. Innervation of individual motor units changes from a polynuronal to a mononeuronal phenotype so that motor unit size and innervation reduces to an adult model, a process that is attenuated by androgens [378,379]. Androgen receptors are located on the muscle, motor nerves as well as spinal cord motor nuclei, although the cellular pathways for regulating developmental synapse elimination are unclear [378-381]. How this may relate to reversing the effects of denervation of the pelvic floor during trauma should be investigated.

3. THE EXTERNAL URETHRAL RHABDOSPINCITER

The skeletal muscle surrounding the urethra forms an incomplete ring in the middle to caudal third of the urethra [382,383]. The muscle is thicker on the ventral and lateral sides of the urethra and on the dorsal surface insert on to the vagina or perineal body, in women or men. It better defined in men, although in both there is a graded transition between smooth and skeletal muscle making a distinctive boundary not easy to identify. In men extension of the male urethral rhabdosphincter covers the distal part of the prostatic capsule by the prostatic apex [384] and here skeletal and smooth muscle fibres intermingle. Various names have been coined for this physiological entity ranging from the external urethral sphincter, rhabdosphincter and urethral striated sphincter. For consistency with the previous consultation it will be referred to here as the urethral rhabdosphincter.

A detailed description of the efferent and afferent innervation of the urethral rhabdosphincter was described in the previous consultation [341] and amplified in a review [363]. The same review also considered in detail the supraspinal control of the urethral rhabdosphincter, including the neurochemistry of the motor neurones in Onuf's nucleus. This report will concentrate more on the physiology and pathophysiology of the skeletal muscle fibres that comprise the urethral rhabdosphincter.

3.1. Muscle Fibre Types of the External Urethral Rhabdosphincter

The muscles fibres are unusual in that they do not attach directly to a skeletal structure so that there is little active shortening on excitation. However, there is attachment to the levator ani muscles that will provide some rigid support as discussed above. The relationship between the urethral rhabdosphincter and other structures in the pelvic floor demonstrates differences between men and women [344]. In females, the striated muscles are embedded in a matrix with many elastic fibrils [385] and is continuous with a perineal membrane to allow connection with the pelvic ischia. In males this attachment to the levator ani is provided by a fairly rigid fascia that contains many smooth muscle cells.

The fibre type of the urethral rhabdosphincter has been determined in human and several animal species. With rabbit, dog and guinea-pig tissue there is a preponderance of fast twitch fibres [386-389]. With one of these studies using canine tissue the fast twitch subset represented about 65% of the total, of which in turn about 80% were type-2B, white, fatigable fibres [386]. This has led to the proposal that the type-I fibres maintain continence at rest, whilst type-II fibres are further recruited when greater resistance is needed to overcome increases of abdominal pressure, as in sneezing or coughing. Most studies used male animals but in the one using males and female animals [387] no differences were seen. With human tissue from males and females slow twitch fibres predominate [390], although in the extension of the urethral rhabdosphincter covering the prostatic capsule and mixed fibre type is recorded similar to that in animal tissues [391].

Electron microscopy demonstrates typical striated muscle sarcomeres with variation of mitochondrial number indicative of oxidative or glycolytic muscle fibres [384]. Classical motor endplates were present with a 40-80 nm neuromuscular cleft. Of interest, less specialised nerve-muscle junctions were also observed, suggestive of autonomic endings with a 50-120 nm neuromuscular cleft, contact slow and fast muscle fibres. From the appearance of vesicles in the nerve endings these were identified as cholinergic, adrenergic or peptidergic endings. However, the concept of a dual somatic and autonomic innervation of the canine prostate was later questioned from anatomical studies that suggested that autonomic nerves merely passed through the skeletal muscle enroute to the urethral smooth muscle [392]. Overall the data are consistent with the urethral rhabdosphincter receiving a motor innervation from the pudendal nerve [382,383], that emerges at S2-4 and runs along the internal obturator and coccygeus muscles and through the pudendal (Alcock’s) canal formed from obturator fascia. The lack of muscle spindles, small unmyelinated (γ-afferents) and Golgi tendon organs, is also a feature of urethral rhabdosphincter [391,393], and implies that there are few spinal reflexes that optimise muscle function.

3.2. Electromechanical Properties of External Urethral Rhabdosphincter Muscle

Measurement of electrical activity of the urethral rhabdosphincter with extracellular electrodes is a valuable tool for evaluating normal and abnormal function of the external urethra [394,395]. However, there is very little information about the electrophysiological or contractile properties of urethral rhabdosphincter muscle to help interpret clinical extracellular recording. Isolated canine circular strips of membranous urethra responded to stimuli designed to excite embedded nerves [392]. At low frequencies (5 Hz) twitch contractions were generated and at 20 Hz fused tetanic contractions developed. Twitch rise-time (about
the characteristics of flux through an L-type Ca\(^{2+}\) channel. Responses were unaffected by atropine or phentolamine, consistent with somatic nerve stimulation. With guinea-pig preparations, twitch characteristics (twitch duration, twitch-tetanus ratio) were similar to those from a fast twitch muscle such as *externum digitorum longus* (EDL) rather than the slow twitch soleus muscle. No equivalent investigations have been made in human samples. A human urethral rhabdosphincter cell culture model was generated that retained a skeletal cell phenotype; some cells developed spontaneous contractions and more in the presence of acetylcholine [396]. It has not been ascertained if they represent a model of differentiated urethral rhabdosphincter myocytes. Their use as a cell replacement therapy for sphincter incompetence or stress urinary incontinence can add to the range of other cell types for this purpose, including muscle-derived and adipose-derived stem cells [397-399].

Ionic currents have been recorded from human and pig myoblasts after four days of culture. Cells were prepared from biopsies of urethral rhabdosphincter, as well as pig adductor muscles as a comparator [400]. Recording micropipettes contained CsCl, to block outward (K\(^{+}\)) current leaving inward currents for analysis. Inward Na\(^{+}\) current was measured in both types of pig muscle cells and was of a magnitude that would support an action potential. In pig myocytes an inward Ca\(^{2+}\) (in fact a Ba\(^{2+}\) current, as Ba\(^{2+}\) travel through Ca\(^{2+}\) channels) was also recorded with the characteristics of flux through an L-type Ca\(^{2+}\) channel. Of interest, with human cells the Ba\(^{2+}\) current had characteristics of flux through an L-type and also a T-type channel. The significance of a T-type Ca\(^{2+}\) channel in urethral rhabdosphincter skeletal muscle is not known but have been proposed to aid the formation of myotubes [401]. However, because T-type channels are activated at membrane potentials near the resting value they have been proposed to enhance the ability of an excitable cell to generate an action potential.

3.3. Electromyography (EMG) and the External Urethral Rhabdosphincter.

The electromyogram is an extracellular recording and as such gives no information about the electrical properties of individual skeletal muscle cells. Rather, it is a measure of total electrical activity of the muscle fibres and allows the investigator to determine if the muscle mass is electrically active or not. The magnitude of the EMG is a function of the number of muscle fibres contributing electrical signals, but *per se* does not inform about the magnitude of the muscular contraction. Concentric needle EMG recording [402] is generally undertaken and allows measurement of several descriptors of the signals, including amplitude, duration, area, mean firing frequency that may be compared in normal and pathological conditions. In some circumstances single fibre EMG recordings [403,404] are possible to record electrical signals from a single muscle fibre, or a few muscle fibres often from the same motor unit, that allows more detailed examination of the gross electrical properties of the muscle fibre or the excitability of the motor unit. The pattern of EMG during the micturition cycle can be very different in humans and animals which in part can reflect the various purposes of voiding, such as to completely empty the bladder or intermittent voiding for marking territory. Thus, in humans, during filling a guarding reflex ensures increased EMG activity in humans, decreasing during voiding, whilst in rats there are characteristic bursts of EMG discharge during voiding [405-407]. Bladder outflow obstruction from detrusor-sphincter dyssynergia is associated with increased EMG activity during voiding [408] and could be alleviated by injection of the botulinum toxin into the sphincter [409]. A recent Cochrane review gave a guarded response indicating some improvements of urodynamic parameters with a single injection of botulinum toxin-A [410].

EMG recordings of complex repetitive discharges (myotonia-like activity) have been made from the urethral rhabdosphincter of pre-menopausal women with urinary retention (Fowler’s syndrome, [411,412]). This enhanced discharge is reflective of greater contractile activation of the skeletal muscle to generate an increased urethral resistance. The aetiology of the condition is not known but it was reported to be associated in some patients with the presence of polycystic ovaries and more recently it was noted that asymptomatic women with such an EMG activity were in the luteal phase of the menstrual cycle [413] when progesterone levels are highest. Muscle biopsies of women in retention did not show hyperplasia or hypertrophy [414] suggesting that an increase of muscle mass did not account for the larger EMG signal. The authors of the original papers [411,412] tentatively proposed that great EMG may be due to ephaptic transmission of electrical signals between muscle cells so produce large and repetitive responses. However, despite there being no experimental evidence of this unusual phenomenon the idea has gained some traction.

Ephaptic transmission is the direct electrical coupling of excitable cells without synaptic transmission (as in nerves) or through low resistance intercellular junction (as in myocardium). It usually occurs in conditions when the extracellular resistance is high so that local electrical fields in one cell generate a change of membrane potential in another. This is generally in unphysiological conditions but can occur between nerve axons [415,416] and the electrical conditions under which it occurs have been summarised [417]. It has been suggested that abnormal ion channel activity, in particular the Cl\(^{-}\) channel CIC-1, in skeletal muscle fibres might modulate muscle fibre excitability and create the appropriate conditions for myotonia [418,419]. Progesterone reduces Cl\(^{-}\) currents through a non-genomic pathway in isolated muscle fibres [420], but it remains to be shown how such channel modulation influences muscle activity.
3.4. Ageing, Lower Urinary Tract Pathology & the External Urethral Rhabdosphincter

Because of the central role of the urethral rhabdosphincter in continence there is interest in changes that occur to its structure and function with ageing and also its relation to urinary incontinence, especially stress incontinence. There is considerable evidence that in humans and in animals there is a reduction of muscle mass with age. Dissection of female cadavers showed there is a linear reduction of the volume of tissue occupied by skeletal muscle fibres as well as the total number of cells [421-423]. In one study the volume occupied by muscle fibres ranged from nearly 90% in a neonate to less than 35% at age 90 [423]. Moreover, the loss was uniform along the length of the urethral rhabdosphincter [424]. Transurethral sonography showed an age-dependent decline of muscle thickness with age, as well as a negative correlation between urethral closure pressure and age [425]. A change of fibre-type has also been reported in rabbits with a decline of fast (type-II) fibres declines at the expense of slow (type-I) fibres [426]. Compared to women with normal continence, reduction of urethral rhabdosphincter function is associated with stress incontinence, but not urge incontinence [427]. A decrease of urethral rhabdosphincter volume is also associated with stress incontinence and well as overall poorer pelvic floor function [428]. Transurethral sonography has also revealed defects to the urethral rhabdosphincter in women with stress incontinence that included reduced contractile function, scarring of the tissue, as well as overall thinning [429]. In men, damage to the urethral rhabdosphincter is also associated with incontinence following prostatectomy [430]. Reduction of the membranous urethra length, and an increase of fibrosis were associated with greater incontinence and a longer post-operative recovery time [431].

Figure 22. Electromyography (emg) and the external urethral sphincter. A: the diagram shows a concentric needle electrode with a central electrode shielded from a reference casing electrode. Signals from the two electrodes pass to a differential amplifier and the output is a record of extracellular signals generated by action potentials in adjacent muscle cells. The superimposition on the end of the electrode shows the disposition of muscle fibres from which recordings may be made. B: A diagram of the urethra at the level of the external urethral sphincter to show an outer layer of skeletal muscle from which needle electrode recordings of emg activity may be made. Below is a schematic of an emg recorded from a normal subject and one with detrusor sphincter dyssynergia (DSD). Tracings of subtracted detrusor pressure, Pdet, are also shown. In the normal subject there is an increase of emg activity at the beginning of contraction (guarding reflex) followed by a period of quiescence to allow voiding. In the DSD patient emg activity is present through out and no voiding here is observed.
1. RELAXIN: TREATMENTS FOR RADIATION CYSTITIS AND THE UNDERACTIVE BLADDER

Relaxin is a 6-kDa hormone, first described in 1926 [432], that is produced mainly by the ovarian corpus luteum to relax the uterus and soften the pubic symphysis during pregnancy [433]. In addition, it is produced in the prostate and testes to enhance sperm motility [434]. It belongs to the insulin superfamily, with seven members exhibiting high structural but low sequence homology; relaxin-1 to -3 and insulin-like peptide-3 to -6 [435]. It is formed as a three-chain pro-hormone, cleaving off one of the chains to form the active heterodimer with 24 and 29 amino acids linked by disulphide bridges. Relaxin receptors are 7-transmembrane G-protein coupled receptors that activate adenylate cyclase. There are four receptors for relaxins (RXFP1-4), with RXFP1 being the most studied in humans and rodents and for which relaxin-2 has the highest affinity. These receptors have a broad distribution [432]; including smooth muscle, connective tissue, the nervous system, heart and as described here the urinary bladder.

Canonical Wnt signaling is believed to stimulate members of the fiddled receptor family to initiate the translocation of β-catenin from the cell membrane to the nucleus to initiate collagen deposition, remodeling and fibrosis [436]. This can be opposed by relaxin-2 binding to one of its four receptors. Relaxin-2 binding increases PKA which inhibits β-catenin. Furthermore, it can also stimulate pathway leadings to gene transcription and increased expression of extracellular matrix (ECM) metalloproteinases [437], augmentation of voltage-gated Ca²⁺ channel current [438], along with decreased collagen synthesis [439] (Figure 23).

**Figure 23.** Pathways for relaxin and Wnt signalling regulating bladder wall fibrosis. Activation of the relaxin receptor pathway can increase extracellular matrix (ECM) metalloproteinase expression, to decrease collagen synthesis and elicit an anti-fibrotic effect, as well as increase expression of voltage gated Ca²⁺ channel proteins in muscle cells. Wnt protein, acting through frizzled receptors, activates β-catenin to allow its translocation to the nucleus where it acts as a transcription factor. β-catenin may regulate gene expression that leads to proliferation of fibroblasts, collagen deposition and increased tissue fibrosis. Protein kinase-A (PKA) activation via the relaxin receptor may prevent β-catenin activity, but this interaction has yet to be described in the bladder.
1.1. Radiation Cystitis

This condition can result from irradiation therapy of pelvic organ tumors in men and women that are estimated to account for 36% and 18%, respectively, of new malignancies diagnosed in the United States in 2016 according to the American Cancer Society [440]. While irradiation is a key therapy for treating these malignancies, the radiation dose is limited by the potential for developing radiation cystitis. Accordingly, irradiation therapy is typically fractionated into daily 0.5-2 Gray (1 Gy = 100 Rads) increments until the desired dose is achieved (e.g., 20-60 Gy) [441].

The acute symptoms of radiation cystitis can occur within days and include bladder inflammation, urgency, frequency, dysuria and incontinence [442]. Initiation factors are disruption of the urothelial cell permeability barrier and sensitization of afferent nerves [443]. In addition to DNA damage, irradiation induces Ca²⁺ influx and intracellular release in urothelial cells that activates nitric oxide synthases. Nitric oxide (NO•), in turn, binds to cytochrome oxidase which can inhibit the mitochondrial respiratory chain. This results in the production of superoxide (•O₂⁻) which reacts with NO• to form peroxynitrite (ONO₂⁻) which further inhibits respiration and damages proteins, leading to swelling and rupture of the mitochondria, cytochrome c release and urothelial cell apoptosis [444]. The leading candidates responsible for this Ca²⁺ influx are transient receptor potential ankyrin-1 and vanilloid-1 (TRPA1 and TRPV1) channels that are highly expressed in urothelial cells [445,446]. TRPA1 is activated by acrolein, a by-product of fatty acid lipid peroxidation generated in cells by ionising irradiation [447]. Activation of TRPA1 by acrolein in urothelial cells (and TRPV1 by capsaicin) results in chemical cystitis with symptomology similar to radiation cystitis [448], as shown in schematic form in (figure 24).

Figure 24. Mechanisms for development of acute and chronic radiation cystitis following exposure to ionizing irradiation. Top left: Urothelial cells are one of the most susceptible to irradiation damage. Oxidative by-products activate TRPA1 and TRPV1 channels to cause a sustained intracellular Ca²⁺ rise, activation of nitric oxide synthase (NOS), inhibition of the mitochondrial respiratory chain and, as a consequence, generation of nitrogen and oxygen free radicals from L-arginine (l-Arg). This sequence of events leads to the initiation of apoptotic pathways, disruption of the urothelial barrier and further inflammation in the bladder wall. Top right: TRPA/V1 channels are present on sensory neurons innervating the bladder and these, on activation, cause neuropeptide release and afferent sensitisation, as observed acutely in radiation cystitis. Mast cell TRPA1 channel activation also induces degranulation and release of inflammatory mediators. Bottom: Self-perpetuating inflammation initiated by ionising irradiation leads to collagen deposition throughout the lamina propria and between muscle cells in the detrusor layer.
Moreover, these channels are highly expressed in mast cells and in sensory nerves innervating the bladder, colon and other pelvic organs, and suggests that irradiation may sensitize afferent nerves. The most radiosensitive cells in the body include lymphocytes and hematopoietic cells of the immune system, the capillary endothelial cells of the gastrointestinal (GI) tract and the urothelial cells of the urinary bladder [444]. Therefore, whole body irradiation >10 Gy can induce considerable morbidities due to a breakdown of the GI tract and urinary bladder barriers in the presence of a compromised immune response.

Chronic radiation cystitis can develop within 6-12 months, with its prevalence reaching ~7% [442]. The consequences include vascular endothelial cell damage, ischemia, collagen deposition and decreased bladder compliance. The main presenting feature for the chronic phase is haematuria which can range from mild to life-threatening and may include urinary retention, secondary to clots obstructing the urethra. It can also greatly reduce bladder compliance and bladder contractile function, due to collagen deposition [442]. Therapy includes transurethral catheterisation with bladder washout and irrigation, laser fulguration, electrocoagulation, pentosan polysulphate and hyperbaric oxygen therapy [449]. These approaches are invasive or time-consuming and often fail to demonstrate optimal efficacy and do not improve bladder compliance for which a new potential treatment is relaxin therapy. Relaxin has undergone phase I clinical trials for treating acute heart failure and scleroderma, validating its safety for use in humans.

A mouse model has been developed to mimic chronic radiation cystitis, whereby a laparotomy is performed so that the bladder may be briefly withdrawn for selective high dose (10 Gy) irradiation (Figure 25A – AJ Kanai unpublished). Delivered to the intact pelvic region such a dose could be lethal (LD50 $\approx$ 8 Gy). Nine weeks after selective bladder irradiation animals were unable to void and exhibited overflow incontinence, despite a decrease of intercontraction interval. Figure 25B shows cystometry (red traces) of control animals (upper panel) and irradiated mice (middle panels). The inability of irradiated bladders to empty normally is associated with decreased compliance due to chronic fibrosis (see also Figure 26, below). The corresponding external urethral sphincter (EUS) electromyogram (green traces) shows in normal animals an increase of activity (a guarding reflex) at the initiation of contraction, but then ‘bursting’ activity that allows voiding – this pattern is characteristic of these rodents. The period around bladder contraction is shown on an extended time-base to the right of each panel. EMG activity in the irradiated animals showed a loss of the guarding reflex and a maintained guarding reflex activity later in the bladder contraction, rather than the bursting activity. However, relaxin administration for two weeks starting at week-7 post-irradiation (400 μg/kg/day infused subcutaneously with implantable ALZET mini-pumps), the cystograms and electromyograms (Figure 25B, lower panel) were similar to those seen in non-irradiated mice, with the return of a normal guarding reflex and bursting activity which permitted voiding. It is important to note that while human and rodent spincters exhibit a guarding reflex as bladder pressures approach threshold, the sphincter in humans completely relaxes during detrusor contraction.
In vitro studies of detrusor muscle samples from irradiated mouse bladders with and without relaxin treatment showed large effects on passive and active isometric tension over a range of resting lengths. An increase of passive stiffness with irradiation was reversed by relaxin (Figure 26A). Moreover the reduction of active force after irradiation was reversed by relaxin treatment to the extent that force exceeded that measured in control animals. This additional recovery was observed not only in nerve-mediated (electrical field-stimulated, EFS) contractions but also with the muscarinic receptor agonist, oxotremorine-M (Figure 26B). Recovery was also observed with contractions elicited by muscle depolarisation, with high-K solution, or purinergic receptor activation, with \( \alpha_1 \beta \) methylene-ATP (ABMA), but in these cases recovery was to the control level. Therefore the recovery of function with relaxin is greater for cholinergic pathways compared to other routes of contractile activation. These beneficial effects of relaxin were mirrored by a reduction of the collagen:tissue ratio (Figure 26C) and an increased expression of \( \alpha_1C \) subunit protein of the L-type Ca\(^{2+}\) (CaV\(_{1.2}\)) channel (Figure 26D). This is the first use of relaxin to treat bladder dysfunction due to irradiation damage and thus represents a potentially effective treatment for radiation cystitis.

Figure 25. Cystometry and electromyography (EMG) of the external urethral sphincter in irradiated mice with and without relaxin treatment. A. Selective bladder irradiation model. B: Cystometry (upper traces) and EMG (lower traces) in control mice (upper panels), nine weeks following bladder irradiation (middle panels) and nine weeks after irradiation and relaxin treatment (lower panels). An expansion of the time-base is shown in the panels on the right to show more clearly the EMG activity during the voiding contraction.
1.2. Underactive Bladder (UAB) Syndrome and Relaxin Therapy

In addition to radiation cystitis, collagen deposition and decreased bladder compliance can occur with ageing leading to bladder underactivity/UAB syndrome. A majority of the elderly may initially exhibit bladder overactivity/overactive bladder (OAB) syndrome which may be managed by current therapies. However, over time, overactivity may likely revert to underactivity for which there are currently no effective therapeutic agents.

Bladder underactivity, according to the International Continence Society, is a contraction of reduced strength and/or duration, resulting in prolonged voiding and/or failure to achieve complete bladder emptying within a normal time span based on a urodynamic diagnosis. On the other hand, UAB syndrome covers a general condition irrespective of whether the cause is afferent dysfunction, lack of CNS control, or myopathy of the detrusor itself [450,451]. There are several animal models for studying bladder underactivity/UAB [452], including: type I and II diabetic mice and rats; partial bladder outlet obstruction (pBOO) and bladder overdistension; ischaemia/reperfusion and oxidative stress (due to H2O2 instillation); pelvic nerve cut and crush; and ageing typically using 18-24 month old rats. Whilst ageing is perhaps the most physiologically relevant of these models, it is also one of the most difficult to study because of survival, variability and cost issues. Accordingly, in the United States, rats for these studies are typically obtained by qualified investigators through the National Institute on Aging (NIA) of the National Institutes of Health. In studies using NIA rats, 24 month-old aged animals exhibited a substantial increase of passive tension at a range of lengths over that measured in 9 month-old adults. Active tension was comparable between the two age groups. However, after two weeks of treatment with relaxin (400 µg/kg/day infused subcutaneously), there was a significant reduction of passive tension (stiffness) in the aged animals and increase of active force increase in both compliance and force generation to a value greater than that in younger animals. These observations are similar to those seen in studies using NIA rats, 24 month-old aged animals exhibited a substantial increase of passive tension at a range of lengths over that measured in 9 month-old adults. Active tension was comparable between the two age groups. However, after two weeks of treatment with relaxin (400 µg/kg/day infused subcutaneously), there was a significant reduction of passive tension (stiffness) in the aged animals and increase of active force increase in both compliance and force generation to a value greater than that in younger animals. These observations are similar to those seen
with irradiated animals and relaxin treatment. However, in this case relaxin treatment did not improve force mediated by cholinergic, purinergic or depolarising pathways (data not shown) but did decrease the collagen:smooth muscle ratio in aged animals. Thus, with aged animals the decrease of collagen content was solely responsible for recovery of muscle performance with relaxin. However, although there was no evidence for upregulation of cellular pathways for force generation by relaxin in aged animals the immunohistochemical expression of the L-type Ca\(^{2+}\) channel α1C subunit, CaV1.2, in detrusor smooth muscle was changed from a patchy to a more homogeneous pattern after relaxin treatment of aged animals. This also suggests the potential value of relaxin to increase bladder performance due to ageing especially in those with bladder underactivity/UAB syndrome.

2. LM11A-31—SELECTIVE BLOCKADE OF P75 NEUROTROPHIN RECEPTORS.

2.1. Prevention Urothelial Loss, Spinal Cord Atrophy and Detrusor-sphincter-dyssynergia Following Spinal Cord Injury

p75 is a neurotrophin receptor (p75\textsubscript{NTR}) and a member of the tumor necrosis factor receptor superfamily. Its intrinsic catalytic activity is very low, but partnering with other neurotrophin (TrkA, TrkB and TrkC) and non-neurotrophin receptors (sortilin and Nogo) they produce high-affinity binding sites for neurotrophins and their precursors [453]. When complexed with Trk receptors, p75\textsubscript{NTR} promotes survival and differentiation increasing the affinity to mature neurotrophins. However, when linked with sortilin, the complex binds pro-neurotrophins activating apoptotic pathways promoting cell death (Figure 27, [454]).

Neurotrophins are a family of proteins, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF) and neurotrophins 3 and 4, which promote neuronal survival and differentiation, modulate synaptic plasticity and play important roles in both developing and mature nervous systems [455]. They are initially synthesized as precursors or pro-neurotrophins consisting of two domains (N-terminal pro- and C-terminal mature) which can be cleaved by intracellular proteases to generate functional forms. They can also be released from cells intact and selectively activate p75\textsubscript{NTR} at subnanomolar concentrations to induce apoptosis [456].

In the urinary bladder, neurotrophins are released by mast cells, urothelial cells and smooth muscle cells and are believed to contribute to lower urinary tract dysfunctions including overactive bladder and interstitial cystitis/painful bladder syndrome [457-459]. It has been shown that levels of both neurotrophins and their receptors increase dramatically following pathological conditions including spinal cord injury (SCI) [460,461]. This has made neurotrophins a potential therapeutic target for a number of years, but with marginal success possibly due to the indiscriminate inhibition of both the pro (apoptotic) and mature (beneficial) forms by antibodies, antisense approaches or drugs.

Little is known about the time course of the neurotrophin, pro-neurotrophin and their receptor level changes in disease. Investigations using rat urinary bladders revealed increased levels of NGF mRNA in acute (4 days) and chronic (5-6 weeks) SCI, however, the levels of NGF protein were significantly decreased acutely after injury and correlated with mRNA levels only with the reemergence of spinal reflexes [462]. A few studies suggest that pro-neurotrophins may be produced shortly after SCI, with a time course from several hours to 14 days, with a peak around 3 days [463,464]. P75\textsubscript{NTR} is also upregulated in SCI, unlike Trk receptors that are poorly expressed [464]. Both NGF and p75\textsubscript{NTR} are decreased nine weeks after induction of diabetes in streptozocin rat bladders [461].
LM11A-31 is a small molecule first reported in 1985 as an antihypertensive agent by a group at Ciba-Geigy followed by a group at Roche in 1990 for the treatment of infections caused by HIV and other retroviruses [465]. Subsequently, it was demonstrated to interfere with proneurotrophin binding to p75NTR, efficiently crossing the blood-brain barrier and improve motor coordination after spinal cord contusion in mice, partially by increasing myelin sparing [466]. Administered orally, it exhibited no toxicity and did not exacerbate any injury-associated pain. The dose of 100 mg/kg twice daily has been shown to be maximally effective in a variety of endpoints [466].

In separate experiments described here, mice were given 100 mg/kg of LM11A-31 as a single dose daily and the treatment was shown to be significantly beneficial. Although little is known about the metabolism of this drug, only very low plasma concentrations were measured after seven oral doses over three days [466]. Very low oral bioavailability suggests that a significant portion of the drug may be excreted in the urine unchanged, which could result in peripheral effects due to higher drug levels in the bladder.

SCI-induced bladder dysfunction includes two major components, detrusor-sphincter-dysynergia (DSD) and detrusor overactivity (DO). These are debilitating problems that carry the risk of complications including urolithiasis, vesicoureteral reflux, hydronephrosis, obstructive uropathy and renal failure. The mainstay treatments are antimuscarinic agents, clean intermittent catheterization and external sphincterotomy which are associated with significant risks of unwanted side effects, infections, haemorrhage and erectile dysfunction. It was proposed that the increase in pro-neurotrophins and activation of p75NTR by proneurotrophins following SCI causes neuronal and urothelial apoptosis in spinal cord and bladder, respectively, leading to detrusor sphincter dyssynergia (DSD) or detrusor overactivity (DO). LM11A-31 inhibits these pathways. (Figure with the courtesy of Youko Ikeda, Irina Zabbarova and Anthony Kanai)
morphological changes were much reduced by pre-treatment with LM11A-31 and daily treatment after injury for the day-10 group. This loss of urothelial integrity at day-1 was confirmed by measurement of transepithelial resistance (TER) using an Ussing chamber system. TER was significantly decreased in bladders of SCI mice day-1 after injury compared to uninjured controls (700±200 Ω•cm² vs 2500±1000 Ω•cm², respectively, n>4). LM11A-31 treatment preserved barrier function in tissue from day-1 post-SCI animals (2000±700 Ω•cm², n=4). This data suggest that proneurotrophins may be involved in urothelial damage and initiating bladder wall remodeling following SCI.

SCI in mice causes bladder outlet obstruction due to the loss of supraspinal connections that initiate and coordinate urethral relaxation and detrusor contraction. Following a recovery period, a spino-somato-loop develops that initiates reflex bladder contractions in response to perigenital stimulation to help empty the bladder. However, the development of detrusor sphincter dyssynergia (DSD) limits urine expulsion and leads to further retention and damage as in the case of radiation cystitis (see section VII.1, above). Characteristic changes to the external urethral sphincter electromyogram of a loss of guarding response and replacement of later bursting activity with continuous increased activity are similar to that observed with damage through radiation cystitis. These changes were accompanied by non-voiding contractions and eventually overflow incontinence. Accordingly, cystometric measurements from SCI mice at two, four and six weeks post-injury demonstrated a significant increase in baseline pressure and non-voiding contractions and a decrease of bladder compliance (see Figure 28B, left panels). Daily treatment of mice with LM11A-31 by oral gavage pre-SCI and then post SCI was carried out until cystometry was performed (Figure 28B, right panels). Treated mice exhibited more efficient voiding, longer intercontractile intervals, higher bladder compliance and smaller numbers of non-voiding contractions.

LM11A-31 has also been demonstrated to improve functional recovery following spinal cord contusion by

**Figure 28. Effect of L11A-31 treatment on bladder wall structure and cystometry after spinal cord injury (SCI).**

A: Effect of L11A-31 on bladder wall structure day-1 and day-10 post-SCI. Haematoxylin and eosin staining. B: Cystometry of mouse bladders from 2-week, 4-week and 6-week post-SCI animals with or without treatment with L11A-31. Cystometry from a normal animal is shown above the SCI traces. (Figure with the courtesy of Irina Zabbarova and Anthony Kanai)
increasing the number of myelinated axons through preventing oligodendrocyte loss [466]. The effect of LM11A-31 (100 mg/kg/day, starting 1-day prior to SCI) on the spinal cord following T8-T9 transection was examined. There was a significant degree of atrophy at 8-week post SCI. However, the spinal cord of SCI mice treated daily with LM11A-31 (100 mg/kg/day, starting 1-day prior to SCI) had significantly less atrophy and demonstrates a long-term protective effect of p75<sup>NTR</sup> inhibition in the central nervous system following SCI.

Inhibition of proneurotrophin-p75<sup>NTR</sup> interaction has been demonstrated to improve functional recovery following spinal cord contusion injury. We have demonstrated that it prevents spinal cord atrophy following transection. This suggests it may prevent neural degeneration centrally to improve motor function as well as reduce DSD which hinders bladder emptying and urine storage. There is also inflammation of the bladder wall following SCI which is believed to arise from a compromised urothelial barrier causing urine infiltration, and does not disappear in chronic patients. Both SCI [468] and inflammation [469] are associated with the increased expression of proneurotrophins and p75<sup>NTR</sup> in the bladder wall. We have demonstrated that LM11A-31 is effective in maintaining structural integrity of the bladder wall preventing urothelial apoptosis soon after SCI and chronically urothelial proliferation and smooth muscle hypertrophy. This suggests proneurotrophins may be involved in urothelial damage and initiation of bladder wall remodeling following supralumbar SCI.

2.2. Urothelial Cell-afferent Nerve Bidirectional Communication: Feedback Modulation of Bladder Sensory Functions

The urothelial lining of the bladder not only acts as a barrier but has been demonstrated to have a sensory function to detect alterations within the lumen that can be relayed to innervating afferent neurons. Urothelial cells can respond to mechanical distention, as well as changes to osmolality and pH and release a number of signaling molecules including ATP, acetylcholine, NO and prostaglandins [470]. It is believed that the primary role of urothelially-released factors is to act upon sensory neurons innervating the suburothelium in order to modify afferent outflow. This modulatory effect occurs in the bladders of various species and ATP is the best characterized of the urothelial transmitters. Mice with gene deletions for P2X<sub>2/3</sub> purinergic receptors subtypes had reduced pelvic nerve activity in response to bladder distention and purinergic agonists [226,471,472], suggesting ATP released by bladder distention stimulates the sensory outflow responsible for signaling the need to void. The release of urothelial ATP also increases in pathologies such as SCI [473], as well as chemical [474] and interstitial cystitis [475,476]. Thus, direct activation and sensitization of sensory nerves by urothelial ATP may be an underlying cause of the bladder overactivity in these conditions.

The communication between the urothelium and afferent nerves is not unidirectional as afferent nerves are capable of releasing a number of neuropeptides and their respective receptors are also localized on the urothelium [477]. It has been demonstrated that urothelial ATP release can be triggered by pituitary adenylate cyclase activating peptide (PACAP) through a PAC1 receptor [478] or by bradykinin through B2 receptors [479]. Additionally, substance P can induce urothelial NO release [480]. The physiological role of neuropeptides on the urothelium is not entirely clear but they have been implicated to have a major role in lower urinary tract (LUT) pathologies [477]. The balance of neuropeptide immuno-reactivity can alter in animal models of cyclophosphamide-induced cystitis [478] and SCI [481]. An increase of excitatory versus inhibitory neuropeptides could be responsible for a range of LUT symptoms from bladder overactivity, inflammation or bladder pain (e.g. interstitial cystitis).

There is significant evidence that the urothelium and afferent neurons form an intimate connection to regulate LUT function. However, the mechanisms by which communication between the urothelium and afferents occurs has not been defined nor has their contribution to normal LUT function. To address this, recombinant pseudorabies viruses (PRV) were used to examine the sensory nerve connections to the urothelium. PRV is part of the alpha-herpes virus family and is capable of crossing between synapses and infecting epithelial cells [482]. PRV express fluorescent markers to trace the afferent nerves innervating the bladder wall from L6-S1 dorsal root ganglia (DRG). The L6 and S1 DRG of C57Bl/6 female mice were exposed, each ganglion microinjected with PRV (10<sup>6</sup> plaque-forming units/ml, 1 µl per ganglion), expressing a Ca<sup>2+</sup>-sensitive green fluorescent protein (GCaMP), and the bladders isolated three-days later for examination by fluorescence microscopy. GCaMP becomes locked in the fluorescent-state following fixation and can be visualised in bladder sections. Accordingly, GCaMP fluorescence was found within nerve fibres throughout the bladder wall and concentrated within the urothelium (Figure 29 A) following DRG injections.
When PRV-GCaMP was injected into the descending colon or *abductor caudalis dorsalis* (tail) muscle, which share sensory innervation with the bladder, a similar pattern of GCaMP fluorescence was observed within the bladder and there was also robust GCaMP expression in L6 and S1 DRG (Figure 29 B,C). These data suggest that PRV preferentially targets the urothelium, no matter the initial route of infection. The clinical implications is that neurotropic viruses can infect the colon and urinary bladder (e.g. polyomavirus) through co-innervating afferent nerves and become dormant in the DRG or urothelium due to suppression by the immune system. An example of such a virus is the Polyomaviridae family associated with human disease, such as nephropathy, particularly in immunocompromised individuals. There are indeed case reports where increased polyomavirus activity has been attributed to worsening of symptoms of interstitial cystitis patients [483,484]. It may be proposed that stressors can reduce immune suppression of the polyomavirus resulting in symptom “flares” characteristic to interstitial cystitis.

One observation following PRV-GCaMP injections was that fluorescence in the urothelium appeared punctate or localised within vesicles. This raises the possibility of endocytic uptake of GCaMP protein released from afferent nerves by urothelial cells. As a wildtype Becker strain of PRV was used, capable of traveling antero- and retrogradely from the cell body [485], it was not possible to determine if there is truly an anterograde release mechanism. Therefore, injections into L6-S1 DRG with fluorescent microbeads (0.02-0.04 µm diameter) were carried out which should not cross synapses or enter urothelial cells, unless there is release from afferents in the periphery and uptake by surrounding cells. Surprisingly, microbead injections resulted in fluorescence in nerve processes throughout the detrusor and robust accumulation of fluorescent vesicular structures within the urothelium (Figure 30 A,B). Whether afferent anterograde transport to the urothelium is present under normal conditions in the LUT is still uncertain, as this mechanism could be in response to the presence of microbeads and activated as a means to eliminate them from the DRG. Further investigation is necessary to understand the significance of afferent-to-urothelium transport in both normal and pathological situations.

Furthermore, following DRG injections, there were large autofluorescent vesicles present in the urothelium that fluoresced through multiple excitation wavelengths. These were most likely lipofuscin vesicles which have been described in the urothelium of aged animals and humans [486,487]. Lipofuscins are thought to be lysosomal vesicles that act as a repository for oxidatively damaged proteins and organelles that cannot be degraded by proteasomes. This may demonstrate injury or stress to sensory nerves that can in turn induce oxidative damage to the urothelium.

**Figure 29. Fluorescent labelling of the urothelium and afferent neurons innervating the mouse urinary bladder. Images were obtained following injection of recombinant PRV-GCaMP (pseudorabies virus with Ca2+ indicator) into L6-S1 dorsal root ganglia, descending colon and tail muscle. A. Intense GCaMP fluorescence in the urothelium and nerve axons/varicosities throughout the detrusor. B: Injection of PRV-GCaMP into the descending colon resulted in a similar pattern of fluorescence in the bladder. GCaMP fluorescence was also found in L6 and S1 DRG following colon injections suggesting cross-infection of the organs occurred via the afferents. C: Tail muscle injections also resulted in accumulation of GCaMP in the urothelium and L6/S1 DRG.**

(Figure with the courtesy of Youko Ikeda, Irina Zabbarova and Anthony Kanai)
Afferent and efferent nerves regulate each other’s activity by release of signaling molecules. The significance of urothelial-to-afferent signaling in normal bladder function has been well established but the role for signaling in the afferent-to-urothelial direction requires further investigation. Afferent nerves do innervate the urothelium (Figure 31A) and could release an array of molecules that appear to be taken up by apical cells. This could be a mechanism by which afferents can remove unwanted proteins. When afferents are damaged or sensitized there may be increased transport of damaged proteins, which cannot be removed/degraded by the urothelium and accumulate in lipofuscins. For example, following oxidative damage to L6/S1 DRG (by surgery or colon irradiation), there is a significant accumulation of autofluorescent lipofuscin vesicles in the apical urothelium, suggesting that oxidative stress in sensory nerves spreads to urothelial cells. The mechanism for this is unclear but could involve localised release of excitatory neuropeptides or increased uptake of oxidatively damaged proteins transported from the DRG (figure 31B). This could in turn increase urothelial signaling to promote afferent sensitization. According, dysregulation of afferent-urothelial communication may underlie a number of LUT pathologies.

Figure 30. Urothelial uptake of fluorescent microbeads from afferent nerves following L6/S1 dorsal root ganglia (DRG) injection. Demonstration of the release of factors from afferent nerves that make contact with the urothelium. Fluorescent microbeads (0.02-0.04 µm diameter) were injected into the dorsal root ganglia (DRG, L6-S1) and allowed to recover for a minimum of seven days. A: Fluorescence in afferent nerves throughout the bladder wall. B: Fluorescence in vesicle-like structures in the urothelium (uro). (Figure with the courtesy of Youko Ikeda and Anthony Kanai)
1. INTRODUCTION

Recent advances in our understanding of the basic science of lower urinary tract function, make it clear that control of bladder function is far more complex than previously believed. As reviewed above, prominent roles have emerged for the urothelium and the underlying suburothelium of the urinary bladder in mechanosensory control and their relationship with afferent pathways in the pathophysiology of lower urinary tract dysfunction (LUTD) including overactive bladder (OAB) and urinary incontinence (UI) [489-491].

According to the most recent classification [492,493], these signal transduction mechanisms have been subclassified into seven different categories (G-protein coupled receptors, Ligand-gated ion channels, Ion channels, Nuclear Receptors, Catalytic Receptors, Transporters, and Enzymes). Among these seven categories, we will especially focus on Ion Channels as sources of novel targets for the treatments of overactive bladder and urinary incontinence in this chapter.

OAB could be a disorder of urothelial dysfunction or sensory dysfunction that causes the occurrence of urgency sensation or urgency UI (UUI). Furthermore, the causes and the natural history of OAB and UI have not been clearly defined, nor do we have any objective tools to help us understand the progression or remission of OAB after treatment. Interest has focused on urinary factors (e.g. cytokines, prostaglandin E2 and nerve growth factor), imaging (video urodynamics, estimation of bladder wall thickness) and genetic (e.g. functional polymorphisms of the cytochrome P450). Here, we focus on novel molecular targets for managing lower urinary tract function and LUTD including OAB and UI.
2. G PROTEIN-COUPLED RECEPTORS (GPCR)S

GPCRs are subclassified into 74 subfamilies including orphan receptors, and acetylcholine-muscarinic receptors are the most important for not only urinary bladder contraction, but also treatment for OAB. In this chapter. The most important nine receptor subfamilies are discussed.

2.1. Orphan GPCRs [494]

The nociceptin/orphanin FQ peptide (N/OFQ) (495,496) is involved in a wide range of physiological responses with effects in the central and peripheral nervous system, the cardiovascular system, the airways, the gastrointestinal tract, the urogenital tract and the immune system [497,498]. The N/OFQ receptor (NOP; also known as ORL1, OP4 or LC132) is a de orphanised member of the G-protein coupled receptor (GPCR) superfamily. NOP is currently classified as a non-opioid member of the opioid receptor family. Although NOP shares considerable structural and localization features with classical opioid receptors, NOP activity is insensitive to the opioid antagonist naloxone.

In the rat, NOP located on capsaicin-sensitive bladder primary afferent fibres inhibit the volume-evoked micturition reflex [499-502]. There are no studies detailing NOP expression in bladder tissue of human origin. However, based on animal data there has been a series of clinical studies using intravesical N/OFQ by Lazzeri. In a pilot study of 14 patients, five normal controls and nine with detrusor overactivity, intravesical instillation of 1 µM N/OFQ increased bladder capacity and volume required to initiate detrusor overactivity; the effect lasted 24–48 hours. Of interest, the effects of N/OFQ were minimal with one patient who had previously received intravesical capsaicin, indicating a capsaicin-sensitive primary afferent neurons [503]. In a follow-up study, N/OFQ was compared with the structurally similar but inactive [desPhe1]N/OFQ (a major metabolite of N/OFQ which does not bind to NOP) in 14 patients with detrusor overactivity due to spinal-cord damage. Intravesical administration of 1 µM N/OFQ but not [desPhe1]N/OFQ increased bladder capacity and volume required for detrusor hyperreflexia [504]. A further study used 18 patients with incontinence and neurogenic DO, who were capable of self-catheterisation: half were group instilled 1 mg of N/OFQ and the remainder with saline for 10 days at the first catheterisation of the morning. Again bladder capacity increased following N/OFQ treatment and the number of daily urine leakage episodes were reduced only in the N/OFQ group. There were no apparent major practical problems and the effects of this single instillation appeared to last the whole day [505].

Collectively, these patient studies broadly agree with those in rats that NOP is probably expressed on capsaicin-sensitive primary afferents and their activation inhibits the micturition reflex. However, basic work has only been done in normal rats, and N/OFQ is only effective in spinally injured patients [506,507]. However, N/OFQ and N/OFQ mimetics have a potential role in the treatment of overactive bladder and their use is not limited to specialist centres capable of intravesical administration. At present any potential development will be for patients resistant to conventional use of anticholinergics [508].

2.2. Acetylcholine-Muscarinic Receptors

The urinary bladder is profusely supplied with autonomic nerve fibers, which form a dense plexus among detrusor smooth muscle cells, although some muscle bundles appear to be more richly innervated than others. The majority of nerves contain acetyl cholinesterase and thus are considered to be excitatory cholinergic [509]. Contraction of normal human detrusor is mediated almost exclusively through muscarinic receptor stimulation by acetylcholine (Ach) and can be completely abolished by atropine [510]. Molecular cloning studies have revealed five distinct genes for muscarinic Ach receptors in rats and humans and five receptor subtypes correspond to these gene products [511]. Muscarinic receptors are coupled to G-proteins; M2, M4 are inhibitory (Gi), whilst M1, M3, M5 are facilitatory (Gq). The signal transduction systems of M1, M3, and M5 preferentially couple to phosphoinositide hydrolysis leading to mobilisation of intracellular Ca²⁺, whereas activation of muscarinic M2 and M4 receptors inhibit adenyly cyclase activity (but see also section II.3 above). Detrusor expresses both M2 and M3 cholinoreceptors and activation of both can elicit bladder contraction [512,513]. Although M2 receptors predominate in receptor binding studies, it is the M3 receptor that is thought to mediate contraction. Desensitisation of muscarinic acetylcholine receptors is one mechanism that reduces detrusor muscle contractile response to incoming stimuli. It is mediated by phosphorylation of M2 and M3 receptors by guanosine phosphate binding (G) protein coupled receptor kinase (GRK) [514-516]. Protein expression of GRK2 is significantly lower in detrusor from bladders obstructed by BPH compared to that from normal bladders [516].

In addition to Ach released from peripheral nerve ending, non-neuronal Ach can be released from bladder urothelium or suburothelial region, although its function in unknown. The non-neuronal Ach release is increased by stretch itself augmented by age [517].

The principal treatment for overactive bladder (OAB) is with anticholinergic drugs, initially believed to inhibit the effect of Ach on detrusor, released from parasympathetic efferents. However, there is now evidence to suggest that anticholinergic drugs could interact with sensory pathways. Stimulation of muscarinic receptor pathways can depress sensory transduction by a mechanism independent of changes in bladder tone, suggesting that muscarinic receptor pathways and ACh could contribute to normal or pathological
bladder sensation [518]; however, there is no apparent evidence in the clinical setting. Recent studies have described muscarinic receptors on the mucosa as well as the detrusor of the human urinary bladder. The density and binding affinity profile of the muscarinic receptor population in the human bladder mucosa was shown to be similar to that of the detrusor muscle by radioligand binding assay. Moreover, commonly used and clinically effective muscarinic receptor antagonists bind to receptors located on the bladder mucosa as well as detrusor, providing support for the hypothesis that muscarinic receptors in the mucosa may represent an important site of action for these agents in OAB [519].

2.3. Adrenergic β-receptors

During the urine storage phase, sympathetic nerve activity is dominant and there is both indirect relaxation of detrusor muscle by adrenergic β-receptors and contraction of urethral smooth muscle by adrenergic α1-receptors [520]. There are three β-adrenoceptor (β-AR) subtypes (β1, β2, β3). The β-AR is a G(s)-protein-coupled receptor and its activation elevates smooth muscle cAMP, which is a key trigger to elicit smooth muscle relaxation. Downstream effectors activated via cAMP-dependent mechanism(s) include K+ channels, including large-conductance, Ca2+-activated K+ (BK) channels (see section II.1.6). β-AR-mediated relaxant mechanisms also include cAMP-independent pathways, supported by pharmacological and electrophysiological evidence. In airway smooth muscle, stimulation of β2-ARs relaxes it by direct activation of the BK channels by G(s)α [521].

β3-receptors were thought to be related only to fat metabolism. However, human detrusor relaxes by a β3-receptor pathway, and its gene expression in the same tissue makes this a significant pathway [522-525]. Several β3-agonists (KUC-7483, YM-178, FK-175) have been developed in Japan, and YM-178 has been launched in September 2011 in Japan, and then USA and European Countries. Although β3-ARs are an attractive target for drug discovery, activation of β1- or β2-ARs can cause undesirable side-effects such as tachycardia or muscle tremors. Consequently, attention has been directed towards the design of more selective β3-AR agonists [526]. GW427353, another novel β3-AR agonist, relaxes the bladder and facilitates storage in dogs [527]. In addition, the β3-AR agonist CL-316243 increases urine storage in spontaneously hypertensive rats [528].

β3-AR agonists can mediate reduced detrusor contractions via the urothelium in pig bladder dome [529], which might underly reduced afferent nerve activity and in addition β3-AR mRNA is present in the urothelium. In chronically ischaemic rat bladders, treatment with mirabegron protects bladder function and morphology, resulting in reduced bladder hyperactivity [530]. These data suggest multiple site of actions for β3-AR agonists, including the urothelium.

2.4. Cannabinoids, GPR18, GPR55, GPR119

Cannabinoids, the active components of Cannabis sativa linnaeus (marijuana) and their derivatives are drawing renewed attention due to their diverse pharmacological activities such as cell growth inhibition, anti-inflammatory effects, and tumour regression [531-536].

The cannabinoid receptor has two subtypes, CB1 and CB2, which are both guanine-nucleotide-binding protein (G-protein)-coupled receptors [537]. Cannabinoid receptors are activated by endogenous ligands that include N-arachidonylethanolamine (anandamide), N-homo-g-linolenylethanolamine, N-docosatetra-7,10,13,16-enylethanolamine and 2-arachidonoylglycerol [493]. CB1 was initially characterized in rat brains [538], and later cloned from rat cerebral cortex [539] and human testis [540]. CB1 distributed mainly throughout the central nervous system, in the cerebellum, hippocampus, and cerebral cortex [541], and is present on peripheral neurons. However, it also found in tissues including pituitary gland, adrenal gland, lung, testis, ovary, uterus, prostate, eye, vascular tissue and peripheral immune system tissues [541-546].

Increased cannabinoid receptor-1 (CB1) expression in human urinary bladder hyper-sensitivity and overactivity disorders is correlated with changes with lower urinary tract symptoms and pain scores [547]. Their findings supported clinical trials of CB1 agonists in bladder disorders. A Cannabis sativa extract enriched in cannabidiol (CBD) botanic drug substance (BDS) and pure CBD reduced cholinergic-mediated contractility and this effect was modulated by TRPV1 in rats but not in humans. CBD is the chemical ingredient of CBD BDS responsible for such activity. If confirmed in vivo, such results could provide a pharmacologic basis to explain, at least in part, the efficacy of Cannabis medicines to reduce incontinence episodes in multiple sclerosis patients [548,549].

GPR18, GPR55 and GPR119 (provisional nomenclature) respond to agents analogous to endogenous cannabinoid ligands, as well as some natural/synthetic cannabinoid receptor ligands, although they show little structural similarity to CB1 and CB2 receptors [493]. The expression of the endocannabinoid-degrading enzyme fatty acid amide hydrolase (FAAH) was measured in human, rat and mouse bladders. The effects of FAAH inhibition during urodynamics were studied in awake rats using a FAAH inhibitor oleoyl ethyl amide (OETA), as well as, rimonabant (CB1 antagonist) and SR144528 (CB2 antagonist). Bladder mucosa of all species expressed FAAH. Rat and human urothelium coexpressed FAAH and CB2. The FAAH inhibitor OETA altered urodynamic parameters that reflect sensory functions of micturition in rats, suggesting a role for the endocannabinoid system in bladder mecanosensitive functions of rats [550].

FAAH inhibition in the sacral spinal cord by OETA resulted in urodynamic effects in normal rats and rats
with bladder overactivity induced by pBOO. The spinal endocannabinoid system may be involved in normal micturition control and altered with bladder overactivity [551]. Inhibiting peripheral FAAH depressed Aδ- and C-fibre activity of primary bladder afferents via CB1 and CB2 receptors. CB antagonists alone exerted facilitatory effects on single unit afferent activity during bladder filling in rats. Thus, the endocannabinoid system may be involved in the physiological control of micturition by regulating bladder afferents [552]. CP55,940 is a synthetic analogue of tetrahydrocannabinol, a psychoactive ingredient of the Cannabis plant. CP55,940 decreases normal rat bladder activity and urinary frequency induced by noxious stimuli, probably by suppression of bladder afferent activity. The effects of CP55,940 were abolished by both CBR antagonists. These data implicate a role for the endocannabinoid system in bladder mechanoreceptor function, and CP55,940 be an effective treatment for patients with lower urinary tract symptoms.

However, the role of CBR subtypes in micturition has yet to be evaluated [553]. Parts of the endocannabinoid system may be involved in regulation of bladder function, possibly at several levels of the micturition pathway. However, it is unclear if either CB receptor has a dominant role in modification of sensory signals or if differences exist at peripheral and central nervous sites. Amplification of endocannabinoid activity by FAAH inhibitors may be an attractive drug target in specific pathways involved in LUTS [554]. Overall the endocannabinoid system is a potential drug target for pharmacological management of LUTS, with a more favourable side-effect profile than antimuscarinic agents [555].

2.5. GABA<sub>B</sub> Receptors

Functional GABA<sub>B</sub> receptors are formed from the heterodimerisation of two similar subunits termed GABA<sub>B1</sub> ENSG00000168760 and GABA<sub>B2</sub> ENSG00000136928. Stimulation of spinal GABAergic mechanisms by intrathecal application of GABA<sub>A</sub> and GABA<sub>B</sub> receptor agonists have been used to treat detrusor overactivity in spinal cord injured rats [556]. Detrusor overactivity can be controlled by modulating the afferent input from the bladder and the excitability of the sacral reflex centre to suggest a novel method to treat overactive bladder patients with oral gabapentin [557]. Fourteen of 31 patients with refractory (OAB) and nocturia improved with oral gabapentin, and it was well-tolerated. It may be considered in selective patients when conventional modalities have failed. Gabapentin also revealed efficacy in treatment of neurogenic DO. There were significant modifications of urodynamic indexes, whereas symptomatic score evaluation and voiding diary data demonstrated a significant lowering of the irritative symptoms [557].

2.6. Glutamate Metabotropic Receptors.

There are two major classes of glutamate receptors: ionotropic receptors which form ligand-gated cation channels and metabotropic receptors (mGluRs) which are a family of G-protein coupled receptors [558,559]. The former include N-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-isoazole-4-propionic acid (AMPA), and kainite receptors, which play essential roles in the control of micturition reflexes [560,561], mGluRs have eight subtypes (mGluR1 to mGluR8) arranged in three groups (I - III) based on sequence homology, transduction mechanism and agonist pharmacology. Less is known about their functional roles in the lower urinary tract. Glutamate is involved in many CNS functions, and thus drugs acting on different glutamate receptors may affect not only micturition.

A selective mGluR5 antagonist, 6-methyl-2-(pentylenyl)pyridine (MPEP) was used with both wild-type and mGluR1 knock-out mice. The study suggested both mGluR1 and mGluR5 were involved in modulating bladder afferent signalling and bladder capacity. Thus, an antagonist, which blocks both mGluR1 and mGluR5, would exert a more beneficial effect on storage dysfunctions, including overactive bladder and urgency urinary incontinence [562]. Similar data from other groups indicate that glutamic acid has a transmitter function in bladder and somato-bladder reflex mechanisms [563,564].

2.7. Prostanoid Receptors.

Prostanoid receptors are activated by the endogenous ligands prostaglandin (PG) D<sub>2</sub> (D), PGE<sub>2</sub> (E), PGF<sub>2α</sub> (F), PGH<sub>2</sub> (H), prostacyclin [PGI<sub>2</sub> (I)] and thromboxane A<sub>2</sub> (T). Prostanoid actions are mediated by specific receptors on cell membranes, including the DP, EP, FP, IP, and TP receptors that preferentially respond to PGD<sub>2</sub>, PGE<sub>2</sub>, PGF<sub>2α</sub>, PGI<sub>2</sub>, and TXA<sub>2</sub>, respectively. Furthermore, EP is subdivided into four subtypes: EP<sub>1</sub>, EP<sub>2</sub>, EP<sub>3</sub> and EP<sub>4</sub> (Table 1, [565,566]). EP<sub>1</sub> signal via IP<sub>3</sub> generation and increase cell Ca<sup>2+</sup> concentration, activation of EP<sub>2</sub> and EP<sub>3</sub> leads to an increase in cAMP, and EP<sub>3</sub> activation inhibits cAMP generation via a pertussis toxin-sensitive G<sub>i</sub>-coupled mechanism and may also signal via the small G-protein Rho. TP signal via the G<sub>q</sub>, G<sub>i</sub>, G<sub>12/13</sub>, G<sub>11</sub>, G<sub>14</sub>, and G<sub>15</sub> proteins, activating Ca<sup>2+</sup><sub>2+</sub>/diacylglycerol pathways, but other G-proteins may also be involved. Prostanoids affect excitation-contraction coupling in detrusor muscle directly by effects on the smooth muscle itself, and/or indirectly via effects on neurotransmission, but the prostanoid receptor most important for detrusor function has not been established.

Bladder outlet obstruction of EP<sub>1</sub>-receptor knockout mice did not prevent the resulting increase in bladder weight but prevented the increase in spontaneous contractile activity (nonvoiding contractions) seen in the wild-type controls [567]. PGE<sub>2</sub> enhances the micturition reflex through C-fibre afferents via EP<sub>1</sub>, thereby EP<sub>1</sub>-selective antagonists may improve bladder storage function [568]. However, the prostaglandin EP<sub>1</sub> receptor antagonist ONO-8359 failed to distinguish itself from placebo and was inferior to tolterodine [569]. The urodynamic effects of an EP<sub>3</sub> antagonist (AH23848) in cyclophosphamide (CYP)-
induced overactive bladder (OAB) generated favourable results [570] and may also be a new target for treatment of patients with OAB. The change in expression of each EP receptor subtype associated with bladder outlet obstruction has been examined, as well as the functional role of EP₄ using ONO-AE1-329 (a selective antagonist for EP₄).

Table 1. Classification of prostanoid receptors: EP₁-EP₄

EP₄ receptor mRNA and protein were clearly detected in detrusor and urothelium from obstructed bladders. ONO-AE1-329 significantly relaxed KCl-induced contractions of bladder strips from rats with bladder outlet obstruction with a significant correlation between the relaxant effect and whole bladder weight [571]. Activation of EP₄ in bladder outlet obstruction (BOO) may suppress detrusor muscle contraction and afferent activity and represent a compensatory mechanism to counteract the deterioration of storage function in BOO. EP₂ and EP₄ mRNA are also over-expressed in urothelium of obstructed human urinary bladder compared to normal bladders, which was significantly correlated with IPSS, especially storage IPSS. Hence, in contrast to previous mouse data, EP₂ and EP₄ also are potential targets for OAB treatment [572].

EP₃ and microsomal PG synthase type-1 decrease collecting duct water permeability, so increasing water excretion, whereas EP₂ and EP₄ bypass vasoressin signaling and increase water reabsorption through different intracellular signaling pathways. PGE₂ has an intricate role in urinary concentration and targeting specific prostanoid receptor signaling pathways could also be exploited for the treatment of disorders such as nocturia or nocturnal polyuria [573].

The role of prostanoids in the pathophysiology of underactive bladder is also under investigation. The roles of nerve growth factor (NGF) and PGE₂ were studied in bladder and urine in STZ-induced diabetic rats. Diabetes mellitus induced hyposensitive underactive bladder which is characterised by an increased inflammatory reaction, apoptosis and urine NGF levels, as well as upregulation of EP₁ and EP₃ receptors and decreased bladder NGF and urine PGE₂ [574].

Potent agonists for EP₂ and EP₃ have been developed. The cyclic carbamate derivatives, 2-melatonin-2-oxo-1,3-oxazolidin-3-yl)ethyl)sulfanyl]-1,3-thiazole-4-carboxylic acid and 2-2-oxo-1,3-oxazolidin-3-yl)ethyl)sulfanyl]-1,3-thiazole-4-carboxylic acid have been identified as the first potent dual EP₂ and EP₃ agonists, with EC₅₀ values of 10 nM or less and selectivity against the EP₁ and EP₄ subtypes [575].

ONO-8055 is also a highly potent and selective agonist for EP₂ and EP₃ on CHO (Chinese hamster ovary) cells, using an increase of intracellular [Ca²⁺] and intracellular cAMP production as indicators of receptor activation. While this compound contracted bladder strips, it relaxed urethral muscle. Awake cystometry showed that ONO-8055 significantly decreased bladder capacity, post-void residual urine and voiding pressure. Compared with vehicle, tamsulosin and ONO-8055 significantly decreased urethral pressure. In vivo, ONO-8055 decreased post-void residual urine, probably by decreasing bladder capacity. A reduction of voiding pressure probably resulted from lowered urethral pressure due to relaxation of the urethra [576].

### 2.8. Tachykinins

Tachykinins are activated by the endogenous peptides substance-P (SP), neurokinin-A (NKA; previously known as substance-K, neurokinin-A or neuromedin L), neurokinin-B (NKb; previously known as neurokinin-B or neuromedin-K), neuropeptide-K and neuropeptide-G (N-terminally extended forms of...
neurokinin A). Neurokinins-A and -B are mammalian members of a tachykinin family, which includes peptides containing the consensus sequence: Phe-x-Gly-Leu-Met. Marked species differences in pharmacology.

Clinical trials showed Aprepitant, a neurokinin-1 receptor antagonist, is efficacious to treat OAB [577]. However, the effect was small but was demonstrated a proof of concept. Cizolirtine citrate (cizolirtine) exerts an inhibitory influence on calcitonin gene-related peptide (CGRP) and substance-P release by primaryafferent fibres and/or dorsal horn interneurons, mediated through presynaptic serotonin and α2-adrenoceptors that are partly related to an increase of the descending noradrenaline pain inhibitory system [576-580]. A dose-finding study was performed as the first step in the clinical development of cizolirtine citrate. The therapeutic potential of cizolirtine citrate 400mg b.i.d. in overactive bladder was demonstrated [581].

2.9. Taste Receptors

The expression of a functional sweet taste receptor has been reported in numerous extragustatory tissues, including the gut, pancreas, bladder, brain and, more recently, bone and adipose tissues [582]. T1R2/3 sweet taste receptors are expressed in human and rat bladder urothelium. Their activation by artificial sweeteners has been proposed to augment bladder contractions, resulting in urinary frequency or OAB [583].

The presence of a previously unidentified cholinergic, polymodal chemosensory cell in the mammalian urethra, but not in bladder, ureter or renal pelvis has been reported. It represents a potential portal of entry for bacteria and harmful substances into the urogenital system. Urethral brush cells express bitter and umami taste receptors and downstream components of the taste transduction cascade; respond to stimulation with bitter (denatonium), umami (monosodium glutamate) and uropathogenic Escherichia coli. They also release Ach to communicate with other cells and intraurethral application of denatonium reflexively increases activity of the bladder detrusor muscle in anesthetized rats. Urinary bladder may be controlled via a previously unidentified cholinergic chemosensory cell monitoring the chemical composition of the urethral luminal microenvironment for potential hazardous content [584].

The bitter taste receptor (TAS2Rs) family perform non-gustatory functions outside the mouth in addition to taste. mRNA for various TAS2R subtypes is also expressed in both human and mouse detrusor smooth muscle. Chloroquine (CLQ), an agonist for TAS2Rs, concentration-dependently relaxed carbocyclic- and KCl-induced contractions of human DSM strips. Furthermore, CLQ treatment significantly suppressed OAB symptoms of mice with pBOO [585].

3. ION CHANNELS

3.1. Ligand-gated Ion Channels

Ligand-gated ion channels are integral membrane proteins that contain a pore to allow the regulated flow of selected ions across the plasma membrane. They are relatively voltage-insensitive and are gated by second messengers and other intracellular and/or extracellular mediators. The channels are opened, or gated, by the binding of a neurotransmitter to an orthosteric site(s) that triggers a conformational change that results in the conducting state. Of the eight ligand-gated ion channel families (5-HT₃, nicotinic-acetylcholine, GABAₐ, glutamate-ionotropic, glycine, P₂X, and zinc-activated channels), only P₂X will be discussed here.

Purinergic mechanosensory transduction occurs where ATP, released from urothelial cells during distension of bladder and ureter, acts on P₂X₃ and P₂X₂₃ receptors on suburothelial sensory nerves to initiate the voiding reflex via low threshold fibres, as well as nociception via high threshold fibres. In human bladder the purinergic component of parasympathetic excitatory cotransmission is small. However, in pathological conditions, such as interstitial cystitis, obstructed and neuropathic bladder, the purinergic component is increased to as much as 40 %. Other pathological conditions of the bladder have been shown to involve purinoceptor-mediated activities, including multiple sclerosis, ischaemia, diabetes, cancer and bacterial infections. Purinergic therapeutic strategies are being explored that hopefully will be developed and bring benefit and relief to many patients with urinary tract disorders [586].

Functional P₂X receptors exist as polymeric transmitter-gated channels. The native receptors may occur as homopolymers (e.g. P₂X₁ in smooth muscle) or heteropolymers (e.g. P₂X₂⁺P₂X₃ in the nodose ganglion and P₂X₁⁺P₂X₃ in mouse cortical astrocytes). P₂X₅, P₂X₇ and P₂X₇ receptors form functional homopolymers which, in turn, activate pores permeable to low molecular weight solutes. The hemi-channel pannexin-1 has been implicated in pore formation induced by P₂X₇, but not P₂X₅ receptor activation [493].

Afferent signals originating from the bladder are regulated by P₂X₃ and P₂X₃ receptors in the urothelium and afferent nerves and antagonists to these receptors are promising agents to treat conditions such as OAB and other sensory disorders including chronic pain states. AF-792 [5-(5-ethynyl-2-isopropyl-4-methoxy-phenoxy)-pyrimidine-2,4-diamine]) is a selective P₂X₃ and P₂X₃ antagonist that inhibits the micturition reflex significantly at 300 nM and increases inter-contraction intervals [587]. After BOO, with bladder overactivity, the expression of M2, M3 and P₂X₃ receptors is increased in rat urothelium, suggesting that changes in urothelium P₂X₃ receptor expression can mediate afferent sensory responses
in the urinary bladder [588]. The P2X$_3$ and P2X$_{2/3}$ receptor antagonist A-317491 is effective at improving the symptoms of CYP-induced cystitis in the rat, suggesting that these receptors are involved in bladder overactivity observed during CYP-induced cystitis [589].

The precise mechanisms that underlie mechanosensory transduction in the bladder remain ambiguous. However, a wide range of ion channels (e.g. TTX-resistant Na$^+$ channels, Kv channels and HCN channels) and receptor-channels (e.g. TRP$_V$$_1$, TRPM$_8$, TRPA$_1$, P2X$_{2/3}$) have been identified at bladder afferent terminals and implicated in the generation and modulation of afferent signals. The expression and/or the function of these ion channels and receptors may be altered in animal models and patients with overactive and painful bladder disorders and may be potential therapeutic targets for bladder diseases [590]. Another report showed also that detrusor from patients with idiopathic detrusor overactivity showed a selective absence of P2X$_3$ and P2X$_5$ that may impair control of detrusor contractility [591].

3.2. Acid-sensing (Proton-gated) Ion Channels (ASIC)

Acid-sensing ion channels (ASICs) are members of a Na$^+$ channel superfamily that includes the epithelial Na$^+$ channel (ENaC), the FMRF-amide activated channel (FaNaC) of invertebrates, the degenerins (DEG) of Caenorhabitis elegans, channels in Drosohila melangaster and ‘orphan’ channels. ASIC subunits contain two transmembrane domains and assemble as homo- or hetero-trimers to form proton-gated, voltage-insensitive, Na$^+$ permeable channels (Table 2).

ASIC$_1$ is the dominant ASIC subunit expressed in bladder urothelium, whereas both ASIC$_1$ and ASIC$_2$ are expressed in bladder smooth muscle. ASIC$_3$ expression is much less abundant, but localised in the suburothelial region. In the mucosa, the ASIC$_1$ gene is more highly expressed in male than in female mice, whereas the expression level of ASIC$_2$ in the bladder muscle is higher in female than in male mice. Thus, ASICs might be involved in observed sex differences in the bladder response to irritation with acetic acid [592]. Capsaicin, acting at TRP$_V$$_1$ receptors, and acid, acting at both TRP$_V$$_1$ and ASIC, induce ATP release from the rat bladder mucosa and highlights the importance of ATP and acid as signalling molecules in modulating bladder function [593]. Urothelial cells express multiple TRP (see also below) and ASIC channels, whose activation elicits ionic currents and Ca$^{2+}$ influx. These “neuron-like” properties might be involved in release of transmitters such as ATP that act on afferent nerves or smooth muscle to modulate their responses to different stimuli [594]. Urinary bladder inflammation induced by cyclophosphamide alters ASIC$_{2a}$ and ASIC$_3$ expression in the rat bladder, although ASIC$_1$ expression is unaffected, and again highlight the potential involvement of ASICs in its development [595]. Up-regulation of ASIC$_{2a}$ and ASIC$_3$ in patients with bladder pain syndrome suggests involvement in increased pain and hyperalgesia. Down-regulation of transient receptor potential vanilloid 1 mRNA might indicate that a different regulatory mechanism controls its expression in the human bladder [596].

3.3. Epithelial Sodium Channels (ENaC)

Epithelial Na$^+$ channels (ENaCs) are responsible for Na$^+$ reabsorption by epithelia lining the distal part of the kidney tubule, and fulfill similar functional roles in some other tissues such as the alveolar epithelium and the distal colon. This reabsorption of Na$^+$ is regulated by aldosterone, vasopressin and glucocorticoids, and is one of the essential mechanisms in the regulation of sodium balance, blood volume and blood pressure. Furthermore, cAMP stimulates the insertion of new ENaC into the apical membrane [597].

MOLECULAR TARGETS FOR MANAGING LOWER URINARY TRACT FUNCTION | 207
The degenerin-epithelial Na\(^+\) channel (ENaC) family has been proposed as a transducer of sensory stimuli in several species [598-600] and these channels seem to be mechanosensitive. In the rabbit urinary bladder ENaC can change their Na\(^+\) transporting properties after changes in hydrostatic pressure [598]. ENaCs in the renal pelvic epithelium of rats participate in activation of afferent renal mechanosensitive neurons by increased renal pelvic pressure [601]. ENaCs are expressed in the mammalian urinary bladder and suggests that amiloride-sensitive Na\(^+\) transport across the apical membrane of the urothelium is mediated significantly by ENaC [602]. Thus, ENaCs could be involved in mechanosensitive transduction in the bladder and their upregulation could contribute to the pathophysiology of changes to sensory nerve function.

**ENaC in human urinary bladder:** The \(\alpha\)-, \(\beta\)-, and \(\gamma\)-ENaC proteins and mRNA are clearly expressed in human bladder epithelium with and without BOO and ENaC mRNA expression correlates significantly with the storage symptom score [603]. A study with samples from bladders of control and neuropathic DO patients showed greater expression of \(\gamma\)-ENaC and ASIC\(\gamma\) was associated with decreased compliance of the donor bladders [604]. The authors proposed that whilst changes to \(\gamma\)-ENaC might impair the mechanosensory function of the urothelium, the increase of ASIC\(\gamma\) might compensate for the excess in local sensitivity.

**ENaC in rat urinary bladder:** Intravesical infusion of the ENaC blocker amiloride significantly reduced the frequency of reflex voiding during bladder filling, increased bladder capacity, both without effect on the amplitude of micturition pressure. Stretch-induced significant increase in the ATP release from whole layer bladder strips and this was greatly reduced by amiloride [605].

### 3.4. Potassium Channels

K\(^+\) channels are fundamental regulators of cell excitability (see also sections II.1.6 and III.4.1). They control the frequency and the shape of action potential waveform, the secretion of hormones and neurotransmitters and cell membrane potential. Their activity may be regulated by voltage, Ca\(^{2+}\) and neurotransmitters (and the signalling pathways they stimulate). They consist of a primary pore-forming \(\alpha\)-subunit often associated with auxiliary regulatory subunits. The three main groups are the 2-TM (two transmembrane domain), 4-TM and 6-TM families – the latter are considered here [493].

**The 6TM family of K\(^+\) channels.** These comprise the voltage-gated Kv subfamilies, the KCNQ subfamily the EAG subfamily (which includes herg channels), the Ca\(^{2+}\)-activated Slo subfamily (actually with 7TM) and the Ca\(^{2+}\)-activated SK subfamily. The pore-forming \(\alpha\)-subunits form tetramers and heteromeric channels may be formed within subfamilies (e.g. \(K_v\)1.1 with \(K_v\)1.2; KCNQ2 with KCNQ3).

Large-conductance, voltage- and Ca\(^{2+}\)-activated K\(^+\) (BK) channels regulate the resting potential and repolarisation of the action potential, and play a critical role in modulating contractile tone of smooth muscle, and neuronal processes. BK channels play an important role in controlling membrane potential and contractility of urinary bladder smooth muscle [606,607]. In addition, small-conductance (SK) channels, are regulators of excitability in detrusor smooth muscle. The role of SK channels in guinea-pig detrusor was examined using the SK channel blocker apamin. Ca\(^{2+}\) entry through voltage-dependent Ca\(^{2+}\) channels activates both BK and SK channels, but Ca\(^{2+}\) release (Ca\(^{2+}\) sparks) through ryanodine receptors activates only BK\(\text{Ca}_\text{a}\) channels [50,55]. BK channels are activated strongly to counteract enhanced spontaneous mechanical activity with detrusor muscle stretch. The role of different K\(^+\) channels in regulating spontaneous contractile activity varies between pathologies. K(ATP) and SK channels regulate detrusor spontaneous contractions from NDO patients and BK channels are not involved. By contrast, BK have a role in tissue from normal bladders [608].

The effects of NS-8, a selective antagonist for BK channels on the micturition reflex in rats has been investigated. During bladder filling, NS-8 decreased the discharge rate of the afferent pelvic nerve and could be used to manage symptoms of urinary frequency and incontinence [608]. The importance of the BK\(\text{Ca}_\text{a}\) channel was shown in that local hSlo cDNA (i.e., the BK\(\text{Ca}_\text{a}\) channel) injection ameliorated detrusor overactivity in a rat model of partial urinary outlet obstruction [609]. It was suggested that expression of hSlo in the bladder functionally antagonised the increased contractility normally observed in obstructed animals and thereby improved detrusor overactivity. Consistent with increased urinary bladder contractility caused by the absence of BK currents, Slo knock-out mice demonstrated a marked elevation in urination frequency [51]. BK channel activation also has a significant role in reducing both cholinergic- and purinergic-induced contractions [610]. Thus, alterations to BK channel expression or function, along with changes to SK and KATP channels, could contribute to pathologies such as overactive detrusor and, represent pharmacological targets for decreasing phasic OAB contractions of detrusor. A novel BK channel blocker, A-272651, represents one of the first small molecule channel blocker and could serve as a tool to characterise the role of BK channels in physiological and pathological states [611].

However, no K\(^+\) channel opener has passed the proof of concept stage, and there is at present no convincing evidence showing that K\(^+\) channel opening is a useful principle for treatment of detrusor overactivity [612]. The safety and tolerability of escalating doses of hMaxi-K, a gene transfer product of human BK ion channel, were confirmed by clinical evaluation and laboratory tests in 11 patients with moderate to severe erectile dysfunction and hMaxi-K gene transfer is a viable approach to treat erectile dysfunction and other smooth muscle diseases with targeted access [613].
The identification of novel BK has been attempted by screening a library of 794 natural compounds using a cell-based fluorescence assay. Kurarinone, a flavanone from Sophora flavescens, was identified as a strong potentiator of BK channels and directly potentiates BK channels [614]. Finally an interaction between phosphodiesterases and BK channels has been identified. Phosphodiesterase type 4 (PDE4) is present in the pig and human bladder neck smooth muscle, where the PDE4 inhibitor rolipram exerts a much more potent relaxation than that elicited by PDE5 inhibitors. In pig tissue the rolipram-induced response is produced through a PKA pathway involving BK channel activation and [Ca^{2+}]_i desensitisation-dependent mechanisms [615].

3.5. Transient Receptor Potential (TRP) Cation Channels – Distribution and Function

The TRP family of channels has been considered in terms of their physiological functions above with respect to detrusor muscle (section II.1.5) and also in the following chapter regarding the urothelium and neural sites. Here their significance as drug targets will be considered. The TRP superfamily of cation channels, whose founder member is the Drosophila Trp channel. Mammalian TRP channels are activated and regulated by a wide variety of stimuli so TRPs can act as sensors of osmotic pressure, volume, stretch or vibration. Many post-transcriptional mechanisms are also possible, that include phosphorylation, G-protein receptor coupling, ligand-gating and ubiquitination.

Key: AA, arachidonic acid; OEA, oleylethanolamide; 4α-PDD, 4α-phorbol 12,13-didecanoate; 52,62EET, 52,62-epoxyeicosatrienoic acid; BCTC, N-(4-tertiary butylphenyl)-4-(3-chloropyridin-2-yl) tetrahydropyrazine-1(2H)-2-carboxamide; DRG, dorsal root ganglion.

In mammals TRPs can be divided into six families; TRPC, TRPM, TRPV, TRPA, TRPP and TRPML based on amino acid homologies. TRP subunits contain six putative transmembrane domains and assemble as homo- or hetero-tetramers to form cation selective channels with varied permeation properties. The TRPC (‘Canonical’) and TRPM (‘Melastatin’) subfamilies consist of seven and eight different channels, respectively (i.e., TRPC1-TRPC7 and TRPM1-TRPM8). The TRPV (‘Vanilloid’) subfamily comprises six members (TRPV1-TRPV6) whereas the TRPA (Ankyrin) subfamily has only one mammalian member (TRPA1). Established, or potential, physiological...
pathological functions of the individual members of the TRP families are discussed in detail in the recommended reviews and are only briefly mentioned here [616, 617].

Thus far, expression of TRPV1, TRPV2, TRPV4, TRPA1, and TRPM8 has been reported in different regions of the urogenital tracts and on sensory nerve endings (Table 3, [618–622]). TRP channels have been significantly linked to mechanosensory transduction and the release of ATP from the urothelium to excite sensory afferents [623]. Candidate mechano-sensitive molecules in urothelial cells underlying ATP release may be ENaCs or TRPs. In addition to mechano-transduction, many TRP molecules are thermo-sensitive (Table 3). Specific mention will be made here of four thermosensitive TRP channels – TRPV1, TRPV4, TRPA1 and TRPM8.

3.6. TRPV1 Channels

TRPV1 is an ion channel activated by capsaicin, heat, protons and endogenous ligands such as anandamide and largely expressed in the urinary tract of mammals. Receptor expression is firmly established in sensory fibers and urothelial cells, and reported in other cell types. Pain perception was the first role attributed to TRPV1 in the urinary tract. However, it is clear that TRPV1 also regulates the frequency of bladder reflex contractions, either through direct excitation of sensory fibers or through urothelial-sensory fiber interaction involving the release of neuropeptides from the urothelial cells. Capsaicin and resiniferatoxin are agonists for TRPV1, and desensitisation of the receptor by them has been investigated for therapeutic purposes to manage bladder pain syndrome and OAB of neurogenic and non-neurogenic origin. However, desensitisation may become obsolescent when non-toxic, potent TRPV1 antagonists become available [624]. TRPV1 channel blockers are used to ameliorate chronic pain, whereas TRPV1 agonists that induce desensitisation are used to treat conditions in which channel overexpression occurs [625]. A splice variant of TRPV1, TRPV1b, in which 60 amino acids are deleted in the intracellular N-terminal region, forms capsaicin-insensitive and stretch-inhibited cation channels [626]. The channel is activated by changes to extracellular toxicity and mediates osmosensitivity changes in the supraoptic nucleus [627]. Such TRPV1 variants might explain partly why some reports have suggested the mechanosensory function of TRPV1 in the bladder [627, 628], although the expressions of variants in the bladder or DRG have not been studied. With bladder strips excised from mice lacking TRPV1, hypoosmolality-evoked ATP and NO releases are diminished [628].

TRPV1 is expressed in the urothelium, interstitial cells and sensory nerve terminals. TRPV1-deficient mice displayed a higher frequency of low-amplitude non-voiding bladder contractions in comparison with wild-type mice [627], suggesting that TRPV1 is required for detection of bladder stretch. The release of both ATP and NO upon stretch was reduced in the bladders of TRPV1-deficient mice. In a clinical setting, capsaicin or resiniferatoxin reduces bladder overactivity through desensitisation of bladder afferents by acting on TRPV1 [624]. Patients with neurogenic detrusor overactivity (NDO) have an increased immunoreactivity of PGP 9.5 and TRPV1 in the suburothelium and an increased TRPV1 reactivity in the basal layers of the urothelium compared to control patients. In addition, patients with NDO clinically responding to intravesical instillations of resiniferatoxin show a significant decrease of this TRPV1 immunoreactivity in both the suburothelium and the basal urothelial layers compared to non-responders, suggesting a role for TRPV1 in the pathophysiology of NDO [491, 629]. The effect on urinary urgency of bladder desensitisation by RTX instillation into the bladder of OAB patients with refractory urgency were investigated and RTX showed significantly greater efficacy than placebo. The specific effect of RTX on TRPV1 receptors suggests that urothelium and sub-urothelial C-fibres play an important role to the generation of urgency sensation [630].

The effects of GRC-6211, an orally active TRPV1 antagonist, were tested on the function of control and inflamed rat bladders. GRC-6211 counteracted bladder hyperactivity induced by cystitis and at high doses it suppressed normal bladder activity by a TRPV1-dependent mechanism [631]. XEN-D0501, a TRPV1 antagonist, is being developed to treat overactive bladder. It is safe and well-tolerated at doses up to 5 mg twice daily for 14 days in healthy subjects and being evaluated for use in management of OAB. Further study is needed for the development of OAB therapy [632].

Botulinum toxin A (BoNT/A) injection into the bladder wall is in widespread use to manage persistent OAB. The effects of BoNT/A on the expression of nerve growth factor (NGF) and TRPV1 in the urothelium and detrusor of rats with pBOO-induced detrusor overactivity has been studied. Although BoNT/A reduced raised NGF levels found in BOO, TRPV1 expression, particularly in the urothelium, was unchanged [633].

3.7. TRPV4 Channels

TRPV4 was originally postulated to serve as a mechano- or osmosensor [634]. Recent studies using mice lacking TRPV4 revealed its involvement of TRPV4 in sensing additionally warmth in vivo [635, 636]. TRPV4 is abundantly expressed in rodent urothelium [637] and knockout mice show an incontinence phenotype of spontaneous voiding pattern, but lower frequency of voiding contractions and increased bladder volume in continuous filling cystometry [638]. In cultured rat urothelial cells, a TRPV4 agonist promoted Ca2+ influx and enhanced ATP release [6377]. These findings indicate a critical role of TRPV4 in physiological bladder function. A study investigated their role in a stretch-sensing mechanism, using mouse primary urothelial cell cultures from wild-type and TRPV4-deficient mice. The results suggested that TRPV4 senses distension of the bladder urothelium, which is
converted to an ATP release signal during filling [639].

If TRPV4 channels are candidates as mechanosensors in the bladder, their inhibition could represent a novel therapy for overactive bladder and storage dysfunction [640]. Recent work showed that the development of cystitis-induced bladder dysfunction is strongly impaired in TRPV4 knock-out mice, and that HC-067047, a previously uncharacterised, potent, and selective TRPV4 antagonist increased functional bladder capacity and reduced micturition frequency in normal mice and rats with cystitis. HC-067047 did not affect bladder function in TRPV4 knock-out mice [641].

TRPV4 and TRPV1 are present in different bladder afferent populations. The synergistic activity of antagonists for these receptors in very low doses may offer the opportunity to treat lower urinary tract symptoms while minimising the potential side-effects of each drug, in bladder hyperactivity and pain induced by cystitis [642]. A dual analysis of voiding behaviour and reflex micturition was performed to examine lower urinary tract function in TRPV1 knockout mice and TRPV4 knockout mice. In reflex micturition, a lack of either channel was involved in non-voiding contractions during bladder filling [643].

3.8. TRPA1 Channels

TRPA1 is the only mammalian member of the Ankyrin TRP (Figure 32) subfamily and is a potential candidate for mechanosensor and/or nociceptor responding to chemicals such as (allyl isothiocyanate (the pungent compound in mustard oil), allicin (garlic) and cinnamaldehyde (in cinnamon) [644,645] as well as cold stimuli <17°C [635,646]. TRPA1 is expressed in rodent and human bladders and sensory C-fibres [637,647] and activation induces bladder contractions, mediated by sensory afferent stimulation and release of tachykinins and prostanoids. In diabetic rats, functional coupling between the tachykinin and prostanoid systems is enhanced, and their impact on DSM contractility in response to TRPA1 activation is increased [648]. The expression levels of TRPA1 mRNA is much greater in mucosa compared to detrusor or prostate tissue and further upregulated in obstructed bladders [619].

The relevance of TRPA1 in OAB induced by spinal cord injury was evaluated in rats using HC-030031 (a TRPA1 antagonist) and the TRPA1 antisense oligodeoxynucleotide (AS-ODN). TRPA1 activity and upregulation exerts an important role in developing OAB following SCI [649]. TRPA1 distribution and the effects of hydrogen sulphide, H2S, as a TRPA1 activator on micturition in conscious rats were examined. The expression of TRPA1 on C-fibre bladder afferents and urothelial cells together with the observation that intravesical H2S initiated detrusor overactivity showed that TRPA1 has a role in sensory. H2S as a TRPA1 activator is also potentially involved in inflammatory bladder disease [650]. Cyclophosphamide (CPS)-induced bladder hyperalgesia can be induced without robust inflammation or changes to primary afferent TRPV1. However, significant changes were observed
in TRPA1 expression, and blockade of TRPA1 alleviated CPS-induced bladder hyperalgesia [651].

The effects of blocking TRPA1 by intrathecal administration of antagonists (HC-030031 and A-967079) on the afferent pathways of micturition in rats with CPS-induced cystitis found a pronounced TRPA1 up-regulation in dorsal root ganglia but less so in the mucosa. Blockade of neuronal activation of TRPA1 by intrathecal administration of antagonists could decrease afferent nerve activity and attenuate detrusor overactivity induced by inflammation [652].

3.9. TRPM8 Channels

TRPM8 are both mechanosensitive and cold-sensitive. A bladder cooling reflex is observed in guinea pigs if pretreated with menthol, a TRPM8 agonist. This reflex is sensitive to ganglion blockade or capsaicin-sensitive C-fibre deafferentation and might be mediated by through TRPM8 [622]. TRPM8 may play a role in the pathophysiology of overactive and painful bladders and provide an additional target for future pharmacotherapy [623].

The TRPM8 channel blocker, N-(3-aminopropyl)-2-N-(2-thienylmethyl)benzamide hydrochloride (AMTB) acts on the bladder afferent pathway to attenuate the micturition reflex and nociceptive reflex responses in the rat [653]. Intravesical infusion of menthol facilitated the micturition reflex, and capsaicin pretreatment had no effect on this response [654]. Bladder afferents expressing TRPM8 in rats are mainly Aδ although some C-fibres will be involved in nociceptive sensations [655].

Brief cold stimuli applied to the skin can evoke a sudden desire to urinate, which can be highly bothersome in patients with overactive bladder. There is no adequate explanation for the mechanism of acute cold-induced urinary urgency (ACUU). Cold and menthol stimuli to the skin generate bladder nerve responses conducted through dichotomizing axons, and these significantly decreased in the presence of the TRPM8 blocker BCTC. This suggests TRPM8 expressing sensory neurons with dichotomizing axons projecting to the skin and bladder may be responsible for the urinary urgency evoked by cold sensation [656]. A novel TRPM8-selective antagonist (DFL23448[5-(2-ethyl-2H-tetrazol-5-yl)-2-(3-fluorophenyl)-1,3-thiazol-4-ol]) has been tested in cold-induced behavioral tests on overactive bladder function in rats and suggested a role TRPM8-mediated signals in cold-induced bladder overactivity [657,658].

3.10. Piezo1 Channels

Piezo1 is a mechanosensitive ion channel protein that in humans is encoded by the gene PIEZO1. Piezo1 and its close homolog piezo2 were cloned in 2010, using an siRNA-based screen for mechanosensitive ion channels [659]. PIEZO1 and PIEZO2 share 47% identity with each other and they have no similarity to any other protein and contain no known protein domains. They are predicted to have 24-36 transmembrane domains, depending on the prediction algorithm used. In the original publication the authors were careful not to call the piezo proteins ion channels, but a more recent study by the same lab convincingly demonstrated that indeed piezo1 is the pore forming subunit of a mechanosensitive channel [660].

Piezo1 is expressed in the lungs, bladder and skin, where mechanosensation has important biological roles. Unlike Piezo2, which is highly expressed in sensory dorsal root ganglia, Piezo1 is not expressed in sensory neurons [660]. Piezo1 channels are pivotal integrators in vascular biology [661] and is also found in red blood cells, and gain of function mutations in the channels are associated with hereditary xerocytosis or stomatocytosis [662-664].

With respect to the urinary tract, mouse urothelial cells label for Piezo1 and TRPV4 (Figure 33). Moreover these cells exhibit a Piezo1-dependent increase of intracellular [Ca2+] in response to mechanical stretch stimuli, leading to ATP release. However, Piezo1 and TRPV4 respond to different intensities of mechanical stimulus. Moreover, GsMTx4, an inhibitor of such channels, attenuated Ca2+ influx into urothelial cells and decreased ATP release upon stretch. The consequence of Piezo1 inhibition by GsMTx4 on urinary tract function is seen in Figure 34. Experiments with a new metabolic cage design show that GsMTx4 did not affect total water intake and urinary loss throughout a dark-light cycle. However, Piezo1 inhibition reduced the number of voids and hence the voided amount per micturition. Hence, Piezo1, possibly acting through sensation of bladder (urothelial) stretch and ATP release, influences initiation of the micturition reflex. Thus, inhibition of Piezo1 might provide a promising means of treating bladder dysfunction [665].
Figure 33  *Piezo1* protein and mRNA expression in human bladder urothelium.  
A: immuno-histochemistry of *Piezo1* (left) and a urothelial label CK7 (right). The merged image is shown below. L: lumen-facing side. SM: smooth muscle-facing side. B: quantitative RT-PCR of human *Piezo1* and TRPV4 transcripts, normalised to β-actin. *p<0.05 vs *Piezo1*.

Figure 34  Metabolic cage system to study the effects of test agents on urinary function  
A: Schematic drawing and photographs (ii–iv) of a metabolic cage system for mice. The system is housed in a sound-proof room at 25°C away from air-flow fluctuations (ii). The special mesh (middle photograph, patent licence no. 2009-187420, Mitsubishi Kumamoto, Japan) allows passage of urine but catches faeces and/or food (right photograph). Each mouse is provided with free access to food and water and housed at a 12/12 h dark/light period. Water intake volume is measured by a drink sensor.  

B: Protocol for a study of a drug on urinary function. After an acclimatisation period three dark/light periods are followed: a drug administration period, preceded and followed by control periods.  

C: Effect of the *Piezo1* inhibitor GsMTx4 on urinary function. Left: Urine production and drinking times in the three dark-periods of the above protocol. Right: values of total urine production, water intake, voided volume and voiding episodes in the three periods indicated in the protocol of part B. Mean data ± SD: *p<0.05, **p<0.01.
4. TRANSPORTERS

Membrane transporters carry solutes across cell membranes ultimately against energy gradients that require ATP. Transporters can be divided into three major classes: P-type ATPases; F-type or V-type ATPases and ATP-binding cassette transporters. The first of these are multimeric proteins which primarily transport inorganic cations. The F-type or V-type ATPases are proton-coupled transporters or as motors and the ATP-binding cassette transporters are involved in drug disposition and transporting endogenous solutes. This solute carrier (SLC) family therefore transports a great variety of solutes includes 52 separate groups with almost 400 members. The SLC transporters include members which function as antiports, symports or equilibrative transporters – the latter allow solutes to travel across membranes down their concentration gradients. Many transporters also express electrogenic properties [492,494].

The vesicular nucleotide transporter (VNUT), SLC17A9, is the most recent member of the SLC17 family to have an assigned function. Uptake of ATP is independent of pH, but dependent on Cl⁻ and membrane potential. Endogenous substrates are guanosine 5'-diphosphate, guanosine-5'-triphosphate, and ATP. VNUT can be inhibited by DIDS and Evans blue dye [666]. The release of ATP from urothelium when stretched may occur through multiple pathways. VNUT is abundantly expressed in the urothelium, and VNUT-deficient mice show reduced bladder compliance and frequent urination and this transporter has been implicated in this pathology [667].

5. CLOCK GENES

Clock genes exist in most cells and organs, and their products regulate oscillations in the sleep-awake rhythm and gene expression rhythms of various metabolic enzymes, channels, and receptors. Of more than ten types of clock genes that have been identified, period protein (Per), cryptochrome protein (Cry), brain and muscle ARNT-like 1 (Bmal1), and clock locomotor output cycles kaput (Clock) play the most important role in regulating cellular master and peripheral circadian rhythms. Such circadian rhythms are driven by several complex feedback loops some of which are under the control of the master clock in the suprachiasmatic nucleus (SCN, Figure 35) [668].

The pathophysiology of nocturia (NOC) and nocturnal polyuria (NP) appear to be multifactorial and complex and their etiologies remain unclear in a large number of patients. There is currently no ideal animal model for NOC and/or NP which in turn hinder any scientific or clinical approaches for examining and evaluating the efficacy of therapeutic modalities for NOC and NP. Recent studies reported that renal and lower urinary tract functions are regulated by clock genes [669,670]. Moreover, melatonin secretion exhibits a circadian rhythm that is regulated by SCN clock genes. The rhythmicity of melatonin secretion regulates circadian rhythms in peripheral tissues mainly by controlling tissues’ hormonal activities. It has also been shown to influence the onset of NOC in patients [671,672]. Based on these findings, a novel hypothesis has been proposed regarding the relationship between abnormalities in clock genes and lower urinary tract functions (Figure 36).
Figure 35. Mechanisms of circadian rhythm formation by oscillation of clock genes. More than ten types of clock genes that have been identified. Per, Cry, Bmal and Clock play the most important role in regulation of circadian rhythms. Particular circadian rhythms are driven by the formation of a large number of complex feedback loops under the control of a master clock in the suprachiasmatic nucleus (SCN). In the core loop, transcriptional factors, Clock and Bmal can activate Per and Cry genes by attaching to an E-box.

Figure 36 Water intake and voiding patterns in a clock mutant mouse model. Upper and middle panels. Comparison between wild type (WT) and Clock mutant (∆19/∆19) mice in micturition patterns. Plots and bar charts show: water intake over two 12hr/12hr light-dark cycles and over one light-dark cycle: average voiding episodes; volume per void; and total voided volume. *p<0.05, **p<0.01 light vs dark for each group: ## p<0.01 WT vs Clock∆19/∆19 for dark cycles: §§ p<0.01 WT vs Clock∆19/∆19 for light cycles. Lower panels. Actograms of WT and Clock∆19/∆19 mice for a two-day period; there is no overall difference.
To investigate the effect of clock genes on lower urinary tract function the voiding behaviour of the ClockD19/D19 mutant mouse, Clock<sup>Δ19/Δ19</sup>, was recorded for 24hr using metabolic cages and compared with wild-type (WT) mice. No significant differences were observed in behaviour patterns between Clock<sup>Δ19/Δ19</sup> and WT mice. However, Clock<sup>Δ19/Δ19</sup> mice showed greater voiding frequencies and urine volumes during the sleep phase when compared to WT mice. Moreover, the diurnal change (between the dark and light periods) in voiding frequency as well as urine volume observed in WT mice was absent in Clock<sup>Δ19/Δ19</sup> mice. Additionally, functional bladder capacity was significantly lower in Clock<sup>Δ19/Δ19</sup> mice when compared to WT mice. Overall, the clock gene mutant mice, Clock<sup>Δ19/Δ19</sup> mice, exhibit several abnormalities that are the main characteristics of the nocturia/nocturnal polyuria phenotype and hence may be used as an animal model for these conditions [673].

**IX. PHYSIOLOGY OF THE ANORECTUM**

### 1. FUNCTIONS OF THE ANORECTUM

The functions of the anorectum are: the storage of stools and their evacuation at convenient times. The rectum acts as a store for stools and as a conduit to the anus, while the sphincters that develop spontaneous contractile tone, are critical for faecal continence but also allow control of defecation. Sphincter defects are associated with faecal incontinence, but the sphincters are not alone responsible for maintaining faecal continence [674].

**Defecation:** The presence of stools in the rectum causes rectal distension and the activation of stretch receptors that initiate viscerovisceral reflexes and the recto-anal inhibitory reflex (RAIR) [675]. The former inhibits colonic activity, while the latter causes anal sphincter relaxation. Once defecation is initiated, the rectal angle straightens, the pelvic floor descends and the tonic activity of the sphincters is inhibited simultaneously with contraction of the rectum. Together, these responses result in the evacuation of the rectal contents [675, 676] and a sensory input from the anus maintains this activity until the rectum is fully evacuated [677].

### 2. STRUCTURE OF THE ANORECTUM

The rectum is a muscular channel that stores stools until convenient to defecate and terminates with the anus which offers control over the passage of stools [678]. The anal sphincter itself consists of the internal anal sphincter (IAS), the external anal sphincter (EAS), and the anal mucosal folds and vascular cushion, all of which contribute to the tight seal of the anus and maintenance of continence [678]. A number of key feature contribute to the maintenance of continence (Figure 37).

#### 2.1. External Anal Sphincter (EAS)

The external anal sphincter (EAS) is a ring of striated muscle that contributes to the maintenance of anal luminal pressure and provides some voluntary control of the anorectum [676]. It is an extension of the levator ani muscle and morphologically separated from the IAS. It is innervated by the pudendal nerve which is a mixed nerve carrying both somatic motor fibres and sensory nerve fibres. During sudden increases of intra-abdominal pressure, spinal reflexes cause the EAS to contract thereby maintaining continence during coughs and sneezes etc [676].

#### 2.2. The Puborectalis Muscle

The puborectalis muscle is also a striated muscle and wraps around the rectum creating the anorectal angle (normally about 90°) which acts to prevent the movement of faeces from the rectum to the anal canal between defecations. Like the EAS, the puborectalis develops tonic contractions and is under voluntary control [679].

#### 2.3. The Internal Anal Sphincter (IAS)

The internal anal sphincter (IAS) is a ring of predominantly slow-twitch, fatigue-resistant smooth muscle that encircles the anus and normally prevents the passage of faecal material, thus maintaining continence [680, 681]. The smooth muscle differs from that of the rectum and the rest of the non-sphincter muscle of the gastrointestinal tract by developing spontaneous tone that is not dependent on nervous innervation or hormonal influences [682]. This intrinsic muscle tone accounts for up to 85% of anal luminal resting pressure and is essential for the maintenance of continence [676]. However, IAS muscle tone is influenced by the autonomic innervation and some hormones (e.g. angiotensin II). Importantly, a non-cholinergic, non-adrenergic (NANC) innervation relaxes the IAS transiently during defeecation. The loss of IAS intrinsic tone can lead to the development of faecal incontinence, whilst chronically elevated IAS tone may hinder healing of anal fissures by reducing blood flow in the sphincter region [683]. It is thus a tissue of interest when considering drug development for these conditions.
3. INNERVATION OF THE ANO-RECTUM

The enteric nervous system (ENS) consists of a network of ganglia (myenteric plexus and submucous plexus) that is present throughout the gastrointestinal tract and regulates gastrointestinal secretion, motility and blood flow [684,685]. In the myenteric plexus of the intestine, multifunctional rapidly adapting mechanosensitive enteric neurones (RAMEN) have been identified that can trigger reflexes [686,687].

The anorectum as part of the gastrointestinal tract is innervated by the ENS, but the region also receives parasympathetic, sympathetic and somatic innervation. These modulate peristalsis and are involved in the defecation reflex. The parasympathetic efferent innervation to the distal colon and anorectum arise from spinal segments S2–S4 and increase rectal muscle tone in humans. In contrast, the sympathetic innervation to this region is carried in the hypogastric nerve which originates in spinal segments T 5–L2 . These sympathetic fibres contribute to continence by inhibiting rectal tone and by increasing contractile tone of the IAS [688-690]. Some voluntary control of defecation is provided by the pudendal nerve, this arises in the sacral (S2–S4) spinal cord and innervates the pelvic floor and puborectalis muscles as well as the EAS [690].

3.1. Sensory Innervation

The sensory innervation of the anorectum has two main functions: firstly, to sample rectal contents and rectal distention, which can lead to initiation of the RAIR or postponement of defecation with voluntary external sphincter contractions if required; and secondly, to provide anal sensitivity [691]. Both unmyelinated and myelinated sensory nerve fibres are present in the anorectum [688]. The nerves mediate a number of distention-induced reflexes including the RAIR with afferent nerve fibres running in the pudendal nerves [692]. The sensory nerves are also a component of the rectal sampling reflex, which involves short-lasting rectal contraction and relaxation of the upper part of the anal canal that allows a sampling of the content of the rectum. Intra-ganglionic laminar nerve endings that are sensitive to mechanical distension have been identified in the rectal myenteric plexus of the rat [693].

3.2. Innervation of the Internal Anal Sphincter

The IAS receives both an excitatory and an inhibitory innervation: the former necessary for the maintenance of sphincter tone and continence; the latter for sphincter relaxation during defecation. As in other parts of the gastrointestinal tract, contraction and relaxation of the IAS smooth muscle are regulated by enteric and autonomic neurones and by the actions of other cell types, including interstitial cells of Cajal.

Figure 37 Water intake and voiding patterns in a clock mutant mouse model. Upper and middle panels. Comparison between wild type (WT) and Clock mutant (∆19/∆19) mice in micturition patterns. Plots and bar charts show: water intake over two 12hr/12hr light-dark cycles and over one light-dark cycle: average voiding episodes; volume per void; and total voided volume. *p<0.05, **p<0.01 light vs dark for each group; ## p<0.01 WT vs Clock∆19/∆19 for dark cycles; §§ p<0.01 WT vs Clock∆19/∆19 for light cycles. Lower panels. Actograms of WT and Clock∆19/∆19 mice for a two-day period; there is no overall difference.
[694]. The IAS is innervated by both sympathetic and parasympathetic fibres [695,696], but excitatory motor innervation to the IAS is almost exclusively sympathetic and abolished by guanethidine, a drug that inhibits transmitter release from adrenergic nerves [682,697,698]. However, when purinergic neurotransmission is blocked by desensitising muscle purinergic P2X receptors with α,β methylene-ATP (ABMA), this also inhibits (about 30%) contractions of the IAS smooth muscle induced by electrical field stimulation (EFS), suggesting ATP is acting as an excitatory neurotransmitter [698]. Since ATP contributes to the response, but guanethidine abolishes contractions, it appears that both noradrenaline and ATP are co-released from adrenergic nerves in the IAS to mediate excitatory neurotransmission. In contrast to the IAS, motor innervation to the rectum also appears to involve co-transmission, but in this case mainly cholinergic and tachykinergic mechanisms are involved [699].

The predominant influence of the sympathetic system has been confirmed with neurogenic responses being inhibited in the presence of α₁-adrenergic antagonists such as prazosin [697,699-701]. However, intravenous infusions of α- and β-adrenoceptor agonists in cats [702] suggest that inhibitory effects via β-adrenoceptor may also be present but masked by the larger responses mediated via α₁-adrenoceptors.

### 4. EXCITATORY NEUROTRANSMISSION

#### 4.1. Sympathetic Innervation

α₁-adrenoceptors: Sympathetic nerve stimulation causes IAS contraction [703] and the main body of evidence indicates that these responses are mediated via α₁-adrenoceptors. Thus, autoradiographic studies with ³Hprazosin have identified α₁-adrenoceptors on the smooth muscle fibres of sheep and human IAS [704]. Furthermore, it has now been shown in many studies with different species, including man, that the sympathetic neurotransmitter noradrenaline and synthetic α₁-adrenoceptor agonists cause large contractions of IAS smooth muscle that are blocked by α₁-adrenoceptor antagonists [704,705-707]. Also, it was demonstrated that stimulation of α₁-adrenoceptors increases resting luminal pressure developed by the sphincter without affecting the anal pressure response to rectal distension [708]. In sheep, mice and human IAS, electrical field stimulation of tissues produces contractions that are blocked by α₁-adrenoceptor antagonists [697,708-711].

Activation of α₁-adrenoceptors mediates contraction of IAS smooth muscle of pig [706], sheep [704] and human [707] and the receptor subtype has been identified as the α₁A-adrenoceptor subtype. Unlike all the cloned α₁-adrenoceptor subtypes the IAS receptor has a low affinity for prazosin [706]. This characteristic is found with a number of functional α₁A-adrenoceptor receptors in various tissues and the receptors are thought to represent a pharmacologically distinct form of the α₁A-adrenoceptor and termed α₁L-adrenoceptors [712]. This conclusion is supported by the finding that deletion of the α₁A-adrenoceptor gene in knock-out mice, results in the absence of the α₁L-adrenoceptor subtype in tissues [713].

#### 4.2. Parasympathetic Innervation

**Cholinergic transmission:** Cholinergic neurones mediate the contraction of gastrointestinal smooth muscle [720] with acetylcholine (Ach) activating M₁ and M₃ muscarinic receptors to induce increases in cytosolic Ca²⁺ and contraction [79,721]. The situation is less clear in the IAS where Ach has both excitatory and inhibitory effects on the smooth muscle. Activation of muscarinic receptors of the human IAS induces contraction that is mediated via the M₁ receptor subtype [722,723]. However, several reports have suggested that muscarinic receptor stimulation can cause relaxation of the IAS. These have been reported for IAS from cats, opossum and human [724-726]. This inhibitory response to muscarinic agonists appears to be due to the release of nitric oxide since inhibitors of NO synthase have been shown to block the relaxations [724,725,727]. To complete the picture it should be noted that in the pig IAS, carbachol fails to elicit contraction and atropine has no effect on neurogenic responses to EFS [698]. Thus the role of muscarinic receptors and Ach as a neurotransmitter appears to be species dependent.

**Purinergic transmission:** The role of ATP and purinergic receptors in the IAS is controversial with some
studies finding excitatory effects and other inhibitory effects. In the porcine IAS desensitisation of smooth muscle P2X receptors with ABMA significantly reduces neurogenic (EFS) contractions. Furthermore, this effect is greater at 5 Hz than at 10 Hz stimulation suggesting that ATP provides a greater contribution to contractions at lower frequencies of stimulation. A similar frequency dependent effect has been observed in visceral and vascular smooth muscle, where the inhibition of ATP breakdown has a greater potentiating effect on neurogenic responses at low frequencies compared to higher frequencies [728].

In contrast, many studies have suggested that ATP is an inhibitory neurotransmitter in the IAS [682,729,730]. ATP has been shown to mediate inhibitory junction potentials and relaxations in guinea-pig and human IAS [726,730], while both ATP and adenosine have been shown to produce concentration-dependent relaxations of the guinea pig [730], rabbit [731], rat [729,732], mouse [733] and sheep [709] IAS smooth muscle. The inhibitory junction potentials induced by ATP were mediated via P2Y receptor [709,729,733]. Thus, P2X receptors may mediate contractile responses of the IAS, whilst P2Y receptors may mediate the inhibitory junction potentials and relaxations. In other tissues such as the bladder, ATP can induce a number of smooth muscle responses via different mechanisms including (1) direct actions via P2Y receptors (2) indirect actions by inducing NO release from epithelial cells and (3) indirect actions via P1 receptors after being broken down to adenosine [586].

5. INHIBITORY NEUROTRANSMISSION

NANC neurotransmitters such as NO, play a major role in the inhibitory neurotransmission of the IAS and are essential for transient anal relaxation during defecation. However, inhibitory neurotransmission in the IAS involves a number of neurotransmitters or modulators that may be co-released to cause relaxation (Figure 38).

Figure 38: NANC relaxation responses to electric field stimulation. Stimulation at 10Hz was carried out in the presence or absence of inhibitors of the synthesis of: NO (L-NNA), cGMP (ODQ), CO (ZnPPIX) or H2S (PAG+AOAA), either alone or in combination. *p<0.05, ** p<0.01, and *** p<0.001 compared to control values in the absence of inhibitors.

5.1. Nitric oxide (NO)

Nitric oxide is predominantly an inhibitory neurotransmitter causing relaxation of the IAS in all species so far examined. Thus inhibitors of NO synthase (NOS) reduce neurogenic relaxations of the IAS in animals and human [698,709,729,734-738]. NO stimulates guanylate cyclase resulting in the activation of cGMP-dependent protein kinase I (cGKI) and the opening of potassium channels to produce inhibitory junctional potentials and relaxation [729,737,738]. The cGMP pathway has been demonstrated in human IAS [739] (Lies et al., 2014). In cGKI-knockout mice NO induced relaxations can still be observed suggesting that a cGKI-independent pathways may also exist in the IAS [735]. The inhibitory actions of NO are exerted directly on the IAS smooth muscle since relaxation remains in the presence of the neurotoxin tetrodotoxin [738]. In the human IAS, NO donors relax tissues and in the presence of atropine and guanethidine, EFS produces tetrodotoxin-sensitive relaxations, which are inhibited by inhibitors of NO synthase [736].
Both neuronal (nNOS) and endothelial (eNOS) isoforms of NOS have been identified in the anorectum: nNOS in the gastrointestinal neurones of the myenteric plexus [740] and eNOS and nNOS in the IAS circular smooth muscle [694,741,742]. nNOS has also been identified in the human IAS using immunohistochemistry [703] and it has been suggested that inhibition of nNOS by reactive oxygen species (ROS) may contribute to pathological conditions of the IAS [743]. Thus, it is clear that NO is the major NANC neurotransmitter mediating neurogenic relaxation of the IAS in animals and human [730,736,744].

5.2. Carbon Monoxide (CO)
Carbon monoxide is another gaseous neurotransmitter that plays a significant role in the gastrointestinal tract and NANC neurotransmission. Direct relaxation of the mouse and opossum IAS has been reported [745,746], while NANC neurotransmission is markedly reduced in knockout mice incapable of generating CO, and restored with the addition of exogenous CO [747]. The synthesis of CO is catalysed by heme oxygenase (HO), which is the rate-limiting enzyme in the catabolism of heme [748]. There are two isoforms of heme oxygenase: the induced enzyme (HO1) and the constitutively expressed isofrom (HO2). The mechanism of IAS smooth muscle relaxation for CO is similar to that of NO, with activation of guanylate cyclase, production of cGMP resulting in hyperpolarisation and smooth muscle relaxation [745,746]. However NO is about 80-fold more potent at activating guanylate cyclase than CO [749]. As with NO, relaxation of IAS smooth muscle has been reported that can occur independently of the cGMP pathway, a process by which CO opens potassium channels directly to cause hyperpolarization and smooth muscle relaxation [750].

5.3. Hydrogen Sulphide (H2S)
H2S is the third gaseous transmitter found in the NANC nerves of the IAS. It is produced from L-cysteine by two enzymes; cystathionine-β-synthetase and cystathionine-γ-lyase, although, a third enzyme (3-mercaptopuroltransferase) also has been associated with H2S synthesis in mammals [751]. Expression of these enzymes is widespread throughout the body, but particularly in nervous tissue [752]. H2S has been implicated in K⁺ channel opening and hyperpolarisation although H2S-induced relaxations have been observed that do not involve K⁺ channels [753].

H2S production has been demonstrated in the gastrointestinal tract, and both cystathionine-β-synthetase and cystathionine-γ-lyase are expressed along the rat and mouse intestine [754,755]. Cystathionine-β-synthetase and cystathionine-γ-lyase have been detected immunohistochemically and at the mRNA level in rat colonic smooth muscle cells [756,757]. H2S is endogenously produced in the rat colon and it regulates colonic motility [754]. It has been reported that NaHS, a H2S donor, relaxes a number of gastrointestinal tissues and inhibits smooth muscle contractile responses to nerve stimulation [758]. There have been few studies of the role of H2S in the IAS, but it was recently shown that H2S contributes to inhibitory neurotransmission in the pig IAS [698]. However, NO remains the main mediator of relaxation in this tissue.

5.4. Vasoactive Intestinal Polypeptide (VIP)
Vasoactive intestinal polypeptide originally isolated from pig intestinal extracts [759] (Said & Mutt, 1970), also participates in NANC relaxation throughout the intestine, including the IAS of many species including man [731,733]. In particular in mice, electrical stimulation, particularly with longer stimulation trains of pulses, induces a slowly developing and long lasting NANC relaxation and hyperpolarisation, which is abolished in the presence of a VIP receptor antagonists and is absent in VIP-knockout mice [733]. It was proposed by these authors that the VIP pathway may be activated with greater rectal distensions, leading to a more prolonged period of anal relaxation.

Using genetic knockout of the biosynthetic enzymes for CO and NO, it has been shown at least in the mouse that the effects of exogenous and endogenous VIP in the IAS are mediated by heme oxygenase HO-synthesized CO [760]. At the postsynaptic level, many studies support the concept that VIP and NO are parallel co-transmitters, acting via the adenylylate cyclase and guanylate cyclase pathways respectively. Based on results from gastrointestinal tract smooth muscle cells, VIP is thought to be the principal neurotransmitter, acting partly via a VPAC receptor, the cAMP pathway and by NO production [761]. In addition, the capacity of VIP to release NO from isolated smooth muscle cells is associated with the induction of iNOS in these cells [761]. Thus, VIP may mediate relaxation of the IAS by a direct effect and also modulation of other neurotransmitters (NO and CO).

In a comprehensive study of inhibitory neurotransmission in the pig IAS, the role of NO, CO and H2S were examined after removing contractile responses with guanethidine (Figure 38). Inhibiting NO synthase reduced relaxations to EFS by about 50%. However after removing NO effects with a NOS inhibitor, the non-nitrergic relaxation of the pig IAS to field stimulation were further reduced by ODQ which suggests the involvement of CO in the relaxation of this tissue. This was confirmed using ZnPiPIX an inhibitor of heme oxygenase which is responsible for the synthesis of CO. This inhibitor reduced IAS relaxation responses by about 20% and this effect was not additive with ODQ. These data suggest that the ODQ sensitive component of the relaxation is composed of predominantly NO (50%) but with a smaller contribution from CO (20%).

In the presence of ODQ, the remaining small, non-NO, non-CO relaxation must be mediated via a neurotransmitter that is cGMP-independent. It has been shown that the enzymes responsible for the production of H2S are present in the enteric nerves and the
myenteric interstitial cells of Cajal [762], both of which can be found in the IAS [708,763]. Inhibition of H2S synthesis with PAG and AOAA depressed relaxation responses to EFS and the depression was additive to that of ODQ and therefore independent of cGMP indicating a small role for H2S in relaxation of the IAS to EFS. Thus inhibitory neurotransmission in the pig IAS involved all three gaseous neurotransmitters (NO>CO=H2S), illustrating the complex mechanisms involved in the transient relaxation of the IAS during defecation.

6. MYOGENIC ACTIVITY IN THE IAS AND RECTUM

6.1. Spontaneous Contractions

The spontaneous development of tone in IAS smooth muscle is an intrinsic property of the sphincter smooth muscle itself and develops independently of neuronal and hormonal influences [682]. Basal tone develops gradually (see Figure 39) and is associated with an elevation of intracellular calcium that involves ryanodine receptors, L-type Ca2+ channels and Ca2+-activated Cl- channels [764]. The elevated intracellular calcium, via calmodulin, activates myosin light chain kinase (MLCK) and triggers an increase in basal tone.

![Figure 39. Noradrenaline and basal tension in IAS. Isolated IAS preparation showing a spontaneous rise in basal tension over 60 min before the addition of noradrenaline (NADr: 10-7.5 to 10-4 M) to generate tonic contractions.](image)

Two intracellular mechanisms result in the development of smooth muscle contraction and spontaneous tone. The first is a direct contractile mechanism involving increases in intracellular calcium which activate calmodulin thereby activating myosin light chain (MLC) kinase and phosphorylation of MLC to induce contraction. Stimulation of G-protein linked receptors, e.g. muscarinic receptors in the rectum or α1-adrenoceptors in the IAS, increases intracellular calcium and induces contraction via this mechanism. Ca2+ release from the sarcoplasmic reticulum of IAS is the initial signal for the generation of IAS smooth muscle basal tone and maintenance, and this increased Ca2+ then activates Ca2+-activated Cl- channels which activated the L-type Ca2+ channels [764]. Also, extracellular Ca2+ influx via L-type Ca2+ channels and contribute to the maintenance of IAS basal tone in many species including man [737, 765].

The second mechanism for muscle tone development occurs simultaneously to elevation of intracellular Ca2+, and is known as Ca2+-sensitisation. This mechanism involves an inhibition of the dephosphorylation of MLC by MLC-phosphatase via the Rho/ROCK pathway [766, 767]. Rho is a small GTP binding protein which can interact with a serine/threonine kinase known as ROCK (Rho activated, coiled containing protein kinase 2). Rho when bound to GTP, activates ROCK which can phosphorylate and inhibit MLC-phosphatase. There are two isoforms of ROCK (I and II) and although both forms are found in smooth muscle it is ROCKII that is expressed in visceral smooth muscle [768]. The inhibition of MLC-phosphatase results in reduced de-phosphorylation of MLC and more contractile force development for a given calcium concentration. Hence the pathway is also known as the Ca2+-sensitisation pathway and leads to tonic myogenic force development.

In tissues that have significant myogenic tone such as the IAS, the Rho/ROCK pathway is active even in unstimulated muscle cells and can result in the development of spontaneous basal contraction. Thus Rho/ROCK levels are greater in IAS smooth muscle than rectal smooth muscle [769, 770]. Moreover, Rho kinase (ROCK) is also important in the maintenance of IAS smooth muscle basal tone [771-773]. The molecular basis for the basal myogenic tone in the IAS was examined and compared to rectal smooth muscle (a mixture of phasic and tonic), and anococcygeus smooth muscle (phasic muscle) in the rat [769]. The levels of Rho/ROCK were higher at the cell membrane in the IAS compared with those from the rectal and anococcygeus smooth muscle. Also, a RhoA inhibitor (C3 exoenzyme) and a ROCK inhibitor (Y27632) caused relaxations of the IAS illustrating a basal level of pathway activation.

For the rectum, the literature on the characterisation of spontaneous phasic activity is quite limited. However the role of this system has been investigated in the rat rectum where both PKC and Rho/ROCK appear to play a significant role in slow-rate high-amplitude spontaneous phasic activity. However, only the RhoA/ROCK pathway mediated fast-rate low-amplitude phasic activity [774]. Extracellular signals for Rho/ROCK activation system in human IAS and rectum have been sought and an extracellular matrix and arachidonic acid pathways provide such a link by activating RhoA/ROCK for the maintenance of basal tone [773].

The IAS had higher levels of expression of the biosynthetic machinery for the renin-angiotensin system (RAS) and the cyclooxygenase (COX) system than the rectum. Furthermore, inhibitors of the RAS and
COX pathways depressed IAS basal tone by 80% and 20% respectively, while the end products of these pathways angiotensin II (ANG II), thromboxane A2 (TxA2) and prostaglandin F2α (PGF2α) increased IAS tone [773].

Following receptor stimulation, two pathways may result in Rho activation. One involves activation of Rho/ROCK after receptor coupling with G12/13-G-proteins [775]. The other involves protein kinase C (PKC) inhibition of MLCP via phosphorylation of PKC-potentiated inhibitor (CPI-17), the endogenous inhibitory protein of MLCP [776]. In human IAS smooth muscle, phorbol esters which activate PKC and the Rho/ROCK pathway cause contraction [777]. Since this pathway controls IAS myogenic tone, drugs that modulate the Rho/ROCK pathway may offer new opportunities for drug development in the treatment of faecal incontinence.

6.2. Smooth Muscle Relaxation

Reduction of intracellular Ca2+ ([Ca2+]i) induces smooth muscle relaxation; although Ca2+-independent smooth muscle relaxation can occur, a phenomenon known as Ca2+ desensitisation [778]. Smooth muscle relaxation ([Ca2+]i dependent or independent of reduced [Ca2+]i) has been associated with activation of cGMP-dependent protein kinase (PKG) and cAMP-dependent protein kinase (PKA). These kinases are induced by gaseous transmitters such as NO, carbon monoxide (CO) and GPCR activation respectively [779-781]. PKG and PKA-induce smooth muscle relaxation even when [Ca2+]i is unchanged (Ca2+ -desensitisation), because activation of PKG inhibits Rho, thereby reducing the sensitivity of the contraction process to calcium [782,783]. Furthermore, PKG can induce calcium desensitisation by phosphorylating CPI-17 [784].

In the sheep IAS, endogenous angiotensin II (Ang II) is another agent involved in maintaining basal tone and contraction of the IAS smooth muscle [773,785,786]. The biosynthetic machinery for Ang II is present in the IAS of rat, and the agent may be synthesised locally [785]. Early studies in the IAS smooth muscle of rat demonstrated the presence of ANG II and also AT1 receptors [785]. AT1 and AT2 receptors are expressed in the IAS smooth muscle of rat [787]. However, ANG II causes contraction of rat IAS smooth muscle by the activation of AT1 receptors at the smooth muscle cell and involves multiple intracellular pathways including influx of Ca2+, and activation of protein kinase C and ROCK [787]. It is concluded that basal IAS tone is partially under the autocrine control of the cellular renin-angiotensin system and is evident in the expression of angiotensinogen, renin, and angiotensin-converting enzyme in the IAS smooth muscle cells [786]. Also, Ang II causes an increase in the IAS smooth muscle tone via activation of RhoA/ROCK in the human [773]. Thus the renin-angiotensin system may mediate IAS basal tone and contractile responses.

7. INTERSTITIAL CELLS OF CAJAL (ICC) AND SPONTANEOUS CONTRACTILE ACTIVITY

Interstitial cells of Cajal (ICC) are specialised cells distributed throughout the gastrointestinal tract including the rectum and IAS [788]. Various populations of ICC exist which have different functions (pacemaker vs neurotransmission) and also morphology. One population makes synaptic connections with efferent parasympathetic nerves and via gap junctions with smooth muscle fibres. The other population of ICC is located in the myenteric/submucosal plexuses, where they are thought to act as pacemakers of contractile activity. In these cells spontaneous phasic slow wave activity passes between ICC and muscle fibres via gap junction and these can summate and initiate phasic contractile activity [15,789]. The contractile functions of the rectum and anus differ (phasic vs tonic) and these differences in function are reflected in the characteristics of their respective ICC. Rectal ICC more closely resemble the spindle-shaped, intramuscular ICC found throughout the rest of the gastrointestinal tract and their density is greater than that in the IAS [694,790].

The function of the anal sphincter is to develop tone rather than phasic contractile activity and the IAS differs from the rectum in having a predominantly sympathetic excitatory input and also a different distribution of ICC. In this tissue, the sympathetic motor fibres do not appear to be associated with intramuscular ICC. Thus sympathetic nerves are likely to innervate directly the smooth muscle of the IAS and may contribute to myogenic tone [694,791].

As in the rectum the IAS has a nitricergic innervation, but unlike the rectum, this does not seem to innervate the ICCs. The role of ICCs has been investigated in mice deficient in these cells (W/Wv mice) and these studies have identified a dense network of ICCs in the IAS of normal but not mutated mice, but relaxation responses to EFS were normal suggesting only a minor role for ICC in the sphincter [792]. It is also unclear whether ICCs are essential for the RAIR, with conflicting reports concerning the effect deletions in mutant mice [793,794]. Thus in the sphincter, ICC may have a role in regulating muscle tone, and basal myogenic tone is lower in ICC deficient mice compared with controls. The intramuscular ICC contribute to the electrical events underlying nitricergic neuromuscular transmission in the mouse IAS [792] and the enzyme heme oxygenase, which produces CO, has been found to be present in the myenteric and submucosal neurons of the IAS as well as in the ICCs found in this tissue [795].

Thus ICC in the rectum and anus differ, reflecting the different functions of these two tissues. There is also growing evidence that ICC play a role in sensory mechanisms in the gastrointestinal tract. Vagal afferent nerve endings are found in close proximity to ICC
and may be involved in stretch perception since in the bladder, they release ATP when stretched, a chemical known to sensitise afferent nerves [796].

8. MUCOSAL INFLUENCES ON THE ANAL SPHINCTER

In the lower urinary tract, the lining of the bladder, the urothelium/lamina propria, releases a number of factors thought to be involved in bladder control (Figure 40). Specifically of interest, the urothelium/lamina propria releases a factor which inhibits contraction of the smooth muscle [797,798]. A similar mechanism was recently shown to inhibit contractility of the smooth muscle of the internal anal sphincter. This inhibition does not involve ATP acting via purinergic P2 receptors and is not NO, CO or H2S [799]. Whilst the precise mechanism of mucosal inhibition remains to be elucidated, it may provide a novel target for development of drugs to increase tone in the internal anal sphincter and thus treat faecal incontinence.

Figure 40. Inhibition of porcine IAS responses to phenylephrine in the presence of an intact mucosa. Denuded tissue strips have mucosa removed. Dose responses to phenylephrine (range 10^-7.5 to 10^-4 M) in control conditions or in the presence of suramin or ZnPPIX. *p<0.05, ***p<0.001 compared to response of denuded tissues.
It is not the purpose to list a number of research projects but to highlight those areas that are more novel and/or under-investigated. Implicit is the appreciation that an understanding of changes to LUT and lower gastro-intestinal tract function associated with clinical conditions can only be achieved by a detailed characterisation of normal function. A description of particular pathways and processes in these tissues will not necessarily lead to targeted drug models but will provide avenues for exploration. Therefore, no particular potential targets amenable to treatment by particular drugs or other external drivers will be identified here. However, potential research areas of interest include:

Understand the basis of spontaneous contractile activity in the bladder, especially the role of any inter-relationship between mucosa and detrusor layers.

1. Characterise the basis of contraction in the trigone.

2. Describe the contractile properties of the *mucularis mucosae* and other non-detrusor muscles in the bladder wall.

3. Identify the role of interstitial cells in regulating the functional characteristics of tissue in which they are embedded in normal and pathological conditions.

4. Characterise the control of water and electrolyte transport by the urothelium and its physiological role in salt and water balance.

5. Determine the functional development of the normal lower urinary tract and the lower gastro-intestinal tract during embryonic development and further changes in childhood.

6. Characterise the changes to lower urinary tract function, at cellular, tissue and system levels in children with congenital anomalies of the tract.

7. Investigate electromechanical coupling of the pelvic floor musculature.

8. Characterise the cellular and tissue physiology of external urethral sphincter skeletal muscle as a prelude to pathological changes to sphincter function.

9. Describe the functional inter-relationship between changes to the lower urinary tract and other visceral organs and tissues.

10. Characterise the role of clock genes to determine diurnal variability in lower urinary tract and lower-gastrointestinal tract contractile and transport functions.

11. Investigate the inter-relationship between excitatory and inhibitory control over ano-rectal function.

12. Describe the underlying mechanisms underlying filling sensations in the lower-gastrointestinal tract.

13. Determine how ageing *per se* affects lower urinary tract and lower-gastrointestinal tract functions.

I. THE UROTHELIUM

The urothelium can be thought of as a first responder to various types of stress that can include physiological, psychological and disease-related factors. The urothelium is an interface between the urinary space and underlying tissues (Figure 1) and as such, forms a high resistance barrier. Beside this necessary function, the urothelium can modulate the volume and composition of urine (1) and actively participates as an integral part of what has been termed a ‘sensory web’ where it receives, integrates, amplifies and transmits information about the external environment to underlying nervous and muscular systems. Alterations of bladder urothelium at the molecular and structural levels have been reported in both patients and animals modeled for various bladder disorders. It is likely that many therapies currently used in the treatment of bladder disease may target urothelial receptors and/or their release mechanisms.

1. ANATOMY AND BARRIER FUNCTION.

The urothelium is the epithelial lining of the lower urinary tract between the renal pelvis and the urinary bladder. Adult urothelium is composed of at least three layers with distinct cell types (the exact number...
of layers is species dependent) and can be distinguished by expression of keratin-5, p63 and uroplakin (Figure 2A,B). These consist of a basal cell layer attached to a basement membrane, an intermediate layer, and a superficial or apical layer that is in contact with urine and microorganisms and composed of large hexagonal cells (diameters of 25-250 µm) known as ‘umbrella cells’. (2-5) These umbrella cells exhibit a distinctive plasma membrane that contains both ‘hinge’ and ‘plaque’ regions (Figure 3). The umbrella cells (which are also termed facet or superficial cells) are interconnected by tight junctions (composed of multiple proteins such as the claudins). Another characteristic of the apical or umbrella cells is the expression of discoidal fusion vesicles or DFVs (Figure 4). In response to bladder filling, these DFVs fuse with the apical membrane releasing crystalline proteins termed uroplakins to the cell surface that assembles into hexagonal plaques. (5-8) The attachment of Escherichia coli type I fimbriae to uroplakins also initiates the host-pathogen response, described more fully in later sections. It has been suggested that ‘non-plaque’ proteins that include receptors and ion channels, may be located to the hinge areas of these cells.

Uroplakins and other urothelial cellular differentiation markers, such as cytokeratin 20, are not expressed in the stratified epithelium of the urethra. There have been suggestions in early studies in some species, that umbrella cells and perhaps also the intermediate cells may have projections to the basement membrane.(4) The ability of the bladder to maintain a highly effective barrier, despite large alterations in urine volume and increases in pressure during bladder filling and emptying, is dependent on several features of the umbrella cell layer. These features include specialized lipid molecules and tight-junction proteins (such as zona occludens-1, occludins, claudins) that reduce the movement of ions and solutes between cells.(4, 9) These proteins can adapt to mechanical stretching of the urothelium during filling and emptying. For example, the claudins are a family of integral membrane proteins (at least 24 members identified in mice and humans) and can be classified as either pore forming (makes the epithelium leakier) or barrier-forming. The importance of claudin-based tight junctions in vivo has been studied in a number of tissues under various conditions. For example, claudins (in particular claudin 4) may play a role in regulation of urothelial proliferation. There is evidence that attachment of uropathogenic Escherichia coli (UPEC) to urothelial superficial cells triggers the rapid induction of claudin-4 within the intermediate cells of the urothelium (Figure 5). (10)

This increase in claudin-4 may explain how the urothelium is able to maintain the integrity of the urothelial barrier following infection and exfoliation of the apical urothelium. In another study, overexpression of the pore-forming claudin-2 in rat urothelium resulted in increased urothelial permeability that seemed to trigger inflammation and altered bladder function.(11) It has not been established whether disruption of the urothelial barrier alone is sufficient to trigger inflammation and altered bladder reflexes or whether association with other factors (such as urine) may be needed to facilitate this response.(12)

In addition, there is evidence in many types of epithelium (including uro-epithelium) that adhesion molecules such as members of the cadherin family play...
important roles in establishing and maintaining epithelial-cell contacts. (13) Altered urothelial-cadherin expression has been reported in IC/BPS patient bladder urothelium.

The lipid composition of the apical membrane is unusual in composition and is rich in cholesterol, phosphatidylcholine, phosphatidylethanolamine and cerebroside. (4) Recent studies suggest that liposomes, consisting of an aqueous core enclosed in one or more phospholipid bilayers, may help to restore urothelial-barrier function. Liposomes have typically been used to transport drug molecules in a variety of cells. Urothelial cells appear to take up liposomes via an endocytotic process, providing evidence for a possible mechanism by which liposomes act as a drug delivery system. (14-16) In addition, empty liposomes have shown promise to repair and enhance the barrier function of a dysfunctional urothelium (Figure 6). (17-19)

The apical surface of the urothelium is also covered with a sulfated polysaccharide glycosaminoglycan (GAG) or mucin layer that is thought to act as a non-specific anti-adherence factor and as a defense mechanism against infection. (20-22) In addition, during bladder filling the umbrella cells become flat and squamous and this shape change is accompanied by vesicular traffic (i.e. exocytosis/endocytosis), adding membrane to the apical surface thereby increasing overall urinary bladder surface area. (5, 23, 24) This process of ongoing replacement of apical membrane by newly fused discoid vesicles also serves to maintain the urothelial barrier. (25) There is evidence that this stretch-induced exocytosis is dependent on activation of epidermal growth factor receptor (EGFR). (26, 27) These processes allow the bladder to accommodate increasing volumes of urine during filling without compromising the barrier function. There is some evidence that superficial urothelial cells exhibit a lower level of endocytotic activity, which may be a protective mechanism against internalization of toxic substances excreted in the urine. (28) Exocytosis/endocytosis (vesicular recycling) may also play an important role in modulating the release of a number of neurotransmitters/mediators as well as regulation of the function of many receptors and ion channels in urothelial cells. (29, 30)

Figure 6: (A) EM picture of liposome, (B), liposomes (in green) attached to primary cultured urothelial cell membrane, In C, liposomes instilled in a rat bladder forming a coating (green) on urothelial surface and D, vesicle-like structures in urothelial cell endosomal compartment (marked as E) containing liposome encapsulated gold marker. (from Hsu et al., 2013, Nirmal et al., 2014 and Rajaganapathy et al., 2015).

2. REPAIR AND REGENERATION

Epithelial integrity is maintained through a complex process of migration and proliferation (to restore cell numbers) and differentiation (to restore function). (31) Basal cells normally exhibit a low (3-6 month) turnover rate, in fact the slowest turnover of any mammalian epithelial cells. (23, 32)

It has been suggested that neither urine-derived factors nor cyclic mechanical changes contribute to urothelial proliferation and differentiation. However differentiation of urothelial cells in culture can be stimulated by prostaglandin (which is abundant in the urine) (1, 33) and accelerated proliferation and regeneration of the urothelium can occur in various bladder pathologies. For example, using agents (protranine sulfate; cyclophosphamide) that damage the umbrella cell layer, it has been shown that the urothelium rapidly undergoes both functional and structural changes in order to restore the barrier in response to injury. (28, 34) Following disruption of the barrier, in the early stages of regeneration the superficial cells may appear smaller in size and often covered with microvilli. (35) In some pathologies, a deficiency or defect in maturation or terminal differentiation of superficial umbrella cells have been reported, though the factors which may be involved are not yet known. (36) Recent evidence has shown that following cyclophosphamide treatment of rodent bladders,
there is a rapid desquamation, proliferation and regeneration of the urothelium. In this study, the intermediate cells (and not the basal cells) seem to be the adult progenitor cells for superficial cells and they are self-renewing. (Figure 7)(37)

The processes underlying urothelial repair is complex involving several structural elements, signaling pathways, trophic factors and the cellular environment. Furthermore, the interaction between these biochemical signals and mechanical forces in the bladder during the course of urothelial repair is not well understood. For example, the initiation of urothelial proliferation or differentiation of intermediate cells is thought to involve up-regulation of growth factors such as fibroblast growth factor and nerve growth factor (NGF).(38, 39) In addition, members of the PPARγ and EGFR signaling pathways may contribute to urothelial ‘re-epithelialization’ in wound repair.(33) There is also evidence that Hedgehog/Wnt signaling acting across the basal urothelial cell-stromal cell boundary contributes to increases in urothelial proliferation in response to injury.(40) Retinoic acid (synthesized from underlying stroma) has been shown to be important for urothelial differentiation.(41)

Though the urothelium maintains a tight barrier to ion and solute flux, a number of factors or stressors such as tissue pH, mechanical or chemical trauma, hormonal changes or bacterial infection and even changes in blood flow can modulate the barrier function of the urothelium.(29, 42) It has been shown that ischemia can augment release of inflammatory mediators such as reactive oxygen species or eicosanoids from urothelial and suburothelial tissues, altering bladder tone and contractility.(43) Stress-mediated activation of the hypothalamic-pituitary-adrenal axis can result in increased production of corticotrophin releasing factor, which can regulate neuroendocrine and autonomic responses to stress. The net effect can include disruption of the epithelial barrier and increased prevalence of infection. In addition, altered levels of circulating estrogens have been associated with changes to the urothelial structure including epithelial...

Figure 7: Intermediate cells are the progenitors for superficial cells in adult urothelium. Uroplakin-expressing cells are labeled using Upk2CreERT2;mtmg line (a) and basal cells labeled using Krt5CreERT2;mtmg line (b). Following cyclophosphamide administration, urothelial regeneration occurs. a- shows intermediate cells are progenitors for superficial cells and b- show basal cells proliferate but do not differentiate into intermediate or superficial cells based on lineage-tracing studies. In the adult- following injury, intermediate cells function as progenitors for superficial cells and are self-renewing. (From Yamany et al., 2014). Panel C- long and thin intermediate cells regenerate the outer protective layer- intermediate cells and progeny (white arrows) appear green (C. Mendelsohn).

shedding or mucosal atrophy. (44, 45) Other conditions such as bladder pain syndrome/interstitial cystitis (BPS/IC), senescence, diabetes or spinal cord injury are also associated with changes in the urothelial barrier. (34, 46) Studies utilizing aged animals have demonstrated significant alterations to the bladder mucosa including areas of mucosal denudation. (47, 48)

A number of bladder disorders can increase susceptibility to injury and apoptosis through pathways including oxidative stress. Oxidative stress, characterized in part by an increase in the level of proinflammatory mediators and reactive oxygen species or ROS, can lead to disruption of various cellular components. (49, 50) Oxidative stress can be produced by bladder pathologies including ischemia or repeated ischemia/reperfusion during a micturition cycle. (51, 52) Indeed, the bladder mucosa exhibits a higher metabolic rate as compared to other regions in the bladder wall and the urothelium is highly vulnerable to any changes in blood flow. Both acute and chronic reduction in blood flow has revealed significant defects in the mucosal barrier with disruption of urothelial tight junctions. Within the urethra and urinary bladder, age-related changes include a thinning of the epithelium and decreased vascularity. Findings from aged animals reveal that urothelial cells show a decreased antioxidant capacity with increased levels of markers for oxidative stress. Further, this is associated with alterations in mitochondria and increased accumulation of an aging pigment termed lipofuscin. (Figure 8). (53) The decline in these various epithelial elements may lead to a decrease in both regenerative ability and also immunological defense mechanisms that are critical for maintaining epithelial integrity.

3. ROLE OF THE UROTHELIUM IN IMMUNE AND INFLAMMATORY RESPONSES

Mitochondria, considered the powerhouse organelles in a cell, play a key role in cellular homeostasis, including generation of ROS, apoptosis, and production of ATP via oxidative phosphorylation. (54) Indeed, the study of bioenergetics and the influence of mitochondrial functions on cell signaling and disease is an emerging and exciting area of research. Mitochondrial dysfunction has been implicated in a number of disorders. These structures are highly sensitive to changes in their cellular environment and can be easily affected by a number of conditions. For example, there is ample evidence that ischemia leads to cellular damage by overproduction of superoxide by the mitochondrial electron chain (Figure 9). Studies have shown that mitochondrial abnormalities (such as increased ROS) can lead to changes in mucosal barrier function in a number of tissues including the urinary bladder. Further, recent studies have shown some evidence demonstrating mitochondrial dysfunction and oxidative stress (elevated ROS) may play a role in urothelial barrier (and sensory) abnormalities observed in the urinary bladder in a number of conditions such as ketamine-induced ulcerative cystitis. (55, 56)

There is new evidence that the human urinary tract contains a diverse microbiota that is likely to play an important role in bladder health and disease. (57) Evidence in the GI tract supports a role for gut microbiota on intestinal barrier function that can be altered by psychological and physical stressors. (58) In terms of the urinary tract, the urothelium is truly the first line of defense against pathogens and irritative substances with a number of mechanisms in place to limit inflammatory responses (Figure 10). (59) Some examples include uromodulin (also known as Tamm-Horsfall urinary glycoprotein), which acts to prevent bacteria from interacting with the epithelial cell surface. (60) Other factors such as β-defensin 1 are secreted from epithelial cells into the urine and restrict bacterial growth. (61)

Both physiological and psychological stress can result in a failure of urothelial and suburothelial ‘defensive’ systems and thereby promote changes in both urothelial barrier and signaling function. For example, alterations in proteins including proteoglycans and bacterial defense molecules may lead to distinctive changes in urothelial structure and play a role in bacteria adherence. (62) In this regard, urinary tract infections produced by uropathogenic *Escherichia coli* (UPEC) are initiated by bacterial adherence to uroplakin proteins on the apical surface of umbrella cells.
cells. The UPEC express filamentous adhesive organelles (type 1 pili) that mediate bacterial attachment, invasion and apoptosis of the urothelial cells. It has been suggested that urothelial differentiation (and increased uroplakin III expression) plays a pivotal role in sensitizing urothelial cells to UPEC-induced infection and possible cell death. Even acute contact (within hours) of the mucosal surface by bacteria may result in altered urothelial barrier function. UPEC can also internalize within umbrella cells forming intracellular colonies (biofilm-like pods) of UPEC that has been implicated in the mechanism of chronic urinary tract infections. UPEC are able to commandeer the endocytic/exocytic machinery of urothelial cells, residing inside fusiform vesicles. This permits the bacteria to escape elimina-

Figure 10: The human urinary tract contains a diverse microbiota. Right-overview of mechanisms that may be employed to curtail inflammatory responses in the bladder following infection. These can include exfoliation of bladder epithelial cells, increased proliferation to regenerate the barrier; mast cell secretion of interleukins (to aid in tissue regeneration); release of chemokines and other factors from macrophages (from Abraham and Miao, 2015).

Figure 11: Following UPEC infection of urothelial cells- activation of the mucolipin TRP channel 3 (TRPML3) spontaneously initiates lysosomal exocytosis- leading to an expulsion of exosome-encased bacteria. (from Miao et al., 2015).

Figure 12: UPEC induces pain separable from other facets of UTI pathogenesis. FimH acts as a tethered toxin that mediates urothelial apoptosis and consequent bladder-barrier dysfunction. LPS plays dual roles through its interactions with TLR4. In addition to triggering inflammation, LPS mediates pelvic-pain responses. (from Rosen and Klumpp, 2014 and Klumpp and Birder, 2016).
tion during voiding and re-emerge into the urine during distension. When expelled into the urine during the storage phase, the urine may provide a nutrient-rich environment optimizing bacterial survival. Infected urothelial cells have also been shown to use their export machinery to reduce bacterial loads. For example, UPEC found in epithelial ‘lysosomes’ are sensed by a transient receptor potential (TRP) mucolipin 3 (TRPML3). This is a cation channel expressed on lysosomes, and this sensing leads to a spontaneous exocytosis of the lysosome expelling the bacteria (Figure 11).(67)

UPEC can trigger an inflammatory response within the urothelium with release of multiple mediators (such as interleukins and cytokines)(68) and the end result of this immune response is structural damage to the urothelial barrier. Recent evidence has shown that hypoxia inducible factor 1-alpha (HIF-1α) can play a role in modulating the innate immune cell function.(69, 70) Human urothelial cells treated with a HIF-1α stabilizing agent exhibited less cell death when exposed to UPEC supporting a role for HIF-1α in defense against UPEC infection.(71) There is also evidence for a role of endotoxin (lipopolysaccharide, LPS) on the bacterial cell wall in mediating the pain associated with UPEC infection. (72) This seems to function independent of urothelial damage, as erosion of the urothelial surface with protamine sulfate in mice failed to elicit bladder pain when instilled with UPEC strain of bacteria. In addition, bacteria can possess a wide range of pain phenotypes, largely dependent upon Toll-like receptors (Figure 12).(73, 74)

Taken together, these findings support the view that UPEC-induced urothelial dysfunction is the transducer of the UTI pain signal.

Disruption of urothelial function can also be induced by more remote pathological conditions that influence neural or hormonal mechanisms. For example, spinal cord transection in rats leads to a rapid alteration in the urothelial barrier including ultrastructural changes and increased permeability.(75) The changes are blocked by pretreatment with a ganglionic blocking agent, suggesting an involvement of efferent autonomic pathways in the acute effects of spinal cord injury on bladder urothelium. Other types of urothelial-neural interactions are also likely, based on the recent reports that various stimuli induce urothelial cells to release chemical mediators that can in turn modulate the activity of afferent nerves.(4, 29) This has raised the possibility that the urothelium may have a role in sensory mechanisms in the urinary tract.

In summary, modification of the urothelium and/or loss of epithelial integrity in a number of pathological conditions can result in passage of toxic/irritating urinary constituents through the urothelium or release of neuroactive substances from the urothelium. This may lead to changes in the properties of sensory nerves and in turn sensory symptoms such as urinary frequency and urgency. Thus chemical communication between the nervous system and the urothelial cells may play an important role in the generation of urinary bladder dysfunction.

![Image 13: Images depicts ‘open type’ paraneurons in the dog urethra. A, paraneuron reaching the lumen; B-D, Scanning EM identifies (arrows) microvillous cells among the epithelial cells. A: x14,000; b: x4600, c: x12,000, d: x16,000. (from Hashimoto et al., 1999).](image13)

4. EPITHELIAL HETEROGENEITY IN THE LOWER URINARY TRACT

Studies (comparing a number of species) have shown that the major part of the urinary tract is lined with a fully differentiated urothelium. (1) Findings in cultured cells reveal a distinct difference in morphology of ureteral and bladder urothelial cells, supporting a difference in cell lineage. Present evidence suggests at least 3 urothelial lineages: 1) those of the ureter/renal pelvis, 2) detrusor/trigone and 3) bladder neck/proximal urethra. (76)

There seems to be no apparent difference between the urothelium of the trigone compared to the detrusor, in contrast to cells from the proximal urethra. (1, 77) In this region, there is a transition from urothelium to a stratified or columnar epithelium accompanied by a lack of urothelial-specific differentiation markers. In addition, specialized chemosensory neuroendocrine cells are distributed within the urethral epithelia. These cells are often exposed to the lumen and may share similarities to Gl enterochromaffin cells or chemosensory cells of the trachea or respiratory tract (often termed 'brush cells'). (78) Including expression of microvilli (Figure 13; 14). These urethral specialized chemosensory cells are able to respond to detect potential noxious stimuli (using the classic taste transduction pathway) by releasing mediators such as acetylcholine. (78, 79) Similar to urothelial cells in the bladder wall, these urethral chemosensory cells are also in close proximity to sensory nerve fibers whereby intraurethral stimulation can lead to activation of underlying cells including bladder smooth muscle. In addition, there are also reports that have identified functional properties of sacral afferents that are able to respond to changes in fluid flow through the urethra. (80) While the functional significance of these findings may not yet be fully appreciated, it is clear that such ‘sentinel’ type cells are able to recognize potentially harmful stimuli (including bacteria) in the urethral lumen and in turn, alter bladder function.

5. ROLE FOR UROTHELIAL CELLS IN VISCERAL SENSATION

While urothelial cells are often viewed as bystanders in the process of visceral sensation, recent evidence...
has supported the view that these cells function as primary transducers of some physical and chemical stimuli and are able to communicate with underlying cells including bladder nerves, smooth muscle and inflammatory cells. (Figure 15)

5.1. Influence of the Extracellular Matrix

The urothelium is able to respond to a wide variety of mechanical stresses during bladder filling and emptying by activating a number of possible transducer proteins. Possibilities of mechanical signals include bladder pressure, tension in the urothelium or bladder wall, torsion, geometrical tension, movement of visceral organs and even urine tonicity and pH. (81) Alterations in the composition of urine are a type of stress whose contents can vary in both their rate of delivery as well as the particular constituents. Additionally, dynamic reciprocal interactions of the urothelium with underlying extracellular matrix (ECM) not only aid in maintaining normal bladder structure but also play an important role in generating signaling responses. The urothelium is highly sensitive to the mechanics of the underlying ECM, thus understanding the complexity and relationship between mechanics and biological activities of cells throughout the bladder wall is important. In this regard, studies using multiphoton imaging have revealed differences in collagen fiber structure and recruitment throughout the bladder wall (Figure 16). (82) It is likely that pathology-induced changes in fiber architecture could alter neural-epithelial interactions including the response to mechanical strain that can influence bladder compliance and sensation.

Additional lines of evidence suggest that urothelial cells participate in the detection of both physical and chemical stimuli. Bladder nerves (afferent and efferent) are localized in close proximity, and some within, the urothelium. (83-86) In addition, urothelial cells express numerous receptors/ion channels similar to that found in both nociceptors and mechanoreceptors.

And finally, these cells secrete a number of transmitters or mediators capable of modulating, activating or inhibiting sensory neurons.

5.2. Urothelial-Neuronal Signaling

Recent studies have shown that both afferent and autonomic effenter nerves are located in close proximity to the urothelium. Peptidergic, P2X- and TRPV1-immunoreactive nerve fibers presumed to arise from afferent neurons in the lumbosacral dorsal root ganglia are distributed throughout the urinary bladder musculature as well as in a plexus beneath and extending into the urothelium. (29, 85) In humans with neurogenic detrusor overactivity intravesical administration of resiniferatoxin, a C-fiber afferent neurotoxin, reduces the density of TRPV1 and P2X3 immunoreactive suburothelial nerves, indicating that these are sensory nerves. (87, 88) In addition, immunohistochemical studies have also revealed both adrenergic (tyrosine hydroxylase) positive as well as cholinergic (choline acetyltransferase, ChAT) positive nerves in close proximity to the urothelium. (84)

A network of cells with morphologic characteristics similar to those of myofibroblasts or interstitial cells is also detected in the suburothelial space of the bladder in both humans and animals. (89-92) These cells, which are extensively linked by gap junctions and have close contacts with nerves, can respond to neurotransmitters, such as ATP released from nerves or urothelial cells, suggesting that they could act as intermediaries in urothelial-nerve interactions. (89, 91, 93) Thus the anatomic substrates for bidirectional urothelial-neural communication exist within the urinary bladder.

5.3. Involvement of the Urothelium in “Sensing” Chemical and Mechanical Stimuli

The involvement of urothelial function in sensory signaling is suggested by the finding that urothelial cells express various receptors that are linked to mechano- or nociceptive sensations. Examples of neuronal “sensor molecules” (receptors / ion channels) that have been identified in urothelium include receptors for purines (P2X1,7 and P2Y1,2,4) adenosine (A1, A2a, A2b and A3), norepinephrine (α and β), acetylcholine (muscarinic and nicotinic), protease-activated receptors (PARs), amiloride- and mechanosensitive epithelial sodium channels (ENaC), bradykinin (B1 and B2), neurotrophins (p75, trkA, EGF family ERbB1-3), corticotrophin releasing factor (CRF1 and CRF2), estrogens (ERx and ERβ), endothelins and various TRP channels (TRPV1, TRPV2, TRPV4, TRPM8 and TRPA1). (94-105) The expression of these various receptors enable the urothelium to respond to a number of “sensory inputs” from a variety of sources. These inputs include increased stretch during bladder filling, soluble factors (many found in the urine) such as epidermal growth factor (EGF), or chemical mediators/peptides/transmitters such as substance P, calcitonin gene-related peptide

Figure 16: Cross-section of rat bladder depicting collagen fiber (green) orientation throughout the bladder wall using multi-photon microscopy (original image Hornsby et al., 2016).
Various stimuli can lead to secretion of numerous chemical substances such as neurotrophins, peptides, ATP, acetylcholine, prostaglandins, prostacyclin, nitric oxide (NO) and cytokines that are capable of modulating the activity of underlying smooth muscle(93, 108) as well as nearby sensory neurons.(29, 30) For example, urothelial-specific overexpression of NGF results in increased bladder nerve ‘sprouting’ and increased voiding frequency.(109, 110) It has been shown that urothelial-derived NO can be released in response to mechanical as well as chemical stimulation and may either facilitate or inhibit the activity of bladder afferent nerves conveying bladder sensation.(111) In this regard, activation of urothelial-receptors and release of inhibitory mediators may explain in part, the mechanism of action for therapies (e.g. β3-adrenergic receptor agonists) in treatment of bladder disorders such as OAB.(112-114)

The mechanism underlying release of chemical mediators from the urothelium, including whether all sensory “inputs” stimulate membrane turnover (i.e. vesicular exocytosis) is not well understood. What little is known about the roles and dynamics of membrane-bound cytoplasmic vesicles in urothelial cell physiology is derived from measurements of membrane capacitance and microscopy of fixed tissues and cells. For example, there is evidence that once released, ATP can enhance both stretch induced exocytosis and endocytosis.(115) Alterations in membrane turnover can not only increase apical surface area (as described above) but also regulate the number and function of receptors and channels at the cell surface.

There is evidence that epithelial cells in different organ systems may express similar receptor subtypes.(116-118) Accordingly, epithelial cells could use multiple signaling pathways, whose intracellular mechanisms differ according to location and environmental stimuli. This would permit a greater flexibility for the cell to regulate function and respond to complex changes in their surrounding microenvironment. Whether urothelial-sensor molecules all feed into a diverse array of signaling pathways or share similarities with systems such as olfaction, whereby hundreds of receptors share identical transduction cascades,(119) is yet to be uncovered.

5.3.1 Purinergic Receptors

Since the first report of distension-evoked ATP release from the urothelium there is now abundant evidence supporting a role for urothelially-derived release of ATP in autocrine and paracrine signaling within the lower urinary tract.(120) ATP is abundant in the cell cytoplasm and can be released extracellularly by several mechanisms including vesicular exocytosis, transporters such as a member of the ATP-binding cassette (ABC) transporter superfamily, or anion-selective channels such as the maxi-anion channel.(99) ATP is released from both the apical and basolateral urothelial surfaces in response to bladder stretch and can act on P2X2 and P2X3 urothelial receptors to stimulate stretch-induced exocytosis (115) (Figure 17A) There is also evidence that pannexin channels, which are expressed throughout the urothelium (Figure 17B and 18), may be involved in modulating voiding reflexes via urothelial release of ATP.(101, 121)

The expression of both P2X and P2Y receptors in nerve fibers and myofibroblasts in close proximity to the bladder lumen and the sensitivity of these cells to ATP suggests that basolateral ATP release from the urothelium may also influence function of myofibroblasts and bladder nerves.(90, 122) Also, since the P2X3 null mice have a lower frequency of voiding contractions during bladder filling, suggests that P2X antagonists could play a role in treatment of OAB. The amiloride-sensitive apical sodium channel, ENaC, may be involved in mechanotransduction by controlling basolateral release of ATP.(123, 124) In addition, intercellular communication mediated by gap junctions in myofibroblasts could provide a mechanism for long-distance spread of signals from the urothelium to the detrusor muscle.(93) Interestingly, this type of nucleotide-mediated wave of cell-cell communication may also play a role in the response to injury.(124) While evidence supports a role for ATP and purinergic receptors in modulating symptoms in
several urologic diseases, the mechanisms underlying activation of the micturition pathway at lower bladder volumes (during urgency) and mediators (amount; type) involved are not understood. In addition, the directionality of transmitter release, the mixture of receptor subtypes in the apical and basolateral domains and interactions between multiple transmitters is likely to affect the nature of the output in both health and disease.

5.3.2 TRP Channels

The ability of capsaicin to evoke NO release from rat urothelium, reported in 1998, provided the first, albeit indirect, demonstration that TRPV1 channels are expressed in urothelial cells and that urothelial cells and afferent nerves, which also express these channels, share a number of common properties. (125) This ion-channel protein is activated by capsaicin, as well as to moderate heat, protons, nitro-fatty acids and lipid channel protein is activated by capsaicin, as well as share a number of common properties. (125) This ion-channel protein is activated by capsaicin, as well as to moderate heat, protons, nitro-fatty acids and lipid metabolites such as anandamide (an endogenous ligand of both cannabinoid and vanilloids receptors). (126, 127) TRPV1-positive nerves are in close contact with urothelial cells. (128, 129) Activation of urothelial cells with capsaicin or resiniferatoxin can increase intracellular calcium, evoke transmitter (nitric oxide, NO or ATP) release, and elicit transient currents. (85, 130) Similar to that in sensory neurons, urothelial-response to vanilloids are enhanced by low pH, blocked by TRPV1 antagonists and eliminated in TRPV1 null mice. (85) In afferent neurons, TRPV1 is thought to integrate/amplify the response to various stimuli and to play an essential role in the development of inflammation-induced hyperalgesia. It seems likely that urothelial-TRPV1 might participate in a similar manner, in the detection of irritant stimuli following bladder inflammation or infection.

Additional TRP channels

Much less is known about the involvement of other TRPs in bladder function or disease. TRPV4 is a nonselective cation channel activated by a number of stimuli including heat, shear stress, changes in osmolarity and lipid ligands is expressed mainly within the epithelium of the urinary bladder. (131) While a definitive role for TRPV4 in bladder function has not been established, there is evidence that null mice exhibit impaired voiding responses and, intravesical instillation of a TRPV4 agonist in the rat triggers a novel voiding reflex which could regulate the late phase of micturition. (86, 132) Additional studies suggest activation of urothelial-TRPV4 facilitates bladder reflexes via activation of mechanosensitive, capsaicin- insensitive) C fibers. (133) In addition, in the awake ewe, TRPV4 may also be involved in a urethra to bladder reflex, proposed to facilitate bladder emptying. (134) Another member of the TRP family, TRPA1 (characterized as a thermoreceptor activated by noxious cold), is expressed in C-fiber afferents as well as urothelium and agonists to this channel induce bladder hyperreflexia. (135) Of interest is the finding that hydrogen sulfide, which may be formed during infection/inflammation, is an activator of TRPA1.

5.3.3 Acetylcholine

There is evidence that the urothelium expresses the full complement of muscarinic receptors as well as enzymes necessary for the synthesis and release of acetylcholine. (106, 136) Further, the urothelium is able to release acetylcholine following both chemical and mechanical stimulation. (106) The mechanism underlying acetylcholine release from urothelium may be through organic cationic transporters (OCTs) rather than vesicular exocytosis, differing from that of bladder nerves. (137) Once released, urothelial-derived acetylcholine is likely to exert effects via a number of sites including smooth muscle, nerves as well as urothelial associated-muscarinic or nicotinic receptors, the latter that could contribute to feedback mechanisms modifying urothelial function. (138) In addition, stimulation of urothelial-cholinergic receptors elicits release of mediators such as nitric oxide, prostaglandin as well as ATP, which could alter bladder sensation by stimulating nearby sensory afferent nerves. (139-141)

Thus, targeting muscarinic receptors and/or urothelial synthesis or release mechanisms may play an important role in the treatment for a number of bladder disorders. By inhibiting SNARE-dependent exocytotic processes, botulinum toxin A (BTX-A) can prevent the release of transmitters from bladder nerves as well as translocation of various receptors and channels to the plasma membrane. (142) Urothelial-derived acetylcholine may not be sensitive to BTX-A, however studies have shown that other transmitters (such as ATP) released by the urothelium can be blocked by this treatment in addition to normalizing the expression of urothelial-receptors (TRPV1; muscarinic) and trophic factors. (143, 144) These and other studies suggest that the urothelium may be a
target for this treatment and that urothelial-released mediators may contribute to sensory urgency.

6. CLINICAL SIGNIFICANCE OF THE SENSORY WEB

Defects in urothelial sensor molecules and urothelial-cell signaling are likely to contribute to the pathophysiology of bladder diseases. For example, a number of bladder conditions (BPS/IC, spinal cord injury (SCI), chemically-induced cystitis) are associated with augmented release of urothelial-derived ATP, which is likely to result in altered sensations or changes in bladder reflexes induced by excitation of purinergic receptors on nearby sensory fibers. (98, 145) ATP can also act in an autocrine manner that would act to facilitate its own release from urothelial cells. Augmented expression/release of urothelial-derived chemical mediators is likely to reduce the threshold for activation of nearby bladder afferents. Thus, the urothelium has the potential for amplifying signals, both within the urothelium and the bladder wall and contributing to a gain of function in sensory processing. Stressors that can impact on this ‘gain of function’ include alterations in levels of trophic factors as well as stress and steroid hormones. For example, altered levels of circulating estrogens may play a role in urinary bladder dysfunction, including urgency and frequency. (44, 146) The resulting structural and functional abnormalities may lead to enhanced signaling between the urothelium and underlying cells.

Changes in epithelial signaling/barrier function would not be unique to the urinary bladder. Activation of keratinocytes alone in mice expressing a light-activated channel can result in nociceptive responses demonstrating signaling between epithelial and neural tissues. (147) (figure 19) In addition, airway epithelia in asthmatic patients as well as keratinocytes in certain types of skin diseases also exhibit a number of similar abnormalities and compromised repair processes. (116, 148, 149) This is particularly relevant given the high incidence of associated diseases that can include both visceral and somatic conditions, many of which exhibit a shared loss of epithelial barrier function. Further, many of these systems do share a number of commonalities that include increased afferent activation of supraspinal centers in order to effectively coordinate efferent outflow as well as dependence on similar types of neurotransmitters (such as ATP) to mediate sensory responses. A recent example is the use of P2X3 antagonists in the treatment of both respiratory and urological disorders. (150) Taken together, epithelial cells can respond to a number of challenges (including environmental pollutants and mediators released from nerves or nearby inflammatory cells) resulting in altered expression and/or sensitivity of various receptor/channels as well as changes in release of mediators, all of which could impact function.

II. AFFERENT PATHWAYS

1. OVERVIEW: PROPERTIES OF AFFERENT PATHWAYS

The bladder and lower urinary tract serves to store and evacuate urine and is controlled by a complex hierarchy of neural mechanisms organized by local, spinal and brain circuits. Most of the time is spent in storage mode during which the bladder accommodates urine and maintains continence via reflexes that prevent contraction of bladder smooth muscle and contract the urethral sphincter. This switches during micturition when the bladder contracts and the sphincter opens to facilitate voiding. This switch relies on sensory signals, which provide the input to the reflex circuits that control bladder filling and emptying and are also the source of both non-painful sensations of fullness and pain. Dysfunction leads to a number of distressing disorders such as overactive bladder syndrome (OAB) and Bladder Pain Syndrome/Interstitial Cystitis (BPS/IC) with symptoms including urgency, pain and urinary incontinence. Currently available therapeutic approaches are aimed primarily at reducing bladder contraction in order to relieve intravesical pressure and maintain continence. Interest in bladder afferent signalling has been fuelled by the

Figure 19: Blue light stimulates multiple types of afferents in KRT-ChR2 transgenic mice. Top- ChR2-YFP expression in glabrous skin of KRT-ChR2 mouse. PGP9.5 positive nerve fibers (red) are in dermis and epidermis (arrows); Bottom- example showing activation of a cutaneous fiber in response to blue laser applied to KRT-ChR2 skin in an ex vivo preparation. (from Baumbauer et al., 2015).
recent realization that symptoms are a feature of dysregulated storage rather than exaggerated contractile responses and therefore targeting afferent mechanisms may be a rational approach to treatment.

Our understanding of bladder afferent signalling has been advanced by studies that are designed to reveal firstly, the morphological features of the afferent terminations in both the periphery and spinal cord; secondly, identify the receptors and ion channels present on these terminations that determine afferent excitability and, thirdly, by recording electrophysiologically the action potentials in afferent fibres it has been possible to characterize the stimulus-response functions of the various populations of afferents conveying sensory information towards the CNS. Such afferent recordings have been performed in vivo in anaesthetized animals and in vitro using isolated tissue preparations. In vivo studies have the advantage that reflex function remains intact although they may be influenced by the use of anaesthetics. Also, by maintaining vascular perfusion, tissue oxygenation will be better maintained, and blood borne factors, including leukocytes, important for neuro-immune functions, can be recruited to the bladder milieu. Similarly, any biochemical factors released into the tissue will be rapidly eliminated into the blood stream. However, an intact vascular supply may also offer a number of disadvantages. Reflex changes in blood flow may lead to secondary alterations in afferent firing, while in the absence of blood flow there is the potential for surgical and pharmacological interventions to probe stimulus-response function. For example, flat-sheet preparations with the urothelium uppermost in a tissue bath allow the pinpoint mapping of receptive fields and the localized application of stimuli directly to the surface of the urothelium. In contrast, surgical removal of the urothelium and sub-urothelial tissue has been used to determine the source of afferent signals from different layers of the bladder wall and the role of urothelial factors in afferent activation. The perfusion medium can incorporate drugs to target specific ion channels and receptors that would be lethal to the whole animal or can be manipulated (calcium-free conditions) to attenuate processes that require calcium entry for downstream signalling. The combination of these different approaches has been essential in understanding the nature of sensory signalling from the lower urinary tract.

### 2. PATHWAYS TO THE SPINAL CORD

Afferent fibres reach the lower urinary tract via pelvic, hypogastric (lumber splanchnic) and pudendal nerves. These nerves are mixed nerves that also contain the efferent parasympathetic, sympathetic and motor fibres supplying the bladder, urethra and sphincters. Axonally transported dyes applied to these nerves are taken up and transported to the cell bodies in the lumbosacral dorsal root ganglia and the terminations in the spinal cord. Mapping the distribution of these dorsal root ganglia (DRG) allows the pattern of innervation to be determined in detail and when used in combination with immunocytochemistry provide information on the neuronal phenotype. Moreover, these neurones can be isolated and maintained in cell culture and the labelling using to identify specific functional properties of bladder projecting sensory neurones.

Only a small proportion of DRG neurones supply the viscer with majority supplying somatic targets in the skin and skeletal muscles. Those supplying the bladder are pseudounipolar with a central projection into the dorsal horn of the spinal cord and a peripheral axon that terminates at different levels in the bladder wall. DRGs supplying pelvic and pudendal afferents originate in the thoracic, lumbar and sacral regions while hypogastric afferents arise mainly from the rostral lumbar dorsal root ganglia. The central projections of these DRG neurones carry the sensory information from the lower urinary tract to second order neurones in the spinal cord. These second order neurones provide the basis for spinal reflexes and ascending pathways to higher brain regions involved in micurition and in mediating sensation.

The cell size of bladder DRGs is consistent with there being 2 populations of afferents with one connecting to small unmyelinated C-fibre afferents and the other to finely myelinated A-delta fibres. These cell bodies can be further classified according to the presence or absence of certain biochemical markers, namely peptidergic and non-peptidergic. Many unmyelinated afferents are peptidergic, containing calcitonin-gene related peptide (CGRP) and many of these also contain substance P as well as various other peptides. However, some small myelinated fibres also express CGRP. Non-peptidergic neurones can be identified by labelling for isoleucin IB4, which recognizes terminal sugar residues on the cell membrane. Both small and medium sized DRG neurones are labelled with IB4. This non-peptidergic subgroup also expresses P2X3 receptors, which is predominantly found in small unmyelinated fibres. TRPV1 and other sensory markers described below have been demonstrated mainly in peptidergic populations.(151)

Staining for these sensory markers have also been used to identify the terminations of sensory afferents in the bladder wall. CGRP-containing afferent fibres are abundant in the bladder wall and distributed within 4 different layers distinct layers: within the urothelium, around the base of the urothelium within the lamina propria, in the muscle and associated with blood vessels in the serosa. These fibres have conspicuous varicosity, which are release sites for stored transmitter indicating a role for these afferents in so called “axon reflexes”. Upon activation the afferents convey information towards the CNS but also release mediators onto cells in their vicinity to mediate localized responses. Targets for these mediators include vascular smooth muscle, detrusor muscle, urothe-
lium, fibroblast-like cells, mast cells and other neurons. In the human bladder, CGRP containing fibres occur only infrequently in nerves in the muscle but are moderately frequent in the suburothelial layer. Some of these fibres synapse on intramural ganglia within the bladder forming the basis for local neural reflexes.(152-155) Ultrastructural studies of human bladder have found only unmyelinated nerves in the urothelium and immediate suburothelial layer, small myelinated nerves being closely associated with the smooth muscle layers.(156) The plexus of afferent nerves in the lamina propria is thickest in the neck of the bladder and in the initial portion of the urethra, and becomes progressively less dense in the adjacent regions such that cranial region of the bladder have no afferent axons. In contrast, the afferent innervation of the musculature is more uniform throughout the bladder.

Figure 20: A. Experimental methods for performing patch-clamp recordings on bladder afferent neurons obtained from rats with chronic cystitis. Chronic cystitis was induced by intraperitoneal injection of cyclophosphamide. Fluorescent dye (fast blue) injected into the bladder wall was transported via Aδ- and C-fiber bladder afferent axons to neurons in the dorsal root ganglia (DRG). L6 and S1 DRG were dissected and dissociated into single neurons by enzymatic methods. Whole cell patch-clamp recordings were performed on fast blue-labeled bladder afferent neurons identified with a fluorescence microscope. B. Characteristics of a bladder afferent neuron (24-µm diameter, C-fiber afferent neuron, top record) exhibiting tetrodotoxin (TTX)-resistant action potentials and a bladder afferent neuron (33-µm diameter, Aδ-fiber afferent neuron, bottom record) exhibiting TTX-sensitive action potentials. The left panels are voltage responses and action potentials evoked by 30-ms depolarizing current pulses injected through the patch pipette in current-clamp conditions. Asterisks with dashed lines indicate the thresholds for spike activation. The second panel on the left side show the effects of TTX application (1 µM) on action potentials. The third panel from the left show firing patterns during membrane depolarization (700-ms duration). The panels on the right show the responses to extracellular application of capsaicin (1 µM) in voltage-clamp conditions. Note that the C-fiber afferent neuron exhibited TTX-resistant phasic firing (i.e., one to two spikes during prolonged membrane depolarization) and an inward current in response to capsaicin, while A-fiber afferent neuron exhibited TTX-sensitive tonic firing (i.e., repetitive firing during membrane depolarization) and no response to capsaicin.
3. FUNCTIONAL PROPERTIES OF BLADDER AFFERENTS

3.1. Electrophysiological properties of afferent neurons

Functional properties of dissociated bladder and urethral afferent neurons identified by retrograde axonal transport of fluorescent dyes injected into the bladder or urethra have been investigated using patch clamp techniques (157-164).

Based on electrical and chemical properties (Figure 20), bladder afferent neurons are divided into two populations (163) in rats. The most common population of neurons (greater than 70%) are small in size, sensitive to capsaicin and exhibit high-threshold, long-duration action potentials resistant to tetrodotoxin (TTX), a Na+ channel blocker. The other population of bladder afferent neurons which are larger in size and insensitive to capsaicin exhibit low-threshold, short-duration action potentials, which are reversibly blocked by TTX. Because the majority of bladder afferent neurons with TTX-resistant spikes are sensitive to capsaicin, these neurons are likely to be the origin of C-fiber afferent axons (165). In rat models of cystitis or spinal cord injury, which exhibit C-fiber-dependent bladder overactivity, it has been shown that capsaicin-sensitive bladder afferent neurons increase their excitability due to decreased density of A-type K⁺ (Kᵥ) currents, associated with the decreased expression of the Kv1.4 α-subunit, which can form the Kᵥ channel(166). Thus, the reduction in Kᵥ current size could be a key mechanism inducing C-fiber afferent hyperexcitability in bladder overactivity conditions in the bladder.

3.2. Functional properties of afferent nerves

Recording from bladder afferents has confirmed the diversity of afferent populations described above based on morphology.(167) Conduction velocity measurements confirm the predominance of fibres conducting action potentials in the A-delta and C-fibre range (Table 1 and Figure 21). The majority of these are mechanosensitive, responding to bladder filling with a range of thresholds from volumes that would be encountered under normal bladder filling to extreme levels of distension that would be considered noxious and give rise to pain. Those with lower thresholds have small myelinated axons while unmyelinated fibres have generally higher thresholds for activation. Other afferents do not respond to bladder filling. Some can be activated by intraluminal chemicals such as hypertonic saline, capsaicin or ATP, suggesting they may function as chemoreceptors. Others may be so called “silent afferents” that have been described elsewhere including the gastrointestinal tract. These afferents can be recruited or sensitized in conditions (neuropathic; inflammatory) resulting in urgency, incontinence and even pain. (Figure 22)

A series of studies have used open-sheet preparations of guinea-pig bladder to examine the diversity of

bladder afferents and to attempt to correlate structure with function. Low threshold afferents have terminals in the muscle where they have been described as having “antenna-like endings” and are referred to as stretch sensitive muscular mechanoreceptors. (168, 169) Since these afferents also respond to contraction of the detrusor muscle there are also called tension receptors since they respond to tension generated by both elongation during stretch and shortening during contraction. High threshold afferents are also likely to terminate in the deeper muscle layers or in the serosa. These mechanosensitive endings have receptive fields (located by mechanical probing) associated with blood vessels. These likely respond to high levels of stretch that distort the bladder wall but may also become sensitized in response to inflammation.

Another class of mechanoreceptor can be activated by stretch and by light stroking of the urothelium. These endings are referred to as muscular-mucosal by analogy to similar endings in the bowel wall but muscular-urothelial mechanoreceptor may be a more correct term. Their sensitivity could arise because the afferent terminal branches to supply the muscle and urothelium or a single ending in the lamina propria might detect changes in muscle tension and stimulation of the urothelium. (170) Zagorodynuk et al suggest that non-peptidergic “grape like” endings in the lamina propria may be the substrate for these endings. Other urothelial endings respond to stroking but not stretch and some of these are stimulated by luminal chemicals such as capsaicin, acid and are temperature-sensitive. Peptidergic afferents identified by dye filling from the pelvic nerve may be the basis for these epithelial responses.

Mechanosensitivity can arise either directly as a consequence of mechanosensitive ion channels on the sensory nerve ending or secondary to chemicals released in response to stimulation, which in turn activate the ending secondary to stimulation of ligand-gated ion channels. As outlined below there is considerable debate as to the role of the urothelium in sensory signaling. One attempt to resolve this has been to dissect off the urothelium and lamina propria and determine the impact on mechanosensitivity. In the case of muscular and serosal mechanoreceptors removal of the urothelium has little impact on distension response, suggesting these endings may be directly responsive, although the nature of the mechanosensitive ion channels has yet to be elucidated. In contrast the response of muscular-urothelial endings to distension is markedly attenuated following removal of the surface layers of urothelium. (169) The same is true for the mucosal endings. This could imply that the urothelium is involved in transducing stimuli. However, an alternative view might be that dissection causes damage to the underlying nerves that are no longer able to respond to any stimulus. An alternative approach to determining the role of the urothelium may rely on pharmacological manipulations that interfere with urothelial signaling. In this respect the response of low threshold mechanoreceptors was unchanged in calcium-free buffer, which would be expected to prevent urothelial mediator release through exocytosis.

More recent studies in the mouse identified similar populations of afferents and used a systematic classification system to establish the relative proportion of these different types of afferents in the pelvic and lumbar splanchnic nerve supply. The basis for classification and the relative distribution of the terminals and projecting pathway is shown in Figure 23. Another important observation in this study was the finding that both low threshold and high threshold mechanosensitivity became heightened following exposure to inflammatory mediators which has implications for our understanding of how sensory signaling is altered in disease and a basis for altered micturition and sensations such as pain. (171) There are also studies that identified and characterized sacral afferents responding to ‘flow’ through the urethra. (80) These are important observations whereby properties of these flow-responsive afferents seem to parallel that of cutaneous afferents. This could be important in terms of restoration of bladder emptying following spinal cord injury.

4. MODULATING AFFERENT SENSITIVITY

The discussion above has emphasized how stimulus-response function can be used to define the features of the various sub-populations of afferents that supply...
the lower urinary tract. The relationship between stimulus and response is not fixed but can be changed according to the mechanical and chemical environment of the sensory ending. Contractions can distort the afferent ending while connective tissue elements will transmit or dissipate stimulus energy within the tissue determining for example whether a response is rapidly or slowly adapting to maintained stretch. Similarly, chemicals released from a variety of cells within the bladder wall and particular the urothelium and lamina propria will influence afferent firing.

Many mediators are released during inflammation, injury and ischemia, from platelets, leukocytes, lymphocytes, macrophages, mast cells, glia, fibroblasts, blood vessels, muscle and neurons. Each cell type may release several of these modulating agents. Some mediators act directly on sensory nerve terminals, while others act indirectly, causing release of yet other agents from nearby cells. This “inflammatory soup” acts on sensory nerve terminals to modify signalling (this is often referred to as “plasticity”). The increased sensitivity to both mechanical and chemical stimuli may contribute to chronic pain states – a feature of clinical relevance. Moreover, since these afferents also trigger reflexes that coordinate bladder function, sensitization can also cause detrusor overactivity or dysreflexia. Various experimental models have been employed to examine changes in the bladder innervation in disease. These include spinal cord injury, bladder outlet obstruction, and various models of hyperactivity based upon chemical injury and autoimmune reactions to name just a few. While these models have generated a wealth of information there is some concern about their translational value and as a consequence their predictive value when testing novel therapeutics.(172)

Local mediators may include neurotrophins, amines, purines, prostanoids, proteases, and cytokines. They produce their effects on visceral afferent nerves by three distinct processes. First, they can act directly, by opening ion channels on the nerve terminals. Secondly, they can sensitize endings, without causing direct stimulation, but causing hyperexcitability to other chemical and mechanical stimuli. This can occur when G-protein coupled receptors (GPCRs) are activated by mediators, which act via second messenger systems, to phosphorylate membrane receptors and ion channels that control excitability. Thirdly, as is the case for neurotrophins, they can change the phenotype of the afferent nerve over long periods. For example, they may alter expression of channels, receptors or mediators in the sensory neuron.(173) (Fig.24) They may also modulate ligand-binding characteristics or coupling efficiency of receptors. The result of sensitization is a leftward shift in the stimulus-response function. This means that for any given level of stimulation a greater afferent barrage is generated. Peripheral sensitization normally develops rapidly and is relatively short-lived. However, in the presence

![Figure 23: LUT afferent nerve classes and distribution. A, fiber classes in bladder wall and urethra. of maintained injury or inflammation, the sensitization can be prolonged by changes in gene expression. Genes influenced in this way include those that determine the amount and pattern of neurotransmitters release by central nerve terminals in the brain and spinal cord. This alters the way that sensory signals are processed within the CNS and contributes to “central sensitization”.(174)

**Role of the urothelium in sensory signal transduction**

The urothelium can no longer be considered a passive barrier protecting against diffusion of urine constituents. Recent evidence suggests instead that the urothelium possesses sensory functions and may transduce mechanical and chemical stimuli to underlying structures including smooth muscle, fibroblast-like cells, immune cells and bladder nerves including the terminals of afferents which are located in close proximity, or even within, the urothelium. The recent evidence supporting involvement of a number of these urothelially-derived factors in sensory signalling and the therapeutic potential of targeting these signalling pathways is considered below.

### 4.1. Nitric oxide

Enzymes responsible for the generation of nitric oxide (NO) are expressed in both the urothelium and in the adjacent nerve fibres. Knockout mice in which neuronal NOS has been deleted do not have an obvious

---

**Figure 24:** Peripheral mechanisms involved in neurotrophin-mediated development of bladder overactivity. In urinary bladder, NGF (shown in blue) is produced by several cell types—including urothelium, mast cells and detrusor smooth muscle cells—upon stretch or inflammation. The urothelium also produces BDNF (red). NGF binding to urothelial TrkA receptors might directly activate urothelial sensory ion channels, such as TRPV1 (purple), or increase expression of TRPV1 and mechanosensitive channels (MSC, pink). Increased TRPV1 and MSC activity stimulate the release of urothelial mediators, such as ATP, which sensitize the underlying afferents. NGF activates TrkA receptors expressed on suburothelial afferent C-fiber terminals, directly sensitizing neuronal TRPV1, MSCs and voltage-gated ion channels (VGCs, orange). The TrkA-NGF complex is internalized (dashed lines) and retrogradely transported to cell bodies in lumbosacral DRG, where de novo transcription of TRPV1, VGCs, MSCs and additional sensory ion channels (including purinergic P2X3 receptor for ATP; green) is initiated. These newly synthesized ion channels are anterogradely transported back to afferent terminals to contribute to peripheral hypersensitivity. Neurotrophin receptors TrkB (red) and p75NTR (black) are also expressed on both urothelium and afferent terminals, although their role has not yet been defined. Abbreviations: ATP, adenosine triphosphate; BDNF, brain-derived nerve factor; BOO, bladder outlet obstruction; BPS, bladder pain syndrome; DRG, dorsal root ganglia; MSC, mechanosensory channel; NGF, nerve growth factor; OAB, overactive bladder syndrome; P2X3, P2X purinoceptor 3; TrkA, tropomyosin-related kinase A; TrkB, tropomyosin-related kinase B; TRPV1, transient receptor potential cation channel vanilloid subfamily member 1; VGC, voltage-gated ion channel.
bladder phenotype. The same is true when inducible NOS is knocked out. However, NO may be involved in bladder dysfunction since expression of NOS is elevated in neurogenic bladder and release of NO may be reduced in experimental interstitial cystitis. Munoz et al.(175) recently found that while electrical stimulation-evoked release of some urothelial mediators (ATP) was attenuated by disruption of the urothelium, release of NO was maintained which may suggest that under these conditions NO is derived from suburothelial structures. Interestingly, NO release triggered by cholinoreceptor stimulation was lost after urothelial disruption, consistent with NO derived from multiple sources including the urothelium.

A previous study by Aizawa et al examined the effect of NO on sensory signalling by directly recording afferent activity arising from the bladder in vivo.(176) Release of NO can be inhibited using non-metabolizable analogues that compete with L-arginine as substrate for NOS. On such inhibitor, L-NAME, increased the afferent response to bladder filling by about 50%, which was reversed by activation of NO pathways with L-arginine. This data suggests that NO is able to inhibit afferent activity, an observation consistent with earlier cystometric analysis of the effect of activating the NO pathway.(177, 178) In addition to studying NO mechanisms in the normal bladder, Aizawa and colleagues also showed that application of L-arginine significantly inhibited hypersensitivity induced by the cyclophosphamide metabolite acrolein that is used experimentally as a model for BPS/IC.(176) The actions of NO are mediated through elevation of the intracellular second messenger cGMP (Figure 25).(179) In contrast, phosphodiesterase (PDE) type 5 terminates the action of NO, and PDE inhibitors can be used therapeutically to prolong the action of NO. Behr-Roussel et al found that inhibition of PDE5 attenuated bladder afferent activity in a rat model of spinal cord injury,(180) an indication that this might represent a target for treatment of hypersensitivity disorders of the bladder such as BPS and OAB.

4.2. Purinergic Signalling

ATP acting via purinergic receptors modulates bladder function mediated by both afferent and efferent pathways involved in urine storage and emptying. There is evidence that ATP is co-released with SP and calcitonin gene-related peptide from sensory nerves.(181, 182) Differences in sensitivity to purinergic agonists in lumbo sacral and thoracolumbar DRG sensory neurons that innervate the bladder via hypogastric and pelvic nerves were investigated.(157) The majority of lumbo sacral neurons (93%) were sensitive to α,β-meATP compared to 50% of thoracolumbar neurons. It was concluded that bladder pelvic and hypogastric splanchnic afferents are functionally distinct and are likely to mediate different sensations.
arising from the urinary bladder. The central projections of pelvic and pudendal afferents overlap within the spinal cord facilitating integration of somatic and parasympathetic motor activity. (183)

Intravesical administration of ATP stimulated the micturition reflex in awake freely moving rats, probably by stimulating suburothelial C-fibres, although other mediators might also be involved.(184) The activities of primary afferents by intravesical introduction of ATP are mediated largely through a subset of capsaicin-sensitive C-fibres.(185) Pretreatment of the anaesthetised guinea-pig with both atropine and α,β-meATP or by ganglion blockers led to complete blockade of neurokinin NK2 receptor-induced contractions. These results suggest that stimulation of NK2 receptors located on capsaicin-sensitive sensory nerves (where NK2 receptors have been demonstrated autoradiographically) leads to bladder contractions via both cholinergic and purinergic parasympathetic motor nerves. Taken together, studies have concluded that excitatory and inhibitory purinergic mechanisms are present not only in the peripheral nervous system/smooth muscle of the lower urinary tract but also in reflex pathways in the spinal cord that control micturition.

It is well established that the urothelium releases ATP in response to stretch and that this acts in a paracrine fashion to influence the function of myofibroblasts and bladder afferent nerves. Prolonged exposure to a desensitizing concentration of α,β-meATP reduced the activity of mechanosensitive pelvic nerve afferents in an in vitro model of rat urinary bladder.(186) P2X2 and P2X3 receptors (Figure 26; Figure 27A) are expressed on unmyelinated afferent fibres innervating the bladder, and thus the hypothesis has been put forward that mechanosensitivity, at least in those afferents in proximity to the urothelium, involved ATP release by stretch and activation of P2X2 and P2X2/3 receptors on the afferents.(96, 187) Mice lacking the P2X3 receptor showed reduced inflammatory pain and marked urinary bladder hyporeflexia with reduced voiding frequency and increased voiding volume.(188) This suggested that P2X3 receptors are involved in mechanosensory transduction underlying both inflammatory pain and hyperreflexia indicating a role in physiological voiding reflexes.(188) A later study using P2X2 KO mice and P2X2/P2X3 double KO mice showed a role for the P2X2 subtype too in mediating the sensory effect of ATP.(189) The increase in pelvic sensory nerve activity was mimicked by ATP and α,β-meATP and attenuated by P2X3 antagonists as well as in P2X3 KO mice and P2X3 receptors were shown to be localized on suburothelial sensory nerve fibres (Figure 27b).(187) In the mouse urinary bladder both low and high threshold fibres sensitive to ATP were shown to contribute to both physiological (non-nociceptive) and nociceptive mechanosensory transduction by single unit analysis of sensory fibres.(190) There are several functionally distinct populations of bladder sensory nerves, not all of which respond to ATP.(168) The excitability of afferent fibres to distension is increased by purinergic agonists.(190) Sadananda et al (191) investigated whether other stimuli, besides bladder distension,
muscarinic receptors localized near the luminal surface of the bladder were stimulated and shown to affect voiding functions via mechanisms involving ATP and NO release from the urothelium that in turn altered the firing properties of afferent nerves. (194) This supported the view that urothelial-afferent nerve interactions can influence reflex voiding functions. In addition, elevated ATP levels have been demonstrated in patients with detrusor overactivity and BPS(195). Munoz et al., using a rat model of detrusor overactivity (diabetic bladder), found increased levels of ATP but normal levels of NO. (175) Conversely in an underactive bladder model, induced by chronic sugar intake, NO levels were increased while ATP remained normal. This suggests that the balance between ATP and NO is altered in bladder dysfunction. From the translational perspective, a P2X3 antagonist, AF-219, has been tested in a proof-of-concept trial in treating symptoms associated with BPS/IC. In 36 and 38 BPS/IC women treated with AF-219 and placebo, respectively, patients treated with AF-219 had improvement in the key symptoms of IC/BPS: pain scores, urinary urgency and general improvement in patient reported symptoms, suggesting the

P2X1 and P2X3 receptors play a pivotal role in the micturition reflex in female urethane-anesthetized rats. (193) It was also shown that P2X3 receptor blockade by phenol red raised the pressure and volume thresholds for the reflex, while P2X1 receptor blockade diminished motor activity associated with voiding and also that P2Y1 receptor blockade may remove an accommodating inhibitory drive to rat detrusor muscle. In the normal bladder, it is believed that a balance between the excitatory effects of ATP and inhibitory effects of NO release may determine micturition thresholds and frequency and that this balance may be disturbed in bladder disorders. For example,

Figure 27: (a) Schematic of hypothesis for purinergic mechanosensory transduction in tubes (e.g. ureter, vagina, salivary and bile duct, gut) and sacs (e.g. urinary and gall bladders, and lung). It is proposed that distension leads to release of ATP from epithelium lining the tube or sac, which then acts on P2X2/3 receptors on subepithelial sensory nerves to convey sensory/nociceptive signals to the CNS. (Reproduced from Burnstock, 1999)

(b) P2X3 receptor immunoreactivity in the mouse bladder. Immunostaining is seen on small suburoepithelial nerve fibres. Calibration bar = 50 μm. (Cockayne et al., 2000)

Figure 28: Sensory fibers in visceral organs, especially the urinary bladder, express high levels of P2X3 receptors that are elevated in pathological conditions; unmasking segmental spinal reflexes that sense ATP content during filling and distension. P2X3 antagonists suppress afferent excitation and raise filling volume thresholds, especially in rodent models of cystitis. The distressing and largely unmet painful and irritative symptoms of bladder pain syndrome/interstitial cystitis and chronic prostatitis as well as lower urinary tract symptoms (urgency, frequency, and nocturia) associated with overactive bladder and benign prostatic hyperplasia, represent important visceral indications for novel P2X3 antagonists. (From Ford AP, 2012)
potential efficacy of P2X3 receptor antagonists for the treatment of BPS/IC symptoms.(196) (Fig 28)

4.3. Cholinergic Mechanisms

The discovery that ACh can be released from the human bladder urothelium has led to the concept that cholinergic mechanisms could contribute to sensory signalling.(197) This concept has been reinforced by clinical findings showing that anticholinergic drugs, the current mainstay for the treatment of bladder overactivity, appear to exhibit efficacy during the bladder storage phase when parasympathetic cholinergic activity is minimal.

A number of studies have examined the effect of cholinoreceptors on bladder afferent firing. However, the data are conflicting and a consensus has yet to emerge. In vivo studies using clinical anticholinergic agents such as oxybutynin and darifenac suggest that inhibiting muscarinic receptors, attenuates the afferent response to bladder filling.(198, 199) However, due to the nature of in vivo studies it is unclear if these effects are direct, at the level of the sensory terminal, or secondary to altered muscle tone following either peripheral or central effects on parasympathetic transmission. Similarly, Matsumoto et al found that stimulating muscarinic receptors induced bladder hyperactivity, and that this was blocked by inhibiting the M2 receptor, suggesting that M2 receptors play a role in cholinergic modulation of bladder afferent excitability. However, it is important to note that in this study, excitability was inferred from cystometry and afferent activity was not measured directly.(200) In contrast, Masuda et al (2009) found that pharmacological activation of muscarinic receptors attenuated micturition reflexes in the rat suggesting that muscarinic receptor activation leads to attenuated afferent signalling.(201) Such inhibition has been observed in afferent recording studies using isolated bladder preparations in which any secondary effects on muscle tone could be controlled.(202) In these studies blocking cholinesterase activity to augment endogenous cholinergic activity lead to attenuated afferent signalling that could be reversed by antimuscarinics. Surprisingly, antimuscarinics alone had no effect on bladder afferent responses to distension suggesting that acetylcholine release during stretch was not part of the sensory transduction pathway but cholinergic influences become manifested only under circumstances in which acetylcholine release is increased.

How ACh and muscarinic receptor pathways could modulate transmission is unclear. It is possible that there is a direct action and in this respect DRG neurons retrogradely labelled from the bladder have been shown to express M2, M3 and M4 receptors.(203) However, stimulation of muscarinic receptors on the urothelium causes the release of other excitatory and inhibitory mediators including ATP and NO.(106, 204) It is possible therefore that muscarinic receptors modulation of afferent activity is indirect via the release of a secondary mediator. Such a view is supported by the observation that bladder hypersensitivity, triggered by cholinergic stimulation was abolished by inhibition of P2X receptors, suggesting that muscarinic receptors and purinergic receptors may

Figure 29: Hypotheses for the pathways mediating the effects of botulinum toxin in afferents
work in tandem to modulate afferent transmission.(205) These studies highlight the complex nature of cholinergic signalling in the bladder, and indicate that more research is necessary to fully understand whether muscarinic receptors on the afferent limb could become a therapeutic target for OAB.

### 4.4. Botulinum Toxin

Botulinum toxin A (BoNT/A) was shown in an early paper to inhibit the release of ATP as well as acetylcholine from parasympathetic nerves innervating the bladder.(206) The effects of purified botulinum neurotoxin type A on cholinergic, adrenergic and non-adrenergic, atropine-resistant autonomic neuromuscular transmission was subsequently confirmed.(207) Botulinum toxin A (BoNT/A) inhibits the vesicular release of acetylcholine and ATP following uptake into presynaptic nerve terminals (see Figure 29) and proteolytic cleavage of the SNARE protein SNAP-25 that prevents docking and fusion of synaptic vesicles at the neuro-muscular junction. BoNT/A was first clinically used in the bladder to treat neurogenic bladder overactivity caused by spinal cord injury.(208) Since then, intravesical injections of BoNT/A has proved a highly effective treatment for patients with detrusor overactivity, with numerous studies reporting improvements in the sensory symptoms of urgency and urinary frequency.(209) (210, 211) Since acetylcholine can be released from the urothelium it is possible that BoNT/A is acting at this level to modulate sensory signalling. In addition, there is recent evidence that SNAP-25, the intracellular target for proteolysis by BoNT/A, is expressed in the urothelium.(106) This is consistent with experimental data showing that BoNT/A inhibits the release of ATP and augments NO release from the urothelium in animal models of spinal cord injury.(211) Others have shown that application of BoNT/A directly attenuated afferent firing in vivo mouse models.(212) Other potential targets for BoNT/A include the suburothelial sensory nerve endings, and in this respect a decrease in suburothelial immunity in response to a cooling stimulus (termed the ‘ice water test’) has been shown to improve symptoms in a model of experimental cystitis.(222) Further, there is evidence that a co-administration of antagonists to TRPM8 and TRPV1 has been shown to improve symptoms in a rodent model for bladder pain.(218, 219)

Interest in TRPV4 has been fuelled by the observation of impaired voiding behaviour in knockout mice.(220) This channel shows mechanosensitivity and is proposed to play a role in the micturition reflex by activating C-fibre afferents.(185) However, the site of action of TRPV4 agonists may in fact be the urothelium which expresses the TRPV4 channel,(86) particularly in association with adherence junctions where they may be preferentially activated by stretch and lead to the release of ATP.(221) Inhibition of TRPV4 has recently been shown to improve symptoms in a model of experimental cystitis.(222) Further, there is evidence that a co-administration of antagonists to both TRPV4 and TRPV1 can potentiate the effect of each drug and reduce bladder hyperactivity in a rodent model for cystitis.(223)

TRPM8 was first described as a cold receptor and interest in its role in the bladder stems from the observation that instillation of cold saline into the bladder elicits a contractile response (at pressures or volumes below the threshold for normal voiding). This response to a cooling stimulus (which has been referred to as the bladder cooling reflex) was originally thought to indicate a supraspinal neurological lesion and the test (termed the ‘ice water test’)(224) has been used in the diagnosis of bladder disorders such as detrusor overactivity. Expression of TRPM8 has been identified on bladder afferent fibers and on the cell bodies in the DRG where it co-localizes with nociceptive markers such as CGRP and IB4.(225) Previously Lashinger et al (2008) showed that application of a TRPM8 channel blocker, decreased voiding frequency and abdominal motor responses in the rat(226) suggesting that in addition to cold sensing TRPM8 may also be involved in the afferent control of micturition and nociception. A recent study by Ito et al. also showed that TRPM8 have a role in activation of mechanosensitive C-fiber bladder afferent
pathways during bladder by using single-unit afferent activity recordings in the normal rat.(227)

Until now the contribution of TRP receptors have been typically studied isolated. However it is possible that in real life conditions several of these receptors are activated together, opening the possibility to the advantage of antagonizing more than one at the same time if a therapeutic objective is pursued.(223)

4.6. Cannabinoids

The multi-centre CAMS study (Cannabinoids in Multiple Sclerosis) reported that the use of cannabis based extracts significantly improved symptoms of urge incontinence and detrusor overactivity in patients with multiple sclerosis. This observation has provoked interest in the study of expression and function of cannabinoid receptors in the bladder. Endogenous cannabinoids can potentially interact with TRPV1 but in addition can act on G-protein coupled cannabinoid receptors 1 and 2 (CB1, CB2). In the human bladder, both receptors could be identified in the urothelium and detrusor where CB1 receptors were more abundant than CB2.(228) In patients with bladder pain syndrome and idiopathic detrusor overactivity (IDO), a significant increase in nerve fibres expressing CB1 in the urothelium was observed, strongly suggesting a role for CB1 in overactive bladder.(229) In contrast, Gratzk and colleagues(230) found CB2 receptors predominated in the urothelium, suburothelium and on sensory nerve fibres and found that CB2 agonists inhibited nerve induced contractions of the bladder providing evidence that CB2 receptors are important in micturition.

Expression of CB1 receptors were also identified in the urothelium and on nerve fibres in the detrusor of mouse bladder.(231) These receptors co-localized with P2X3 receptors, suggesting an interaction between cannabinoid and purinergic systems. In addition, a synthetic cannabinoid active at both CB1 and CB2 receptor was shown to inhibit the evoked release of CGRP from afferent nerve terminals.(232) Cannabinoid receptor was shown to inhibit the evoked release with P2X3 receptors, suggesting an interaction between cannabinoid and purinergic systems. In addition, a synthetic cannabinoid active at both CB1 and CB2 receptor was shown to inhibit the evoked release of CGRP from afferent nerve terminals.(232) Functional experiments also found a reduction in distension evoked afferent firing in response to application of a CB1 agonist. In particular, high threshold afferents typically associated with noxious stimuli were directly affected. A recent study by Aizawa et al. using a peripherally restricted inhibitor (URB937) of the endocannabinoid-degrading enzyme fatty acid amide hydrolase (FAAH), upregulation of the peripheral endocannabinoid system reduces bladder overactivity and C-fiber hyperexcitability in the rat bladder provoked by PGE2, suggesting an important role of the peripheral endocannabinoid system in bladder overactive conditions induced by afferent hypersensitivity.(233) There is also evidence that the fatty acid amid anandamide, which activates both CB1 as well as TRPV1 receptors on primary afferents, is upregulated in a model for inflammatory pain and induces bladder hyperreflexia.(234) Taken together these studies suggest that CB receptors in the bladder may have a modulatory role in sensory afferent signalling and a greater understanding of which could lead to new therapeutic strategies for treatment of bladder disorders. Understanding the differential roles of CB1 and CB2 receptors may add a new dimension to our ability to target these pathways.

4.7. Adrenoreceptors

Alpha-1-adrenoceptor (α1-AR) antagonists are the current first line for treatment of lower urinary tract symptoms (LUTS) due to benign prostatic hyperplasia (BPH). A systemic review and meta-analysis showed that alpha blockers in general improve BOO as shown by a positive changes of bladder outlet obstruction index.(235) By inhibiting prostatic smooth muscle contraction, these agents reduce bladder outlet obstruction (BOO). In addition, recent data report an improvement in other symptoms, such as frequency suggesting that they may also act via the afferent system to influence storage function. Adrenoceptors have been detected throughout the urothelium and on the sensory neurones innervating the bladder.(236, 237) Bladder afferent responses to distension in vivo are inhibited following intravesical application of the clinical α1-AR antagonist Tamulosin. Moreover, chronic systemic treatment with two different α1-AR antagonists inhibited reflex voiding in a rat model of BOO.(238) A previous experimental study by Nagabukuro et al investigated changes in afferent firing following treatment with a number of commonly used clinical drugs. The study found that Tamulosin treatment significantly attenuated activation of the early gene c-fos in the spinal cord, used as a marker for sensory neuronal activation.(239) A recent study also showed that α1A- or α1D- adrenoceptors in the rat bladder are involved in the activation of the bladder mechanosensory Aδ-fibres during bladder filling by directly recording afferent activity arising from the

Figure 30: Representative photomicrographs of cholinergic fibers expressing both VACHT and b3AR-IR through the human bladder. Double labeling using immunocytochemistry revealed that virtually all neuronal profiles expressing the cholinergic marker VACHT also express b3AR-IR throughout the suburothelial plexus, muscular layer and around blood vessels. VACHT-IR (red), b3AR-IR (green) and the nuclear marker DAPI (blue); U-urothelium and SU-suburothelium. (from Coelho et al., 2015)
In addition, interactions between sympathetic efferent and primary afferents can occur via a chemical cross-talk that can enhance the sensitization of nociceptive afferents in both somatic and visceral pain conditions. In support is evidence that prolonged activation of peripheral alpha adrenoceptors can augment bladder pain likely through sensitization of TRP (TRPV1) channels on nociceptive afferents and increased release of algogenic substances such as ATP. The increased bladder pain and hyperactivity was blocked by silodosin, implicating a role for activation of peripheral alpha 1A adrenoceptors in visceral pain.

In contrast to the α-adrenoreceptors, the beta adrenoceptors (βARs) mediate relaxation of the bladder smooth muscle in response to sympathetically released noradrenaline. The β3-AR subtype is the predominant isoform responsible for relaxation of the human detrusor and β3-AR agonists are now clinically available for the treatment of OAB. A previous study by Kullmann et al demonstrated the presence of the β3-AR in the urothelium and observed inhibition of voiding contractions in response to the β3-AR agonists TAK-677 and BRL37344. This effect was independent of any changes in smooth muscle tone suggesting that β3-AR could also participate in bladder afferent function. A more recent study has shown that β3-AR is expressed in nerve fibers in both suburothelium as well as the detrusor layer in the human bladder (Figure 30). In terms of the neurochemical nature, while there was a modest expression of β3-AR in sensory fibers, the presence of β3-AR in cholinergic fibers were the most abundant. While a number of possibilities exist, these findings suggest that β3-AR may modulate contractility of the smooth muscle and indirectly regulate bladder sensory functions.

In patients with IBS often report bladder symptoms including nocturia, frequent and urgent micturition, and incomplete emptying. The counterpart is also true with patients with BPS complaining of gastrointestinal symptoms such as constipation. In experimental models inflammation of the colon has been shown to lead to increased frequency of bladder contractions and altered micturition reflexes. In contrast, experimental bladder inflammation has been reported to sensitize the bowel to distension. Such cross-organ sensitization has also been demonstrated between the uterus, pelvic urethra and vagina. In men there is the potential for cross-organ sensitization between the prostate and other pelvic organs.

The mechanisms underlying cross-organ sensitization have not been fully elucidated but there are possibilities.
tentially several levels at which the sensory innervation to the different pelvic structures can interact. In terms of periphery mechanisms there is evidence that afferent fibres branch extensively to innervate multiple target structures. Different retrograde tracer injected into the bladder and bowel results in a number of DRG neurones carrying both labels although the numbers are low (Figure 31A-C).(251) Similarly, dichotomizing afferents have been shown to innervate the colon and uterus with DRGs expressing TRPV1 and P2X3 receptors implying a role in nociception.(252) Sensitization of the endings in one organ by local inflammation, steroid hormone or via various neurotrophic factors would likely impact on overall sensitivity following upregulation in excitability in all terminal receptive fields.(253) A recent study also showed in rats that colonic inflammation induces up-regulation of urothelial NGF expression in the bladder and that the reduction of overexpressed NGF in the mucosa is associated with the significant improvement of bladder overactivity and pain behavior, suggesting that the local NGF upregulation plays an important role in cross sensitization in pelvic organs.(17) There is also evidence that visceral organ cross talk may be due to a change in epithelial permeability in one target organ (i.e. urinary bladder) that may in turn, alter epithelial permeability in another structure.(254) Studies have utilized contrast-enhanced magnetic resonance imaging (CE-MRI) to quantitate changes in epithelial permeability in both IC patients and in animal models for cross-sensitization.(Figure 32) (255, 256) Findings from these studies revealed that this method may provide a quantifiable method to assess epithelial permeability and could be used to study underlying mechanisms, stratify patients and monitor therapy.

Central sensitization may also contribute to cross-organ sensitization (Figure 31D). Excitability of spinal neurons receiving afferent input from the bladder has been shown to respond to afferent input from other pelvic structures such as the colon.(257, 258) Second order neurones in the spinal cord therefore receive convergent input from various visceral structures (i.e. viscero-visceral convergence) as well as somatic inputs (visceral-somatic convergence). The later explains the phenomenon of referred pain where sensations from the viscera are experienced in the associated somatic sensory field, the classic example being angina. Such viscero-somatic convergence has been extensively investigated and only recently has viscerovisceral referral received attention. Nevertheless convergent inputs would explain the poor localization of pelvic pain and the difficulty in diagnosis and treatment. There is also recent evidence that desensitization of TRPV1 receptors in the bladder reduces the excitability of bladder projecting neurons but has no effect on spinal cord neurones receiving convergent bladder/somatic input.(259) Taken together, these studies suggest that targeting additional levels of the pain-processing pathway (both centrally and in the periphery) may be required in order to provide better clinical outcomes for patients with chronic pelvic pain disorders.(260)

Clemens recently coined a term “afferent neurourology” to describe the study of sensory signaling related to the genitourinary tract, which encompasses other organs besides the bladder including the prostate, urethra, vagina, testicles and scrotum.(261) Therefore, disorders in afferent neurology would include other urologic symptoms perceived by the patients outside of the bladder including disorders, for example, such as chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS), pelvic pain syndrome, vaginal pain syndrome, and urethral pain syndrome. Clemens’ review suggests that many of these afferent urologic symptoms, including BPS/IC, may be due to systemic pathophysiology rather than localized to the organ of suspicion.

### III. EFFERENT PATHWAYS TO THE BLADDER

Three main neural pathways regulate lower urinary tract efferent activity: 1) sacral parasympathetic (pelvic) nerves provide excitatory input to the bladder; 2) thoracolumbar sympathetic nerves provide inhibitory input to the bladder and excitatory input to the bladder neck and urethra; and 3) sacral somatic (pudendal) nerves innervate the striated muscles of the sphincters and pelvic floor (262, 263) (Figure 33). This section will describe the spinal and then peripheral pathways controlling efferent drive to the bladder.

Parasympathetic and sympathetic pre-ganglionic neurons release acetylcholine, which acts on nicotinic receptors to activate post-ganglionic fibres. In some species they also release opioid peptide transmitters and express nitric oxide synthase(264); there is also evidence of involvement of pituitary adenylate cyclase activating peptide (PACAP), a peptide present in visceral afferent neurones, and of prostaglandins within the spinal cord.(265)
Parasympathetic post-ganglionic fibres terminate predominately at the detrusor muscle and release acetylcholine, resulting in detrusor contraction during voiding. Studies in animals have shown that sympathetic post-ganglionic fibres predominately terminate at the mucosal and urothelial level, releasing noradrenaline (NA), contributing to bladder relaxation during storage (via stimulation of beta-adrenergic receptors expressed in detrusor).

1. PREGANGLIONIC NEURONS

Parasympathetic preganglionic neurons are located in the lateral part of the sacral intermediolateral gray matter in a region termed the sacral parasympathetic nucleus. The neurons are small, fusiform-shaped cells which send dendrites into lateral lamina I of the dorsal horn, the lateral funiculus and medially into the dorsal grey commissure (DGC). The bladder pre-ganglionic motor neurons are located in the S1-S3 segments in the cat,266) dog(267) and monkey.(268) The rat is different, as preganglionic motor neurons are located at L6-S1;269, 270) unilateral ventral root rhizotomy at the L5 level in the rat decreases peak cystometric pressures.(271) The parasympathetic preganglionic neurones project through the ventral spinal roots to the major pelvic ganglion.(272, 273) At spinal levels L1–L2, both the intermediolateral horn and the DGC contain sympathetic preganglionic neurones whose axons also project to the major pelvic ganglion. Electrical stimulation of the lumbar sympathetic chain evokes firing in the pelvic nerve and in postganglionic nerves on the surface of the bladder and colon, at latencies of 60-150 ms.(274) With ageing, there is selective attrition of preganglionic sym-

Figure 33: Innervation of the lower urinary tract (LUT). The LUT is comprised of the bladder, urethral sphincter and urethra. The LUT receives the bulk of its innervation from three nerves. The hypogastric nerve carries sympathetic innervation to the LUT; contributing spinal nerves exit the spinal cord (SC) between L1 and L2. Muscle activity for storage is mediated by –AR expressed in the trigone, bladder neck and urethra (excitatory) and by –AR expressed in the bladder dome (inhibitory). The pelvic nerve contains parasympathetic input originating in the sacral cord and controls micturition via cholinergic muscarinic receptors (mAChR) expressed throughout the LUT. The human pudendal nerve exits the sacral SC and provides somatic innervation to the striated muscle of the external urethral sphincter. In addition to their efferent function, each of these nerves carries afferent input from the LUT. Abbreviations: AR, adrenergic receptors; DRG, dorsal root ganglion; EUS, external urinary sphincter; g, ganglion; IMG, inferior mesenteric ganglion; L, lumbar spinal cord; mAChR, muscarinic cholinergic receptors n, nerve; nAChR, nicotinic cholinergic receptors; NO, nitric oxide; P2X, purinergic receptor; S, sacral spinal cord; (+) denotes excitatory synapses; (-) denotes inhibitory synapses. (from Inskip et al., 2009)
pathetic neurones in L1–L2, which project to the pelvic ganglion, with reductions in the extent of the dendritic arbor of remaining cells. (272, 273, 275)

In spinal cord injured patients, where disruption to pathways at pre-ganglionic levels is observed, several groups have used neural stimulation techniques to restore normal bladder function. Stimulating parasympathetic pre-ganglionic roots at S3 with implanted electrodes elicits two principal responses(276): at low levels of stimulation, the external urethral sphincter, external anal sphincter and pelvic floor muscles are contracted. At high levels of stimulation, parasympathetic activation contracts the detrusor muscle, leading to efficient emptying of the bladder when the sphincter muscle relaxes(277)

The recent increase in the use of sacral neuromodulation for the treatment of detrusor overactivity has resulted in numerous potential theories of its actions, including stimulation of efferents, direct effect on the muscle, stimulation of the afferents, induction of spinal plasticity, and modifications of cortical activation.(278)

The DGC also contains a group of interneurones, which have recently received more attention as main players in the guarding reflex (these are further discussed below in Bladder and Outlet.(279)

2. GANGLIA

The peripheral ganglia are the link in the relay of autonomic innervation to the lower urinary tract and reproductive organs, along with a substantial part of the extrinsic motor innervation of the lower bowel. There are species differences in organization and neurochemistry of pelvic ganglion cells and their spinal inputs. Large mammals have a plexus of pelvic and intramural ganglia, containing both sympathetic and parasympathetic neurones. The guinea pig is intermediate in complexity, with separate posterior and anterior plexuses innervating different pelvic organs. In the rat and mouse, the pelvic plexus consists of the major pelvic ganglia (MPG) and a number of small accessory ganglia.

Within the pelvic plexus there is topographical representation of the pelvic organs. In the female dog, neurones supplying different pelvic organs are located in separate ganglia, which possess a distinctive composition of neurone types and different preganglionic supply.(280) Neurones retrogradely labelled from the urinary bladder mainly occur in ganglia located at the vesico-ureteric junction. They comprise catecholaminergic calbindin neurones and noncatecholaminergic neurones containing calbindin or NOS, with relatively sparse pericellular varicose nerve fibres. In male mice,(281) the major pelvic ganglia are close to the dorsal surface of the prostate gland. Their main inputs are the pelvic nerves, and the hypogastric nerve from the inferior mesenteric ganglion. The major outputs are the penile (cavernous) nerve and the supply to the urogenital organs.

Functionally, the preganglionic sympathetic and parasympathetic neurones synapse on post-ganglionic fibres within the specific ganglia, releasing acetylcholine, which acts on nicotinic receptors. Patients with megacystis-microcolon-intestinal-hypoperistalsis syndrome (MMHIS)(282) have reduced or no alpha-3 nicotinic receptor subunit.(283) Selective gene knockout mice lacking the alpha-3 nicotinic receptor subunit alone or the beta-2 and beta-4 subunits in combination,(284) develop severe bladder distension soon after birth, and later overflow incontinence. The detrusor muscle in these animals contracts in response to field stimulation or muscarinic agonists, but not nicotinic agonists.(285) indicating the potential importance of alpha-3, beta-2, and beta-4 nicotinic receptor components in functional control of voiding, but not their location.

About half of the cholinergic ganglion cells contain VIP, distributed throughout most of the ganglion, with a cluster near the origin of the penile nerve. Neurones with NPY are numerous and apparently randomly distributed throughout the ganglion, with marked variation between mouse strains. All noradrenergic neurones contain NPY, but many NPY neurones are not noradrenergic. Many of the cholinergic NPY neurones also contain VIP. Neurones immunostained for choline acetyl transferase (ChAT) have a complementary distribution to noradrenergic neurones. ChAT is seen in varicose axon terminals closely associated with ganglion neurones. Neither NPY nor VIP is present in pre-ganglionic terminals, except for a small number of individual neurones. The latter may arise from visceral fugal neurones in the myenteric plexus of the lower bowel.(286) Tyrosine hydroxylase (TH) is expressed by one-third of neurones, almost all co-expressing dopamine beta hydroxylase (DBH). Numerous TH axons are present in the hypogastric nerve, but very few in the pelvic nerve, supporting a primarily sympathetic origin. Non-neuronal cells containing TH are also present, resembling small, intensely fluorescent cells observed in many other autonomic ganglia.

Intramural Bladder Neurons and Pelvic Ganglia

The bladder wall itself contains intramural ganglia, and small clusters of autonomic ganglion cells are present in the adventitial connective tissue and among the detrusor muscle bundles. Intramural ganglia have been observed in the bladder of mammalian species, including humans.(287-291) There is species variation in the extent of intramural innervation of the bladder; ganglia are present in many species such as the cat and guinea pig, while the rat bladder contains the postsynaptic innervation alone.(292) The ganglia are found throughout the bladder wall and vary considerably in size.(293) Quinacrine, a fluorescent dye that selectively labels high levels of ATP bound to peptides in granular vesicles, positively stained a subpopulation of neurones in ganglia in the guinea-pig bladder (Figure 34 A). (294, 295) Subpopulations of neurones in bladder ganglia also show immunoreactivity to vasoactive intestinal polypeptide (VIP), nitric oxide synthase (NOS), neuropeptide Y.
(NPY), ChAT and galanin (Gal) in varying amounts (Figure 34B).(296) Thus, intramural ganglia, perhaps a subpopulation of largely parasympathetic postganglionic neurons probably release ATP. Postganglionic sympathetic nerves, identified with antibodies to TH and NPY, also synapse on these neurones. Nicotinic receptors have been identified on intramural nerve cell bodies within the bladder.(285)

Parasympathetic ganglia on the surface of the cat urinary bladder contain several types of principal ganglion cells (coexpressing various neuropeptides, ACh, NA, ATP and nitric oxide (NO) as well as small intensely fluorescent cells. They are innervated by both parasympathetic and sympathetic preganglionic axons. By using high-frequency field stimulation, it is possible to delineate the cholinergic-purinergic ganglion cells.(297, 298) These in turn provide an excitatory input to the detrusor smooth muscle.

Intramural ganglia,(274, 299, 300) and since ATP is released as a cotransmitter from sympathetic nerve terminals, sympathetic nerves may be a source of ATP in the bladder ganglion. However, the principal sympathetic modulatory mechanisms in the ganglia are mediated by NA acting on α-adrenoceptors.(301) The precise physiological roles of purinergic agents in bladder ganglia are not clear. Purinergic slow hyperpolarising potentials following stimulation of preganglionic nerves indicates that purinergic agents are released in ganglia during neural activity. Since ATP is present in bladder postganglionic neurons as well as in cholinergic and adrenergic nerve terminals, there are different possible sources of purinergic transmitter. Although adenosine has been proposed as the inhibitory transmitter,(302) it is possible that the extracellular breakdown of ATP to adenosine could be important in the mediation of the slow hyperpolarising responses. It is also important to note that preganglionic nerves contain both parasympathetic and sympathetic postganglionic axons, so various neural pathways could be involved in eliciting the slow hyperpolarising potential. Adenosine deaminase is present in sacral preganglionic neurons in the rat.(303) Therefore preganglionic pathways may be purinergic as well as cholinergic.

3. TERMINAL NERVE FIBERS

Smooth muscle cells in the bladder are grouped into fascicles, several of which make up a muscle bundle. They receive a dense innervation, which runs in line with the axis of the fascicle and is derived from coarse nerve trunks in the connective tissue around the fascicles and bundles. This innervation mediates the widespread co-ordinated detrusor contraction accompanying voiding. The anatomical relationship between the preterminal innervation and the muscle fascicles has been described in a serial sectioning study in the human bladder.(304) The nerve supply is distributed by a series of dichotomous branchings, illustrated schematically in Figure 35.(305) Adjacent to the muscle bundles, 1 or 2 primary nerve trunks run parallel to the long axis of the bundle. These give rise to circumferential peribundle branches. Both the longitudinal and circumferential trunks give off transverse interfascicular branches, entering the bundle perpendicular to its long axis, approximately at the midpoint of the bundle. Within the bundle they give axial interfascicular branches running along the long axis within and closely adjacent to individual fascicles, ending in the preterminal and terminal varicose intrafascicular axial innervation.

The majority of nerves running in the detrusor stains positively for acetylcholinesterase and for vesicular acetylcholine transferase (VACHT)(293, 305, 306) and are thought to be parasympathetic. Electrical field stimulation studies have been used to elucidate the neurotransmitter content from muscle strips (with or without mucosa). Acetylcholine and ATP appear to provide the bulk of the excitatory input, since electrical field stimulation responses are blocked by muscarinic receptor antagonists combined with purinergic antagonists. Both transmitters are released in the innervated muscle layer and persist after removal of urothelium. By using high-frequency field stimulation, it is possible to delineate the cholinergic and purinergic component.(207) Apart from acetylcholine and ATP, there are additional substances present in parasympathetic efferents (VIP, NOS, Gal), which allow

Figure 34: (a) Fluorescent histochemical localization of quinacrine in whole-mount stretch preparation of adult rabbit urinary bladder showing a ganglion cell containing at least 6 fluorescent nerve cells. The nuclei (arrow) are non-fluorescent. Calibration bars = 50 μm. (Crowe and Burnstock, 1985.)

(b) Double staining to show colocalization (yellow/orange) of P2X3 receptor immunoreactivity (red) with NOS in intramural ganglia of the cat urinary bladder. (from Ruan et al., 2006)
immunohistochemical subclassification of nerve fibres, and raise the question as to whether additional transmitters (other than ACH/ATP) have a role in normal micturition function or disease pathophysiology.

Cholinergic nerves are also present in the suburothelium. Although sparse in rodents in human bladder they form a dense plexus in the suburothelium. These cholinergic fibers are not sensory in nature and they do not stain for CGRP. (244) The final target for the ACh presumably released from these nerve endings is not known but in the humans a relatively well organized muscularis mucosae exists and muscarinic receptors M2 and M3 have been identified. (143) In addition, the suburothelium contains terminal nerve fibers that contain NPY and TH and some contain NOS. In the muscle of the trigone, the most common axons contain both VIP and NPY, with noradrenergic axons forming only a sparse supply. Indeed, noradrenergic neurons are rare in the detrusor and absent in mucosa. (281)

### 4. TRANSMITTERS

#### 4.1. Glutamate

Glutamate is present in the terminals of primary afferent neurons in the spinal cord along with interneurons and fibres originating in the medulla oblongata. In general, glutamatergic neurons tend to be excitatory, contrasting with generally inhibitory effects of glycinergic neurons; however, excitatory/ inhibitory effects of transmitters can be reversed by the nature of the post-synaptic neuron. Thus, glutamatergic neurons can indirectly have an inhibitory effect if an inhibitory neuron is interposed before the ultimate target. (307) Glutamate acts on spinal neurons through a variety of receptor subtypes. These include NMDA receptors, which are important in controlling polysynaptic reflex pathways at the lumbosacral levels. The NMDAR1 glutamatergic receptor sub-unit is present in the spinal cord of male rats, and is expressed in the SPN. Glutamate is present in the dorsal root ganglion cells supplying the bladder, (308) and the NMDAR1 sub-unit is also present in L6 dorsal root ganglion cells of the rat. (309) In female rats intrathecal injection of an NMDA receptor antagonist decreases bladder contraction pressure. (310) With ageing, there is a decrease in the density of glutamatergic synaptic inputs, which may influence urinary tract function. (311)

#### 4.2. Glycine/ gamma amine butyric acid

Glycinergic and GABAergic interneurones have a major role in neural control processes mediating bladder function. (312) Glycinergic/ GABAergic projections to the lumbosacral cord inhibit the micturition reflex and also inhibit glutamatergic neurons. (313) Rectal distention prolongs the interval, decreases the amplitude and shortens the duration of bladder contractions in rats; this effect is not seen after simultaneous intrathecal injection of low dose strychnine (a selective glycine-receptor antagonist) and bicuculline (GABA-A receptor antagonist), suggesting that the inhibitory rectovesical reflex involves glycinergic and GABAergic mechanisms in the lumbosacral spinal cord, which may be synergistic. (314)

Indeed, in the spinal cord, several transmitters synergetically mediate the effects of modulatory pathways that influence the onward progression of efferent activity. In a rat model of neurogenic bladder dysfunction (autoimmune encephalomyelitis), an exaggerated descending excitatory control arises at the spinal segmental level, which gives rise to detrusor overactivity. Some animals with autoimmune encephalomyelitis develop detrusor areflexia rather than overactivity; (278) in these animals, the excitatory control is probably dominated by segmental inhibition, mediated primarily by glycine receptor activation. A change in the ratio of excitation and inhibition was also observed in humans suffering from spasticity.

and pain.\(^{315}\) This balance of inputs, and the potential plasticity of neuronal circuits, is crucial in understanding pathophysiological processes.

4.3. Serotonin

Spinal reflex circuits involved in voiding function have a dense serotonergic innervation.\(^{316}\) Immunocytochemical studies in rats, cats and primates show that lumbo-sacral sympathetic and parasymphathetic autonomic nuclei receive serotonergic inputs from the raphe nuclei.\(^{317, 318}\) Activation of the central serotonergic system can suppress voiding by inhibiting the parasymphathetic excitatory input to the urinary bladder, and 5-HT elicits a prolonged activation of thoracic sympathetic preganglionic neurons. Stimulation of the raphe nuclei in the cat inhibits reflex bladder activity.\(^{319, 320}\) 5-HT\(_{1A}\) and 5-HT\(_{2A}\) receptors are present in the SPN. However, in different species serotonin (5-hydroxy tryptamine, 5-HT) may have varying functions in the central nervous control of bladder activity. For example, activation of 5-HT\(_{1A}\) receptors facilitates reflex bladder activity in rats,\(^{316, 321}\) and has been used to reverse the effects of diabetes mellitus.\(^{322}\)

Inhibitory effects on bladder activity are most likely mediated primarily by 5-HT\(_{1A}\) receptors. The transmitter released by inhibitory interneurons has not been identified. Activation of 5-HT\(_{1A}\) and 5-HT\(_{2A}\) receptors also results in inhibition of afferent input passing from the bladder to the brain. Blockade of 5-HT\(_{1A}\) receptors in raphe neurons would increase raphe neuron firing and enhance serotonergic control of spinal reflex mechanisms. This effect would promote urine storage by enhancing sphincter activity and depressing bladder activity.\(^{323}\)

4.4. Adrenergic

Descending catecholaminergic neurones are primarily located in the upper medulla or pons.\(^{324}\) (In clinical use, non-selective \(\alpha\)-adrenergic antagonists influence urine flow and storage phase lower urinary tract symptoms; the two effects probably occur by different mechanisms, and central or peripheral locations may be responsible.\(^{325}\) Reflex bladder activity is modulated by at least two spinal \(\alpha\)-adrenergic mechanisms. Firstly, there is inhibitory control of reflex bladder contractions, probably by modulation of afferent processing. Secondly, there is excitatory modulation of the amplitude of bladder contractions due to regulation of the descending glutamatergic limb of the spinobulbospinal bladder reflex pathway.\(^{326, 327}\) \(\alpha\)\(_{1A}\) adrenoceptors comprise 70% and \(\alpha\)\(_{1B}\)-adrenoceptors 30% of the \(\alpha\)-adrenergic receptors in the rat lumbar spinal cord,\(^{328}\) while \(\alpha\)\(_{1D}\) adrenoceptors do not appear to have a significant role.

Blood pressure, vascular resistance and tissue blood flow are also regulated by \(\alpha\)-adrenergic receptors. Aging is thought to impact pelvic blood flow and thus, bladder function. Pharmacological blockade of the vascular \(\alpha\)\(_{1B}\)-adrenoceptor may increase pelvic blood flow and contribute to an improvement in bladder dysfunctions associated with aging and/or hypertension.\(^{329}\) \(\beta\)\(_{3}\)-adrenoceptors, although well documented peripherally, are also present in the rat sacral spinal cord. They are upregulated in rat models of partial urethral obstruction.

4.5. Substance P

Substance P-containing terminals are closely opposed to both sympathetic and parasymphathetic preganglionic neurons projecting to the major pelvic ganglion.\(^{330}\) Substance P containing afferents in the pelvic nerve terminate in the outer laminae of the dorsal horn and in the region of the SPN and DGC.\(^{331}\) Substance P is also located in intraspinal neurons located in the dorsal horn\(^{332}\) or DGC.\(^{333}\) In young adult rats, substance P in the ventral horn is almost exclusively co-localized with serotonin and derived from descending axons of medullary neurons\(^{334}\) and is also often co-localized with serotonin in axon terminals in the lumbo-sacral spinal cord.\(^{335}\) Functionally, substance P affects micturition reflex activity;\(^{336}\) intrathecal administration of Substance P at spinal levels L5–S1 induces bladder contraction.\(^{337}\) Studies in the rat show that substance P levels decline with ageing in both the dorsal and ventral regions of the lumbo-sacral cord.\(^{338}\) Substance P-immunoreactive innervation of the dorsolateral nucleus (supplying the EUS) is not obviously altered with ageing.\(^{339}\)

4.6. Purinergic

ATP and Neuromodulation in the bladder

ATP is released as a cotransmitter from sympathetic, parasymptathetic, sensory and motor nerve terminals, at synapses in autonomic ganglia and in the central nervous system (CNS). It is broken down by ectonucleotidases to adenosine that then acts on prejuncttional P1 receptors to modulate the release of neurotransmitters.\(^{340-349}\) P1 (A1) receptors are expressed on the nerve terminals on the bladder, while postjunctional smooth muscle receptors are of the A2 subtype.\(^{345, 350}\) Where the junctional cleft is narrow, ATP itself acts on prejunctional P2 receptors to modulate transmitter release.\(^{351-354}\)

Identification of purinergic receptor subtypes mediating contraction and relaxation of bladder

Although ATP undispputedly contracts the urinary bladder of most species\(^{355-357}\) it can also cause relaxation, indicating that there are multiple purinergic receptors present in the bladder. Investigations of the excitatory actions of purine and pyrimidine nucleotides on the guena-pig bladder revealed the following order of potency: \(\beta\)\(_{1}\)-meATP > ATP > GTP \(\approx\) CTP > ADP, while adenosine, AMP, GDP, GMP, guanosine, CDP, CMP and cytidine had no contractile activity up to \(10^{-3}\) mol/l.\(^{358}\) The response to ATP was biphasic in the rabbit urinary bladder, suggesting that more than one type of excitatory receptor to ATP was pre-
sent.(359, 360) Contractile responses of the rat bladder induced by ATP and α,β-meATP, a selective agonist to P2X1 and P2X3 receptors, were fast and transient, reaching a maximum in about 20s; in contrast, contractions in response to adenosine 5’-O-2-thiodiphosphate and uridine 5’-triphosphate (UTP), which activates P2Y receptors, were slower and sustained and were barely affected by α,β-meATP desensitisation.(361)

Immunohistochemical studies showed that P2X1 receptors are the dominant subtype in the membranes of the smooth muscle cells in the rat detrusor and also vascular smooth muscle in blood vessels in the bladder.(362) In another immunohistochemical study of the rat bladder, clusters of P2X1 receptors were described on smooth muscle cells, some, but not all, of which were closely related to nerve varicosities.(363) It has been claimed that there is an interaction of P2X2 and nicotinic ACh receptors in smooth muscle cells from the base, but not the dome, of rat urinary bladder.(364) ATP, as well as adenosine, reduced pelvic nerve-evoked bladder contractions; however, since methylxanthines did not fully antagonise the responses, this suggested that P2Y receptors might also be involved in purine inhibition.(365) These P2Y receptors are located on nerve terminals in the bladder providing prejunctional inhibition of release of excitatory neurotransmitters and both Reactive blue 2 and Coomassie brilliant blue G antagonise the inhibitory actions of ATP on nerve-mediated contractions.(359) Bladder contractions are mediated predominantly via P2X1 receptors, while P2Y2, P2Y4, P2Y6, and A2b receptors mediate relaxation.(366) ATP is released together with noradrenaline and neuropeptide Y from sympathetic nerves. It is also released as a co-transmitter with acetylcholine from parasympathetic nerves supplying the bladder. Cotransmission likely offers subtle, local variations in neurotransmission and neuromodulation mechanisms.(367)

4.7. Parasympathetic Co-transmission

In normal conditions, the human detrusor contraction is totally cholinergic.(368) NANC contractions can be seen in human bladders with IDO.(369) Atropine-resistant responses of the urinary bladder to stimulation of parasympathetic nerves have been recognised for many years.(370-373) They were later shown to be due to non-cholinergic, non-adrenergic transmission.(374-376) In 1972 evidence was presented to support the view that the atropine-resistant component in guinea-pig bladder was purinergic, i.e. due to adenosine 5’-triphosphate (ATP) released as a co-transmitter with acetylcholine (ACH) from the purinergic nerves supplying the bladder.(377) Supporting evidence included: mimicry by ATP of the non-adrenergic, non-cholinergic (NANC) nerve-mediated excitatory responses (Figure 36a); block by quinidine of contractions both to NANC nerve stimulation and to exogenous application of ATP, but not to ACh; and depression during tachyphylaxis of NANC responses produced by high concentrations of ATP. Evidence for ATP release from NANC nerves came in later papers (Figure 36b).(378) There has been unequivocal support for this hypothesis(373) in guinea-pig bladder,(295, 379-382) but also in mouse,(383, 384) pig,(385) hamster,(386) marmoset and ferret,(387) dog,(388) monkey,(389) cat,(390) shrew,(391) sheep,(389, 392) rat,(393-397) rabbit(210, 398-402) and human.(403-407) Prejunctional inhibition of both cholinergic and purinergic components of the nerve-mediated responses of the rat bladder by adenosine was taken as supporting evidence for cotransmission.(408, 409)

After the early proposal that ATP contributed to the contractile responses of the urinary bladder to parasympathetic nerve stimulation,(377) much debate followed. A paper entitled 'Evidence against purinergic motor transmission in guinea-pig bladder' was published by Ambache (410) based mainly on the relative insensitivity of the bladder to ATP and the inability of ATP to match precisely the atropine-resistant neurogenic responses. Nevertheless, several other laboratories confirmed and extended the evidence in favour of purinergic transmission. Desensitisation with ATP selectively depressed responses to ATP and to field stimulation (particularly at low frequencies), but not those in response to carbachol.(398) Quinacrine, a fluorescent dye known to bind to high levels of ATP in granular vesicles, produced positive staining in neurons and nerve fibres in the bladder.(378) Release of ATP during stimulation of NANC excitatory nerves was demonstrated using the firefly luciferin-luciferase assay method,(295, 378) also 6-hydroxydopamine-induced sympathctomy did not affect the release of ATP in response to intramural nerve stimulation. One hundred-fold lower concentrations of the slowly degradable analogue β,γ-methylene ATP (β,γ-meATP), compared to ATP, were shown to mimic contractions of the atropine-resistant responses of the rat bladder. This suggested that the relative insensitivity of the bladder to ATP may be due to its rapid degradation to adenosine 5’-monophosphate (AMP) and adenosine, which cause relaxation of the bladder.(393)

Evidence for purinergic and cholinergic components of parasympathetic nerve stimulation of the bladder in an in vivo preparation of urethane-anaesthetised guinea-pigs was presented.(411) Ganglion stimulants, nicotine and dimethyl-phenylpiperezinium, increased intravesicular pressure in anaesthetised cats by an atropine-resistant mechanism that was mimicked by ATP.(412) In vivo responses of the cat bladder to pelvic nerve stimulation suggested that purinergic transmission plays a role in the initiation of bladder contraction and perhaps in the initiation of urine flow, while cholinergic transmission is involved in maintenance of contractile activity and flow.(413) The purinergic component of parasympathetic cotransmission mediated Ca2+/calmodulin activation of myosin light chain kinase in smooth muscle, while the muscarinic receptors provide supporting sustained responses.(384)
The limited information about parasympathetic co-
transmission may be due to the fact that it is easier to
eliminate surgically or chemically postganglionic sym-
pathetic nerves, where cotransmission in sympathetic
nerves by noradrenaline and ATP is well established,
than it is to disrupt surgically or chemically postgan-
glionic parasympathetic nerves. The first hint that
ATP and ACh might be cotransmitters in parasympa-
thetic nerves supplying the bladder came from an ul-
trastructural study of vesicles.\(^{(414)}\) Indirect evidence
for purinergic cotransmission came from studies of
botulinum neurotoxin (BTX) type A and neuromuscu-
lar transmission in the guinea-pig bladder where both
cholinergic and purinergic components of the excita-
tory responses to nerve stimulation were significantly
reduced by BTX.\(^{(206)}\) A spectrum of nerves exists,
utilizing different proportions of ATP and ACh, from
predominantly ATP in cat and guinea pig through to
roughly 50:50 in rat and dog to predominantly ACh in
healthy human bladder.

The M\(_3\) muscarinic receptor appears to be the sub-
type responsible for excitatory cholinergic transmis-
sion in the bladder, although M\(_2\) receptors are also
involved in some species.\(^{(415)}\) In M\(_3\) knockout (KO)
mice functional impairments were milder than those elicited by active blockade of muscarinic receptors in
wild type mice.\(^{(416)}\) This suggested that non-cholin-
ergic (purinergic) transmission may compensate for
the chronic loss of M\(_3\) receptors.\(^{(416)}\) In an in vitro
preparation of whole rabbit bladder, exogenous ATP
and electrical field stimulation in the presence of atro-
pine produced a transient rapid rise in intravesical
pressure.\(^{(417)}\) Studies of whole rabbit bladders led to
the conclusion that neurally released ATP is im-
portant in the initiation of micturition, but ACh is nec-
essary for bladder emptying.\(^{(400, 418)}\)

**4.8. Sympathetic Co-transmission**

The sympathetic innervation of the bladder originates
in the thoracolumbar spinal cord and reaches the

---

*Figure 36: (a) Contractile responses of the guinea-pig bladder strip to intramural nerve stimulation (NS; 2 Hz,
0.2 ms pulse duration, supramaximal voltage for 20 s) and ATP (8.5 μM). Atropine (1.4 μM) and guanethidine
(3.4 μM) were present throughout. (b) Effect of changing the Ca\(^{2+}\) concentration on the release of ATP from
the guinea-pig isolated bladder strip during stimulation of intramural nerves. Upper trace: mechanical record-
ing of changes in tension (g) during intramural nerve stimulation (NS: 2 Hz, 0.2 ms pulse duration, supramax-
imal voltage for 20 s). Lower trace: concentration of ATP in consecutive 20-s fractions of the superfusate.
The Ca\(^{2+}\) concentration in the superfusate varied as follows: i = 2.5 mM (normal Krebs); ii = 0.5 mM; iii = 0.25
mM; iv = 2.5 mM. The successive contractions were separated by 60-min intervals as indicated by the breaks
in the mechanical trace. Atropine (1.4 μM) and guanethidine (3.4 μM) were present throughout. The tempera-
ture of the superfusate was between 22°C and 23°C. (from Burnstock et al., 1978).*
bladder via the hypogastric nerves and the sympathetic chain. The sympathetic system provides inhibitory control over activity of the detrusor muscle and excitatory input to the trigone and urethra. Sympathetic innervation of the detrusor has been reported to be sparse, although the trigone region is relatively densely innervated by sympathetic nerves. (419, 420) Sympathetic nerve fibres supply the bladder largely in the hypogastric nerve. Stimulation of the hypogastric nerve has been reported to cause an increase or decrease in pressure in the urinary bladder, but always excites the urethra. (297, 421, 422) Inhibitory sympathetic transmission in the detrusor is important during the filling phase of the voiding cycle. (423, 424) The transmitters released from sympathetic nerves act directly on smooth muscle, but they may also act prejunctionally on parasympathetic nerve terminals to inhibit both cholinergic and purinergic excitation, involved in the voiding phase of the micturition cycle.

ATP is well established as a cotransmitter with noradrenaline (NA) in sympathetic nerves. (349, 425) Although purinergic transmission predominately originates from postganglionic parasympathetic or intramural nerves, in the cat at least, ATP is also released from the hypogastric nerve, which is predominantly sympathetic, although it may also contain parasympathetic elements. (426) When the cat hypogastric nerve is stimulated it causes the bladder to contract. The contraction was reduced by ANAPP3, (427, 428) implying that ATP is being released. In addition, 6-hydroxydopamine, which destroys sympathetic nerves, prevents this contractile response, indicating that the ATP is released from sympathetic nerves. (427) Guanethidine, in a dose that blocked the bladder relaxation induced by hypogastric nerve stimulation and mediated by NA acting on β-adrenergic receptors, (429) did not affect hypogastric nerve-mediated excitation. However, in guanethidine-treated animals, ANAPP3 blocked the excitation. These findings suggest that ATP is released from the hypogastric nerve.

One of the basic features of sympathetic neuromuscular cotransmission appears to be that the cotransmitters released act synergistically. (430, 431) However, there do not appear to be any reports of synergistic cotransmission in the urinary bladder involving either parasympathetic or sympathetic nerves. ATP is likely to be a cotransmitter with NA in perivascular sympathetic nerves supplying blood vessels in the bladder. (350) Experiments using a whole rabbit bladder preparation, showed that pre-treatment with isoprenaline, a β-adrenergic agonist, significantly inhibited contractions to ACh or ATP. (432) Thus in pathological conditions such as bladder-urethral dysynergia, involving simultaneous firing of sympathetic and parasympathetic nerves, both cholinergic and purinergic bladder contractions could be suppressed while the urethra was contracted.

5. PELVIC ORGAN INTERACTIONS AT THE EFFERENT NEURAL LEVEL

5.1. Bladder and Outlet

Neural coordination of physiological and behavioral functions depends on convergence within the nervous system of information from relevant areas. There is extensive convergence of pelvic organ input (433, 434) at the levels of the spinal cord, dorsal column nuclei, solitary nuclei, medullary reticular formation, and thalamus. (435) The fundamental role of spinal and supraspinal mechanisms in maintaining normal lower urinary tract synergy, between the bladder and sphincter, is well recognized.

In this context, the role of spinal interneurons must be considered. Involuntary bladder emptying during urine storage is considered to involve somatic nerve activity originating from cells in the lateral ventral horn, in a region called Onuf’s nucleus. Normally, cholinergic sphincter moto-neurons project to the urethral striated muscle/rhabdosphincter via the pudendal nerve, resulting in its contraction. This contraction can be activated by bladder afferent activity conveyed through pelvic nerves, and is considered to be organized by interneuronal circuitry in the spinal cord. It is thought to come into play in response to sudden increases in bladder pressure – for example, during a cough, sneeze, laugh. With aging, there is a loss of innervation at the terminal muscle level, which is displayed as a loss of striated muscle fibres in the sphincter and thus, a loss of urethral closing pressure. (436)
Synergic lower urinary tract function may also be a feature of the peripheral innervation, independent of CNS co-ordination. In the female minipig, pre-ganglionic pelvic nerve stimulation evokes a pressure increase in the bladder and a pressure decrease in the urethra.(437) It remains to be determined whether this observation suggests pre-determined, separate inputs to the bladder (excitatory to the bladder, inhibitory to the outlet), or whether the divergence occurs at postganglionic motorneuron level, which send branches supplying both bladder and urethra. In the latter arrangement, release of different neuromuscular transmitters from branches of the same motorneuron, or interposition of an additional intermediary cell would be required. The former is circumstantially supported by the observed co-localization of acetylcholine- and nitric oxide-related enzymes.(438)

5.2. Bladder and Bowel

Clinicians are familiar with the detrimental effect of bowel disorders on lower urinary tract activity. Physiologically, the efferent limb of the micturition reflex is inhibited by afferent input from the rectum;(439) thus, rectal distention inhibits bladder activity via glycinergic and GABAergic mechanisms in rats. Dual labeling studies show that many neurones in Barrington's nucleus supply both colon and bladder, with smaller populations supplying the two organs separately (Figure 37) – with dorsal neurons being bladder-related and ventral neurons being colon-related.(440) At the level of the major pelvic ganglion, double-labeled cells are relatively infrequent, but processes of colonic-retrograde-labeled cells often surround cell bodies of equivalent cells for the bladder. Dual-labeled cells in the spinal cord are rare.

5.3. Bladder and Prostate/Uterus

Voiding dysfunction is commonly associated with symptoms of chronic prostatitis/chronic pelvic pain syndrome, suggesting a prostate-bladder neural re-

Figure 37: A, Fluorescent micrographs of sections at the level of (A1) the major pelvic ganglion, (A2, B1, B2 and C1) the lumbosacral spinal cord and (C2) Barrington’s nucleus of rats injected with PRV-Beta-GAL in the bladder and PRV-GFP in the colon and having different survival times. The visceras, tracer and survival time are indicated in each photomicrograph. BD, bladder. CO, colon. A1. Separate labeling from both viruses is apparent in the MPG at 48 hours. A2. In the same case, only occasional cells are labeled in the spinal cord. B1. Substantial labeling from both organs is visible in the preganglionic parasympathetic column of the spinal cord and most cells are singly labeled from either the colon or the bladder. The arrow points to a rare double-labelled neuron. B2. Bladder- and colon-related neurons in close proximity. Processes from the colon-related neuron (arrow heads) are apposed to the bladder-related neuron. C1. Increasing survival time results in greater number of double-labelled cells (arrows). In most double labeled cells PRV-Beta-GAL label from the bladder is surrounded by PRV-GFP label from the colon. C2. Section from Barrington’s nucleus from the same case as C1 indicating that only a few cells are transsynaptically labeled from the bladder and none from the colon at the survival time. Arrow heads point to the surface of the fourth ventricle and stars indicate the location of trigeminal mesencephalic neurons. Calibration bars: 50 µm A1 and A2, 30 µm B2 and C1, 50 µm B2, 50 µm C2. From Rouzade-Dominguez et al., 2003.
the prostate is suggestive of a higher centre efferent coordination.

Neurons labeled from the prostate are found mainly in L1-L2 whereas neurons labeled from the bladder are found mainly in L6-S1. Double-labeled neurons are located in L1-L2 mainly in the dorsal gray commissure. However, the number of bladder neurons are much greater than that of prostate, and both neurons increase significantly at longer incubation times.(443) At the brainstem level, double-labeled neurons are more common (Figure 38).

Inflammation of the uterine horn or colon gives rise to inflammation in the bladder, an effect that can be eliminated by sectioning the hypogastric nerve.(444) Similarly, inflammation of the bladder causes heightened sensitivity of uterine cannabinoid receptors, likely inhibiting its adrenergic input.(445) Bladder overactivity induced by inflammation is influenced by estradiol, probably mediated through effects on the sympathetic nervous control of the bladder.(446) There are several potential mechanisms by which neural input could contribute to emergence of inflammation in neighboring organs (Figure 39);

1. A dorsal root reflex; hypogastric afferents from the inflamed organ could, via a spinal interneuron, sensitize and antidromically activate other hypogastric afferents from a non-inflamed organ.(447)

2. Axon reflexes occurring in hypogastric sensory nerves that branch to supply more than one pelvic organ. Though such branching has not yet been specifically identified, a small proportion of single afferent fibres may branch to supply the colon and bladder.(447)
3. Input from the inflamed organ (via the hypogastric nerve) activates neurons in the dorsal horn that activate postganglionic neurons in the pelvic ganglion via thoracolumbar preganglionic neurons. (448)

4. A spinal mechanism could be mediated by intraspinal connections to lumbar sacral preganglionic neurons (as seen for gynaecological organs). (449, 450)

5. A suprasacral mechanism could be mediated through the brain stem. (449, 450)

6. EFFERENT INHIBITION

The sympathetic pathway contributes to inhibition of parasympathetic efferent input to the detrusor smooth muscle. In isolated whole bladders, there is a high level of spontaneous contractile activity. (220, 451, 452) suggesting active neural inhibition of the bladder during urine storage. In a novel perfused decerebrate preparation of the whole rat, ganglion blockade using hexamethonium also leads to an increase in spontaneous activity. (453) Rat brainstem/spinal cord/bladder preparations or neonatal spinal cord/bladder preparations show tonic inhibition, arising at L6-S1 and involving a peripheral ganglionic synapse. (453, 454) Clearly, efferent inhibition of the bladder facilitates urine storage.

In the neonatal rat, considerable activity arises in the bladder wall when inputs from the lumbar sacral spinal cord are disrupted. (455) Selective spinal cord and root lesions indicate that intrinsic bladder activity of the neonatal rat is tonically inhibited by parasympathetic efferent outflow. This path is additional to the predominant cholinergic preganglionic efferents mediating the main voiding reflexes. The functional difference in the two sets of cholinergic ventral root efferents may result from differing synaptic targets, since both are blocked by the nicotinic antagonist hexamethonium. Thus, inhibitory efferents must synapse with noncholinergic inhibitory neurons in the major pelvic ganglia, in contrast to excitatory efferents synapsing with the cholinergic detrusor innervation.

In addition to efferent input, local reflexes may contribute to the inhibition of detrusor activity, probably driven by interstitial cells, (456) so that peripheral autonomous activity increases as a result of bladder distension. (457) This has been proposed to signify the presence of a regional regulatory influence (458) and a peripheral “pacemaker” (49) and various mechanisms for the propagation of activity within the bladder wall.

7. PERIPHERAL EXCITATORY MECHANISMS

Agonist exposure appears to elicit contraction by two different mechanisms, comprising a component derived from direct stimulation of the muscle cell (“classical” efferent), and a separate component that is more phasic, responsible for the obvious pressure fluctuations. The latter ‘intrinsic’ mechanism may involve an intermediary cell type. (459) Optical imaging and calcium-/ voltage-sensitive dyes in whole rat bladder preparations have detected electrical activity moving in a coordinated manner from localized regions over the entire bladder. (460) The isolated whole bladder shows regionalized responses when exposed to cholinergic/ muscarinic agonists. (461, 462) Dynamic migrating localities of contraction and relaxation.
elengation, give rise to a complex mix of micromotion phenomena, including micro contractions, micro stretches and propagating waves.

Several species show differences in contractile activity according to the region of the bladder from which a muscle strip is taken. Different effects are seen according to stage of development: spontaneous activity is high in bladder strips from neonatal rats, but small or almost non-existent in adults and reemerges in older bladders.(463) The likely functional significance of peripheral excitatory mechanisms is exemplified by the rodent neonate voiding reflex, which is induced by parental stimulation of the perineum, prior to establishment of mature control by the higher micturition centres.(464) The physiological role of such activity in the older adult is not known, but could include: 1. Optimization of the bladder wall configuration for volume contained, to ensure efficient voiding regardless of volume,(465) 2. Stimulation of ‘in series’ receptors for signaling bladder volume,(466) 3. A mechanistic component of accommodation during filling, a counterintuitive suggestion supported by the observation that accommodation in the colon involves synchronous contraction and relaxation,(467) 4. Maintaining the voiding contraction until complete evacuation is achieved.(468)

7.1. Perinatal development and ageing of efferent nerve signalling in urinary bladder

The main pathway in nerve activation of the urinary bladder of newborn mice is cholinergic with a relatively low contribution of the purinergic component, compared to adult bladder, which is equally dependent on cholinergic and purinergic activation.(469) At foetal day 26, large numbers of ganglia (25-38), each containing 30-40 quinacrine-positive neurons, were seen in the detrusor wall, while only 5-12 ganglia contained 3-12 acetylcholinesterase-positive nerve cell bodies at the same foetal age.(470) Neurogenic contractions of bladders from newborn rats were atropine-sensitive. During the first 2 weeks, the atropine-resistant component of these contractions increased progressively to reach adult-like conditions.(471) Responses to adenosine (inhibitory) and ATP (excitatory) mediated by P1 and P2X receptors, respectively, were present as early as postnatal day 2.(472) Adenosine was more potent in the neonate than in the adult, while the potency of ATP increased with age, peaking between postnatal days 10 and 25, but then declined. Expression of P2X1 receptor transcripts was much lower in foetal human bladder than in adult bladder, while P2X4 and P2X7 receptors were also present in the foetus.(473) The P2 receptor expression shifted from the dome to the body of the bladder with increasing gestation.

There are few reports describing changes in purinergic signalling in the ageing bladder. A comparison of contractions in detrusor muscle strips from unobstructed bladders of young and aged rats showed that, with age, there is an increased sensitivity to ATP as well as NA, but with no change in response to ACh and KCl.(474) There is a reduction in acetylcholinesterase-positive nerve fibres in the human bladder with increasing age,(291) and decreased fluorescence intensity for catecholamines in neurons in the hypogastric ganglion, which supplies sympathetic fibres to the bladder. Ageing impairs neurogenic contractions mediated by ATP, but less so ACh, in guinea-pig urinary bladder.(475) ATP released as a cotransmitter from parasympathetic nerves of rat bladder produces increased contractile responses with age.(476) The purinergic component of nerve-mediated contractions of the human bladder was also increased with age, largely due to increased release of ATP,(477) and the sensitivity of the bladder to α,β-meATP increased with age.(478) Purinergic transmission increases with age in the human bladder, but cholinergic transmission decreases. This appears to be due to increased release of ATP and decrease in ACh release.(477) The authors suggest that purinergic receptor antagonists may provide a useful addition to muscarinic receptor antagonists for the treatment of older patients with overactive bladder. Down-regulation of P2X1 mRNA expression with age in the detrusor muscle of male patients has been reported with and without bladder outlet obstruction.(479)

7.2. Plasticity of efferent nerve signalling in bladder in pregnancy and disease

The first symptoms of urinary incontinence in adult women can arise after the first pregnancy and the risk of incontinence increases with multiple deliveries.(480) The sensitivity of the rat detrusor muscle to ATP was not modified by multiple pregnancies, but there was increased sensitivity to adrenergic and cholinergic stimulation,(481) although other studies reported that the responses were reduced.(482, 483) The responses to ATP increased during pregnancy in both rat and rabbit bladders.(482, 483) Detrusor responses to purinergic stimuli are influenced by sex hormones.(484) Chronic treatment with oestrogen induced an increase in the responses to purinergic (as well as muscarinic and α-adrenergic) agonists in the rabbit bladder body and mid-section, but not the bladder base.(485) Oestradiol and tamoxifen, the oestrogen receptor antagonist, inhibited contractions of rabbit detrusor strips produced by α,β-meATP.(486) There was an increase in P2X3 receptor mRNA expression in the bladder after ovariectomy.(487) Since ATP is a cotransmitter in sympathetic nerves, it would appear that less ATP as well as NA is available in pregnant compared to non-pregnant bladders.

Valuable reviews concerning the roles of purinergic signalling in overactive bladder (OAB) syndrome are available.(488-494) Women with OAB have high urinary levels of ATP compared to controls and the nucleotide levels increase with water intake and it was suggested that higher urinary ATP may be a useful prognostic marker for detrusor overactivity.(495, 496) Transient receptor potential vanilloid (TRPV) 1 and P2X3 receptors are both present in the human bladder and they may become upregulated and contribute
to OAB.(497) In OAB there was an increase in expression of P2X3 receptors in subepithelial sensory nerves leading to increased bladder activity.(498) OAB is common among patients with Parkinson’s disease and suppression of this overactivity by A2A receptor antagonists has been reported, which are probably acting in the CNS to regulate the micturition reflex.(499) Uridine diphosphate via P2Y6 receptors regulates abnormal bladder smooth muscle activity in OAB enhancing P2X1-mediated contractions.(500) Neurogenic bladders are hyper-responsive to ATP.(405) A purinergic component of 40% of parasympathetic nerve stimulation was identified in neurogenic bladders.(501)

In a mouse model of bladder overactivity, bradykinin facilitated the release of ATP from nerve terminals via prejunctional receptors.(502) In the P2X3 receptor mouse KO, the bladder is hyperactive.(187, 188) The P2X3 and P2X2/3 antagonist AF-219, which is orally bioavailable and metabolically stable,(493) is being explored as a therapeutic agent for urinary tract dysfunction. Mice treated with ketamine, a recreational drug, for 8 weeks showed side effects in the bladder and enhanced P2X1 receptor expression and non-cholinergic nerve-mediated contractions were observed.(503)

The purinergic atropine-resistant contraction was prominent in human obstructed or unstable bladders but not those with neurogenic instability (504) P2X receptor expression was increased in patients with idiopathic detrusor instability.(369) A further possible explanation for the increased potency of ATP in contracting detrusor muscle from unstable bladders may be due to reduced extracellular ATP hydrolysis.(505) Reduction of P2X3 and P2X5 receptors in human detrusor from adults with urge incontinence has been reported.(506) The increase in purinergic transmission in unstable bladders may be due to a contribution of increased neural release of ATP, reduction in ecto-ATPase activity or to changes in gap junctions between muscle cells.(507) Preparations obtained from hypertrophic human bladders were more sensitive to ATP than healthy preparations.(508) ATP is released during cystometry in women with detrusor overactivity and may contribute to urgency. (509)

In detrusor strips taken from patients with interstitial cystitis (IC), the atropine-resistant contractile component was increased to about 43% of the total response.(404) The atropine-resistant component in the neurogenic bladder was abolished following desensitisation with α,β-meATP and the detrusor muscle showed increased sensitivity to the agonist actions of α,β-meATP, indicating that it is purinergic transmission via P2X1 receptors. P2X3 receptors were upregulated during stretch of cultured urothelial cells from patients with IC.(510) Detrusor overactivity was induced by intravesical application of ATP. The enhanced penetration of endogenous ATP may be due to urothelial damage contributing to urinary frequency and bladder pain in hypersensitive bladder in bladder pain syndrome (BPS) and IC.(511) In cyclophosphamide-induced cystitis in rats, there were substantial changes in both sympathetic and parasympathetic efferent nerves, which alter the afferent nervous input from the bladder.(512) Changes in parasympathetic innervation occur prejunctionally, while changes in sympathetic innervation occur postjunctially.

P2X1 receptor expression in bladder smooth muscle increased considerably in the symptomatically obstructed human bladder.(369, 513) Both cholinergic and purinergic transmission are important for pressure generation and emptying of the bladder.(514) The force of contraction produced by ATP and α,β-meATP on hypertrophied smooth muscle was significantly lower than in controls, and the rate of contraction slower.(515) The sympathetic innervation of the bladder neck was diminished in patients with bladder outlet obstruction,(516) suggesting that there may be a reduced role for sympathetic nerve-released ATP as well as NA.

Multiple sclerosis (MS) patients often have peripheral problems, including bladder dysfunction (517-519) and it has been claimed that peripheral nerve damage occurs in the MS bladder.(153) A selective change in purinergic transmission occurred in mice infected with the Semliki Forest Virus, while cholinergic transmission remained unchanged.(520) There was an increase in the contractile responses to β,γ-meATP and in the purinergic component of nerve-mediated contractions.

IV. NEURAL CONTROL OF PELVIC FLOOR MUSCLES AND RHABDOSPHINCTERS

The urethral rhabdosphincter and pelvic floor muscles are important in maintenance of urinary continence and in preventing descent of pelvic organs (i.e. pelvic organ prolapse, POP). It is estimated that 11% of US women will undergo a surgical procedure for POP or urinary incontinence during their lifetime.(521) Because of the importance of understanding pelvic floor function, recent clinical and preclinical studies have focused on this topic. Reviews of functional anatomy(522) and neural control(523) of the pelvic floor muscles and the urethral and anal rhabdosphincter have been published.(524)

1. STRUCTURAL ELEMENTS OF THE PELVIC FLOOR (FIG. 40)

The pelvic floor (522) in women is a bowl-shaped structure comprised of bone, muscle, and connective tissue. The rim of the bowl is formed by the bones of the pelvic girdle (sacrum, ilium, ischium, and pubis). The “bottom” of the bowl is lined with striated muscle:
the iliococcygeus and pubococcygeus (which together comprise the levator ani - LA - muscle), the coccygeus, and puborectalis(522, 525, 526) muscles. The muscles are attached to the bone and to each other with various connective tissue supports. These three components, bone, muscle, and connective tissue provide support of the pelvic viscera (i.e. rectum, vagina, and bladder) but also allow for excretory and sexual function.

The viscera, as well as striated muscles that serve as true sphincters - urethral and anal rhabdosphincters, attach to pelvic floor muscles and each other by connective tissue but do not attach directly to bone. The urethrovaginal sphincter, the compressor urethrae, the ischiocavernosus, and bulbospongiosus muscles are additional striated perineal muscles that are intimately associated with the viscera(522, 525, 526) During embryogenesis, the rhabdosphincter and perineal muscles develop from the cloaca with a two-week delay in striated muscular differentiation compared to the LA and other skeletal muscles.(527, 528) Furthermore, rhabdosphincters are completely separated from the LA muscles by connective tissue.(525) Thus, the striated muscles associated with the viscera (i.e. rhabdosphincters) are quite distinct from the striated skeletal muscle of the pelvic floor (e.g. LA). The urethral rhabdosphincter has been referred to by many names, including the external urethral sphincter, the striated urethral sphincter, and other names. The term "external urethral sphincter" is downplayed because the urethral rhabdosphincter is not really external to the lower urinary tract; it surrounds the middle of the urethra. Therefore the term urethral rhabdosphincter is recommended.

2. PERIPHERAL INNERVATION OF THE LEVATOR ANI (LA) MUSCLES

The LA muscle of the pelvic floor is innervated by the LA nerve in human, (Figure 40A)(529, 530) squirrel monkey(531), dog(532) and rat.(533, 534) The LA nerve primarily arises from sacral spinal roots (e.g. S3-S5 in humans) and travels along the intrapelvic face of the LA muscle with a high degree of variability in branching patterns.(530) In humans, there is some controversy whether or not the pudendal nerve also innervates the LA muscle.(535) In human female fetus samples, a contribution to LA innervation by the pudendal nerve was only seen in about half the samples. A detailed study of women 45-55 years of age, using an elaborate Sihler’s stain to trace branches down to single fibers, did not describe any contribution of the LA muscle from the pudendal nerve.(529)
In animal studies, a number of findings refute an innervation of the LA muscles by the pudendal nerve:

1. a marked decrease in LA muscle mass and myocyte diameter, as well as vacuolization of the muscle following transection of the LA nerve but not after pudendal neurectomy.(531)
2. transection of the LA nerve abolished LA muscle EMG activity in rats,(533) while transection of the pudendal nerve had no effect on LA EMG activity but abolished rhabdosphincter activity.
3. an absence of contractions of LA muscles upon electrical stimulation of pudendal nerve efferent fibers (Thor and Karicheti, unpublished observations in cats and rats).
4. only a single motor endplate zone is found in the LA muscle, located at the point of LA nerve insertion into the muscle.(531)
5. large $\alpha$ motor neuron axons (i.e. 10 $\mu$m diameter), which are a hallmark of skeletal muscle innervation, are not found in the pudendal nerve.(534, 536)
6. distinct populations of motor neurons, extremely unique in phenotype, are labeled following application of tracers to the pudendal nerve versus the LA nerve(537-539).

Thus, divergent techniques support the conclusion that only the LA nerve innervates the LA muscles with no significant contribution from the pudendal nerve in non-human species. These direct observations, coupled with the distinct embryological origins of LA muscles versus rhabdosphincter and perineal muscles(527, 528), as well as a respective “compartmentalization” of the rhabdosphincter and perineal muscles by connective tissue(525), are in line with distinct “special somatic” motor innervation of the rhabdosphincter by the pudendal nerve versus typical skeletal motor innervation of the LA muscle by the LA nerve. The work in human female fetal samples(540, 541) suggests that an innervation of the LA muscle by the pudendal nerve should be considered, especially during the perinatal period. Whether these pudendal branches to the LA muscle recede during maturation or aging should also be considered in light of the difficulty identifying them in older women.(529)

The complexity of the perineal region, which consists of various small muscles (pubococcygeus, compressor urethrae, urethrovaginal sphincter, urethral and anal rhabdosphincter, ischiocavernosus, and bulbocavernosus), blood vessels, connective tissues, and nerves, makes dissection, identification, and nomenclature of specific nerve branches and muscles difficult in cadavers. Indeed, even the nomenclature of the muscles themselves is uncertain.(525) A recent study has suggested more attention to detail and more rigorous adherence to “origin – insertion” nomenclature standards are being adopted.(529)

Detailed anatomical, histological, and physiological studies of the small, intricate muscles of the perineum coupled with studies of their afferent and efferent neurons in humans and larger laboratory species (where they can be readily visualized) is an important area for future research. As a first step, agreements regarding muscle classification should be established in regard to which muscles actually comprise the LA or pelvic floor versus those that are more intimately associated with the viscera. In other words, should “pelvic floor muscles” include only the skeletal striated muscles such as pubococcygeus, iliococcygeus, coccygeus, and puborectalis muscles, while non-skeletal striated muscle such as urethralis, urethrovaginal sphincter, and compressor urethrae be distinguished from the pelvic floor? Are these latter muscles similar to the urethral and anal rhabdosphincter? Presumably, characteristics of their muscular function, their innervation, their pharmacological responses, or physiological integration with visceral function may allow better understanding of their roles in excretion or sexual function.

Clarity regarding pudendal versus LA nerve innervation is also important because attributes ascribed to pudendal nerve involvement may be more correctly ascribed to LA nerve involvement. For example, the intrapelvic positioning of the LA nerve on the surface of the muscles may expose it to damage as the fetal head passes through the birth canal(530) and may contribute to the correlation between parity and POP.(522) This positioning also allows exposure to electrical current applied with a St. Mark’s electrode situated in the rectum with subsequent EMG activation of the LA muscle. The LA nerve positioning, close to the ischial spine, also risks entrapment by sutures used for various POP suspension surgeries or may account for dyspareunia, pelvic pain, and/or recurrent prolapse(542) associated with such surgery. Finally, since the ischial spine is a landmark for transvaginal “pudendal nerve” block,(540) the possibility that this procedure also anesthetizes the LA nerve should be considered.

2.1. LA Motor Neurons

Retrograde tracing studies in cats,(543) dogs,(532) and squirrel monkeys(531) identify LA motor neurons in a longitudinal column in the sacral ventral horn of the spinal cord, while in rats(544, 545) they are in the L6-S1 ventral horn. In contrast to dense packing of sphincter motor neurons in Onuf’s nucleus,(537, 538, 546) the LA motor neurons are distributed more diffusely. Furthermore, LA motor neurons show a bimodal distribution of large neurons (presumably $\alpha$ motor neurons) and small neurons (presumably $\gamma$ motor neurons) in contrast to the uniform intermediate size of pudendal motor neurons. The two sizes of LA motor neurons are in keeping with the presence of muscle spindles (whose intrafusal muscle fibers are innervated by $\gamma$ motor neurons) in LA muscle,(547, 548) while muscle spindles are absent from the rhabdosphincter muscles;(547, 549-551) consequently LA may exhibit $I\alpha$ (muscle spindle) evoked
monosynaptic stretch reflexes, whereas the urethral rhabdosphincter does not.(552)

LA motor neuron processes (dendrites or axon collaterals) project into two important areas in the sacral spinal cord.(553) One area, medial lamina VI, is where primary afferent fibers from muscle spindles and Golgi tendon organs terminate.(554, 555) again suggesting an important role for stretch-activated reflex contractions of LA muscles. The second area is to Onuf’s nucleus that contains rhabdosphinctor motor neurons. These LA motor neuron processes form close appositions with sphincter motor neurons in both monkey(531) and rat.(544) Presumably, these appositions reflect a neuroanatomical substrate for coordination of the rhabdosphincter and the pelvic floor muscles during micturition and defecation. These projections could be dendrites receiving common afferent input with rhabdosphinctor motor neurons or axon collaterals transmitting information to rhabdosphinctor motor neurons, which might provide insight into functional coordination.

Ovariectomy in rats reduced LA neuron dendritic arbors, while estradiol and progesterone expanded them, indicating hormonal regulation.(556)

2.2. LA Afferent Innervation

Afferent LA fibers innervate muscle spindles(531, 547) and Golgi tendon organs(557) which are common in skeletal muscles but absent in the rhabdosphincters.(547, 549-551) Cholera toxin B (CTB) injection into the LA muscle(553) of squirrel monkeys labels approximately 4 times as many afferent neurons versus motor neurons. About 25% of these primary afferent neurons are large, myelinated (i.e. RT-97 neurofilament positive) neurons and are negative for the peptide transmitter calcitonin-gene-related peptide (CGRP), binding sites for islectin-B4 (IB-4), and the growth factor receptor, TrkA. Of the remaining small, RT97 negative neurons, approximately 50% contain CGRP, IB-4 binding sites, and TrkA. It is tempting to speculate that large, myelinated afferent neurons signal proprioceptive information from muscle spindles(531) and Golgi tendon organs and in turn control reflex activity of the LA muscles, while the small peptidergic, IB-4, TrkA positive neurons transmit nociceptive information. In addition, large sensory neurons may regulate bladder reflex pathways during LA motor activity; while the small peptidergic fibers might play a role in bladder hyperreflexia associated with pelvic floor trauma or nerve entrapment.

CTB labeled afferent terminals were only seen in medial lamina VI of the lumbosacral spinal cord,(553) an area for termination of large, myelinated proprioceptive terminals(554, 555). The absence of CTB labeling in the superficial dorsal horn, which should contain the central terminals of small peptidergic, IB-4, and TrkA positive afferent neurons, is likely due to an inability of small afferent neurons to transganglionically transport CTB rather than a true absence of LA nociceptive terminals in the region.

3. PERIPHERAL INNERVATION OF URETHRAL AND ANAL RHABDOSPINDCTERS

The urethra and anal canal are surrounded by bands of striated muscle fibers; the urethral and anal rhabdosphincters, respectively as they pass through the pelvic diaphragm. The muscles do not attach to skeletal structures and thus act as true sphincters (i.e. contraction produces virtually no movement except constriction of the lumen). In addition, there are small, thin bands of striated muscle (compressor urethra, urethrovaginal sphincter, bulbocavernous, and ischiocavernosus) that surround the urethra, vagina, and/or rectum and have connective tissue attachments to the perineal body.(552)

The urethral rhabdosphincter, anal rhabdosphincter, bulbocavernosus, and ischiocavernosus muscles are innervated by the pudendal nerve,(538, 539, 558, 559) which originates from the S2-4 sacral roots and passes along the lateral surface of the internal obturator and coccygeus muscles and through Alcock’s canal (Figure 40B). As the nerve passes through the canal, it branches into the inferior rectal nerve (which innervates the anal rhabdosphincter), the perineal nerve (which innervates the urethral rhabdosphincter, the bulbospongious muscle, the ischiocavernosus muscle, superficial transverse perineal muscle, and the labial skin), and the dorsal nerve of the clitoris. The branches of the perineal nerve are more superficial than the dorsal nerve of the clitoris and, in most cases, travel on the superficial surface of the perineal musculature. The terminal branch of the perineal nerve to the striated urethral sphincter travels on the surface of the bulbocavernous muscle then penetrates the urethra to innervate the sphincter from the lateral aspects (Figure 40B). The specific innervation of the smaller bands of muscles attached to the perineal body has not been characterized.

Nerve fascicles(560), as well as the motor nerve terminals and end plates(548) of the urethral rhabdosphincter, are preferentially located along the lateral aspects of the urethra in rat. Overlap, or crossing of the midline, between the left and right pudendal nerve terminal fields has been described in monkey anal rhabdosphincter(561). The rhabdosphincter of both men and women contain neuronal nitric oxide synthase (nNOS), which is contained in a subpopulation (43%) of the muscle fibers, as well as nerve fibers, with concentration at the neuromuscular junction in humans and sheep.(562, 563) Additionally, nNOS has been localized to pudendal motor neurons, which innervate the rhabdosphincter in rats, cats, monkeys, and humans.(564, 565) NOS is responsible for producing the transmitter nitric oxide (NO). While NO is known to increase cGMP levels in many types of smooth muscle; its role in control of striated muscle and in neuromuscular transmission is not well established.(566) An NO donor has been shown to
reduce urethral pressures at the level of the rhabdosphincter,(567) but it is difficult to determine if the effect is on smooth or striated muscle.

The possibility that the urethral rhabdosphincter receives a “triple innervation” from somatic, parasympathetic, and sympathetic nerves(568) as raised in early histological studies. However, this has been disputed by subsequent studies(569) that showed no physiological effects of autonomic nerve stimulation on striated sphincter function and showed that the autonomic fibers are only “passing through” the outer layer of striated muscle to reach the inner layers of smooth muscle.

Figure 41: A-C. Composite drawings (A1-C1) and photomicrographs (A2-C2) of pudendal motor neurons in cat labeled by application of horseradish peroxidase (HRP) to the pudendal nerve as seen in transverse (A), horizontal (B), and sagittal (C) sections. The photographs provide raw data from 1 of the single sections used to make the corresponding composite drawing. Note that the dendrites of pudendal motor neurons project into the lateral funiculus (LF). D=dorsal, V=ventral, M=medial, L=lateral, R=rostral, C=caudal. DDB=dorsal dendritic bundle, LDB=lateral dendritic bundle. Primary afferent terminal labeling can also be seen in Lissauer’s tract (LT), the lateral pathway (LP), medial pathway (MP), and dorsal gray commissure (DGC) in panel A1. (Primary afferents were not drawn in panel A1, only motor neurons). Adapted from Thor et al., 1989. D. Composite drawing of a single pudendal motor neuron labeled by intracellular injection of HRP showing the transverse (D1) and sagittal (D2) distribution of dendrites (Designations, such as 1d/l, 2l, 3l, 6 etc., indicate individual dendrites that are seen in both panels D1 and D2). The arrow head in the insert of D1 indicates the cell’s axon. The dashed line in D2 represents the border between the ventral horn and ventral funiculus. Inset in D1 is a 3D rendition of the neuron. Adapted from Sasaki et al 1994. E. Diagrams comparing locations of urethral rhabdosphincter and ischiocavernosus (IC) versus anal rhabdosphincter and bulbospongiousus (BS) motor neurons in various species.
3.1. Urethral and Anal Rhabdosphincter Motor Neurons

Pudendal motor neurons that innervate the urethral and anal rhabdosphincters (and bulbocavernosus and ischiocavernosus) muscles are situated along the lateral border of the sacral ventral horn in Onuf’s nucleus in human(570) monkey,(571) dog, cat(572, 573) and guinea pig.(574) Studies in cat,(539) monkey,(538) and human(570) show that urethral rhabdosphincter motor neurons occupy a ventrolateral position and anal rhabdosphincter motor neurons occupy a dorsomedial position within the confines of Onuf’s nucleus (Figure 41A). However in other species, urethral and anal rhabdosphincter motor neurons are located in separate nuclei (Figure

![Figure 42: Membrane properties, responses to noradrenaline, and involvement of TASK and SKCa channels in retrogradely-labeled rhabdosphincter motor neurons recorded using patch clamp electrophysiology in L5/6 spinal cord slices from 6-14 day old female rats. Comparison of resting membrane potential (RMP, A), input resistance (B), and rheobase (C) in urethral rhabdosphincter motor neurons (dorsolateral nucleus, DLN), axial motor neurons (Ventral nucleus, VN), and hindlimb motor neurons (retrodorsolateral nucleus, RDLN). D) Noradrenaline (NA, 20 µM) depolarizes rhabdosphincter motor neurons and induces robust firing. E) NA and phenylephrine (PE), and alpha1 adrenoceptor agonist, increase input resistance, rheobase, and firing rate-current injection (F-I slope) relationship in a prazosin-sensitive (alpha1 adrenoceptor antagonist) manner in rhabdosphincter motor neurons. Significant and reversible, mean increases in RMP (F) and firing frequency (G) in rhabdosphincter motor neurons produced by NA (20 µM). Doxapram (H), a TASK channel blocker, at 10 µM (D10) and 100 µM (D100), mimics NA’s ability to depolarize rhabdosphincter motor neurons. Decreasing extracellular pH to 6.5 (I), which closes TASK channels, mimics NA’s ability to depolarize these neurons. NA significantly reduces the afterhyperpolarization (AHP) in rhabdosphincter motor neurons (J) in a prazosin-resistant manner. Apamin (A), an SKCa channel blocker, reduces AHP (K), increases the F-I slope (L) and occludes NA’s ability to reduce the AP and increase the F-I slope. Apamin does not influence the input resistance (M) or holding current (N), nor occludes NA’s ability to do so. From Yashiro et al., 2010.](image-url)
41E). In rat,(537) anal sphincter (and bulbospongiosus) motor neurons are located medially in the ventral horn, just ventrolateral to the central canal; while the urethral sphincter (and ischiocavernosus) motor neurons are located in the same region as other species, i.e. along the lateral edge of the ventral horn.

Sphincter motor neurons are different from motor neurons that innervate skeletal muscles. They are densely packed within the confines of Onuf’s nucleus and exhibit tightly bundled dendrites that run rostrocaudally within the confines of the nucleus. Transverse dendrites are particularly unique in bundling and projecting laterally into the lateral funiculus, dorsally towards the sacral parasympathetic nucleus, and dorsomedially towards the central canal (Figure 41).(539, 573) This is similar to bladder preganglionic neurons,(575) suggesting that rhabdosphincter motor neurons and preganglionic neurons receive inputs from similar spinal regions. The dense packing and dendritic bundling of sphincter motor neurons may be related to their special sphincteric function and facilitate simultaneous activation of sphincter motor units. Recurrent axon collaterals (Figure 41D)(573) in the absence of recurrent inhibition(576) suggests a recurrent facilitation that may also reinforce simultaneous activation. Finally, the arrangement of peripheral motor nerve terminals bilaterally at dorsolateral and ventrolateral positions in the urethra may also provide symmetrical force generation.(548)

Rhabdosphincter motor neurons are also physiologically different from skeletal muscle motor neurons in that they do not exhibit significant monosynaptic inputs,(552) Renshaw cell inhibition(552), nor crossed disynaptic inhibition(576). Patch clamp recordings from urethral rhabdosphincter motor neurons in spinal slices(577) demonstrate higher resting membrane potentials, higher membrane resistance, and a lower rheobase compared to other motor neurons in the slice (Figure 42A-C). These in vitro results are similar to in vivo results that also showed unique passive membrane properties (e.g. high input resistance, low rheobase, short after-hyperpolarization, membrane bistability, and non-linear responses to depolarizing current injection, which was recently reviewed.(578) This combination of biophysical properties is uniquely conducive to simultaneous, prolonged, tonic activity, in keeping with the anatomical and functional properties described above.

3.2. Afferent Innervation of the Urethral and Anal Rhabdosphincters

Various studies have characterized primary afferent neurons sending axons into the pudendal nerve.(537, 539) However this nerve carries the innervation to many visceral structures (e.g. urethra, genitalia, rectum, vagina) in addition to skin and rhabdosphincters, thus it is difficult to specifically characterize the sensory innervation of the sphincters per se. Nevertheless, the paucity of large sensory neurons in sacral dorsal root ganglia following application of tracers to the pudendal nerve suggests that the sensory innervation of the rhabdosphincters does not contain large myelinated fibers (i.e. Type Ia and Ib) that innervate these sensory organs(549–551, 579) that typically innervate muscle spindles, Golgi tendon organs, or Pacinian corpuscles. Indeed, multiple investigators using various techniques have not found muscle spindles or Golgi tendon organs in the rhabdosphincters. This is consistent with the finding that the pudendal nerves lack small g motor neuron axons (which innervate muscle spindles)(579) and the absence of rhabdosphincter connections to bone by tendons. On the other hand, Pacinian corpuscle-like structures have been found in the urethra of cat(551) and may play a role in sensing urine flow during micturition to inhibit sphincter activity and/or reinforce detrusor contractions.

The spinal terminals of pudendal primary afferent fibers are distributed throughout laminae I, V, VII, and the dorsal gray commissure (Figure 41A2), while labeling in laminae III and IV is well-defined and restricted to the medial third of the dorsal horn.(539) This restricted pattern in laminae III and IV is consistent with the somatotopic organization expected for cutaneous mechanoreceptors originating in the perineal skin(580). Local injection of tracers targeted to the urethral and anal rhabdosphincters(539) only produced labeling of the spinal terminals of primary afferent neurons in lateral and medial lamina I, the intermediate gray matter, and the dorsal commissure gray matter, not in laminae III or IV. Since the HRP likely spread into the urethra and rectum, it is possible that this labeling occurred in visceral as well as rhabdosphincter afferent pathways. However, since no labeling was seen in large diameter primary afferent neurons nor in terminals in medial laminae III and IV (cutaneous fields) nor medial lamina VI, an area where large diameter myelinated fibers of muscle spindle and Golgi tendon organs nerves terminate(554, 555) it is reasonable to conclude that the rhabdosphincters are not significantly innervated by large myelinated nerve fibers typically associated with other striated muscle.

4. REFLEX ACTIVATION OF URETHRAL AND ANAL RHABDOSPHINCTERS

Rhabdosphincter motor neurons can be activated via segmental (536, 581, 582) and descending pathways (Figure 43).(523, 583) The segmental inputs can be activated by stretch receptors and nociceptors in the bladder or urethra or genitalia.(584) Electrophysiological studies in cats(539, 581, 582, 585) show that stimulation of either pelvic nerve or pudendal nerve afferent fibers can activate polysynaptic spinal segmental reflexes that can be recorded at central delays of 1.5 msec with intracellular electrodes in sphincter motor neurons(586, 587) and at a latency of about 10
msec from electrodes placed on pudendal nerve efferent fibers or inserted directly into the urethral or anal rhabdosphincter muscles. The segmental reflex is considered polysynaptic based on the latency and retrograde transsynaptic labeling of interneurons in laminae I and V of the dorsal horn and in the dorsal gray commissure by pseudorabies virus (PRV) injected into the urethral rhabdosphincter. The dorsal horn interneurons are likely those that participate in the segmental reflex activation of sphincter motor neurons while the dorsal gray commissure interneurons are likely inhibitory (see below). Studies in rats also show that electrical

Figure 43: Drawing of proposed model for spinal and supraspinal excitation and inhibition of rhabdosphincter pudendal motor neurons. Example depicts evoked potential recorded by an electrode on the pudendal nerve in response to electrical stimulation of pelvic nerve (0.5 Hz; table showing the predominant effects of various receptor subtypes on evoked potentials recorded from the pudendal nerve or urethral rhabdosphincter). Red stellate shapes and lines represent excitatory neurons and their axonal pathways, respectively; black oval shape and line represent an inhibitory interneuron and its axonal pathway. Simulation of the pelvic nerve activates a polysynaptic spinal reflex arc that produces an evoked potential recorded from axons of sphincter motor neurons in Onuf’s nucleus at a latency of about 10 msec. This stimulation also activates inhibitory interneurons that, after 50 msec delay, produce inhibition of sphincter motor neurons for about 1,000 msec. Presumably this arrangement allows low frequency pelvic afferent activity (1 Hz) to increase sphincter activity during urine storage and to inhibit sphincter activity when the pelvic afferent activity markedly increases (> 5 Hz) as might occur with very large bladder volumes or during a micturition contraction. The model includes GABAergic, glycineric, or enkephalinergic inhibitory neurons located in the dorsal gray commissure. Supraspinal pathways originating in the medullary nucleus retroambiguus (NRA) and the pontine “L region” can activate sphincter motor neurons during Valsalva maneuvers and during urine storage, respectively. When micturition occurs, neurons in the pontine micturition center (PMC) provide descending activation of the GABAergic, glycineric, or enkephalinergic neurons in the dorsal gray commissure to inhibit sphincter motor neurons and allow voiding to begin. Various other areas of the brain (e.g. medullary raphe serotonergic pathways, pontine locus coeruleus noradrenergic pathways, etc) provide “modulation” of the reflexes. Those excitatory and inhibitory modulatory pathways that have been explored pharmacologically are also listed in the table.

Abbreviations: IC=inferior colliculus; NG=nucleus gracilis; NC=nucleus cuneatus; TrigN=spinal nucleus of the trigeminal nerve; LRN=lateral reticular nucleus; pyr=pyramidal tract; mlf=medial longitudinal fasciculus; il=lateral lemniscus; bc=brachium conjunctivum; bp=brachium pontis; GABA=gamma amino butyric acid; GLY=glycine; ENK=enkephalin; TRH=thyrotropin releasing hormone; NMDA=N-methyl D-aspartate; AMPA=a-amino=3=hydroxy=5-methyl=4=isoxazolepropionic acid; 5-HT=5-dihydroxytryptamine (from Thor 2010).
stimulation of afferent axons in the pelvic nerve elicits reflexes in pudendal nerve efferent fibers or the urethral rhabdosphincter(591, 592) similar to the cat. Also similar to the cat, PRV injected into the urethral rhabdosphincter(593) labels interneurons in laminae I and V of the dorsal horn and in the dorsal gray commissure.

Previously, the afferent inputs from the urinary bladder have been emphasized as being of primary importance for activation of the segmental reflex by pelvic nerve stimulation because bladder distension will activate the urethral rhabdosphincter(594). This reflex activation is often referred to as the “guarding reflex” or “continence reflex”. However, recent studies are placing greater emphasis on urethral afferent fibers.(595, 596) It is tempting to speculate that the guarding reflex is actually activated more vigorously by urethral afferent fibers if urine inadvertently begins to pass through the bladder neck and into the proximal urethra, with a requirement for a rapid closure of the more distal urethral sphincter (i.e. guarding against urine loss) compared to simple bladder distension or increases in intravesical pressure.

The greater importance of urethral afferent fibers is also suggested by experiments where bladder afferent fibers are electrically stimulated. For example, in studies by McMahon et al(581), electrical stimulation of pelvic nerve fibers close to the bladder was not able to evoke pudendal nerve firing in a large proportion of cats but placement of electrodes more centrally on the pelvic nerve was able to evoke firing. Karricheti and Thor (unpublished observations) also found that stimulating nerve bundles close to the bladder is often ineffective in producing a spinal reflex to the urethral rhabdosphincter, but in the same animals it evokes reflex activity on the hypogastric nerve (indicating that the electrical stimulation is activating bladder afferent fibers). Furthermore, it was possible to consistently evoke a reflex when the stimulus was applied more centrally on the pelvic nerve, which would include fibers from the urethra. Since the more central electrode placement would also activate colonic and genital afferent fibers, additional experiments are needed to specifically compare urethral versus bladder versus colonic afferent fibers in evoking the “guarding reflex”.

Electrical stimulation of pudendal afferent fibers also evokes a spinal reflex to activate the rhabdosphincter in cat(597, 598) and rat.(592) Since some urethral afferent fibers (as well as rectal, genital, and cutaneous afferent fibers) travel in the pudendal nerve, it is possible that the spinal urethral rhabdosphincter activation by pudendal afferent stimulation is also a manifestation of the “guarding reflex”.

Sphincter reflexes in the cat also exhibit prolonged changes in excitability following short trains (5-10 second) of electrical stimulation of afferent axons in the pudendal nerves.(597) Recordings from sphincter motor neurons in the sacral spinal cord and from rhabdosphincter peripheral motor axons revealed that stimulation of pudendal afferent axons elicited not only short latency transient responses but also sustained activity persisting for 3-30 seconds after the end of the stimulus train.(597) The persistent activity was associated with a small membrane depolarization and was terminated by small hyperpolarizing currents. Similar persistent activity has been observed in hindlimb motor neurons with slow axonal conduction velocities similar to those of sphincter motor neurons. (599)

5. INHIBITION OF URETHRAL RHABDOSPHINCTER (URS) REFLEXES DURING VOIDING

Voiding is induced voluntarily or reflexively by neural circuitry in the brain.(600) For voiding to occur, there must be contraction of the bladder and simultaneous relaxation of the urethral rhabdosphincter. These responses are mediated by descending projections from neurons in the pontine micturition center (PMC) that excite the sacral autonomic outflow to the bladder and inhibit the motor outflow to the sphincter (Figure 43). This coordination is lost following spinal cord injury.(600) Electrical or chemical stimulation in the PMC in cats excites the bladder and inhibits sphincter EMG activity(590, 601, 602) and hyperpolarizes sphincter motor neurons.(597) The descending inhibitory pathway from the PMC to sphincter motor neurons is thought to involve spinal GABAergic inhibitory neurons in the dorsal commissure of the sacral spinal cord (Figure 43).(603, 604) A role for glycinergic and enkephalinergic interneurons in the dorsal commissure has also been proposed(590, 604-606) in mediating inhibition of the sphincter during voiding (Figure 43).

In addition to supraspinal inhibitory mechanisms, a “spinal, urine storage reflex, inhibitory center” (SUSRIC) was found that inhibited both the somatic and the sympathetic urine storage reflexes controlling the urethral rhabdosphincter and smooth muscle, respectively, in the cat. (588) Activation of this inhibitory center by electrical stimulation of the pelvic nerve afferent fibers occurs simultaneously with the activation of the URS reflex itself. The latency of the inhibition was < 50 msec and had a duration of 500-1,000 msec. Activation of this inhibitory center explains the diminished capacity of the URS evoked reflex to follow frequencies of pelvic afferent stimulation greater than 5 Hz. Physiological stimulation of the pelvic nerve afferent fibers, which occurs with distension of the bladder, has also been reported to inhibit rhabdosphincter EMG activity in both spinal intact(582) and spinalized cats in the absence of a bladder contraction and its associated inhibitory mechanisms. Possibly the inhibition of rhabdosphincter activity by distension of the bladder represents a physiological corollary for the inhibition of rhabdosphincter activity by high frequency electrical stimulation of pel-
vic nerve afferent fibers. Although the inhibitory effects are localized to the spinal cord caudal to the T12 level, they are regulated by supraspinal systems that respond to 5-HT1A receptor activation and enhance sphincter activity through disinhibition. A possible clinical correlation of SUSRIC activation may be the elegant demonstration in men that conditioning stimuli applied to the dorsal nerve of the penis (i.e. pudendal nerve afferent fibers) inhibited urethral rhabdosphincter contractions reflexively evoked by magnetic stimulation of the spinal cord applied at intervals of 20 - 100 msec after the conditioning stimulus. (609)

### 6. SUPRASPINAL ACTIVATION OF RHABDOSPHINCTERS AND PELVIC FLOOR MUSCLES

Supraspinal activation of urethral and anal rhabdosphincter motor neurons can be mediated in response to voluntary (i.e. corticospinal(571)), as well as involuntary reflexic inputs (e.g. during coughing, sneezing, vomiting) presumably from nucleus retroambiguus in the caudal medulla (Figure 43)(610-613). Nucleus retroambiguus also innervates the pelvic floor muscles(614), as well as abdominal muscles, consistent with a role in raising intra-abdominal pressure during Valsalva maneuvers. Generally, the pelvic floor and rhabdosphincter muscles are activated as a functional unit when voluntarily contracted. However, differential activation of the rhabdosphincter and the pelvic floor muscles has been demonstrated,(615) indicating distinct CNS control systems and innervation.

Rhabdosphincter motor neurons are unique among somatic motor neurons in receiving input from the paraventricular hypothalamus,(583) although the function of this input has not been determined. In addition, their input from brainstem serotonergic and noradrenergic neurons is among the densest in the spinal cord.(616, 617)

### 7. NEUROCHEMICAL ANATOMY OF RHABDOSPHINCTER MOTOR NEURONS

In addition to their unique morphology, neurophysiology, and supraspinal inputs, rhabdosphincter motor neurons in Onuf’s nucleus also exhibit a plethora of unique and highly diverse neurotransmitters, receptors, ion channels, and growth factors (Figure 43) and indicate a role in continence and/or sexual function.

#### 7.1. Pharmacology of Urethral and Anal Rhabdosphincters (Figure 43)

The excitatory amino acid neurotransmitter, glutamate, mediates initiation of action potentials in rhabdosphincter motor neurons (and subsequent rapid contraction of the muscle) by binding to NMDA and AMPA receptors.(618-623) Thus it is useful to think of these transmitters as part of the “hardwired” reflex circuitry that is involved in all or none activation of consistent and reliable storage reflexes, as compared to monoamines and peptide transmitters.

The inhibitory amino acids glycine, acting through strychnine-sensitive ionotropic receptors,(624) and GABA, acting through both GABA-A (ionotropic) and GABA-B (metabotropic) receptors(625-627) are thought to be major inhibitory transmitters regulating rhabdosphincter activity. Clinical studies indicate that systemic(324) or intrathecal(627) administration of the GABA-B agonist, baclofen, may reduce bladder sphincter dyssynergia in some patients with neurogenic bladder.

In addition to amino acid transmitters, the monoamine transmitters (norepinephrine and serotonin) are also important in modulating rhabdosphincter motor neuron activity. (628) It was the preferential distribution of norepinephrine and serotonin terminals in Onuf’s nucleus(616, 617) that led to extensive animal studies of noradrenergic and serotonergic control of rhabdosphincter function and eventual clinical studies of duloxetine, a norepinephrine and serotonin reuptake inhibitor, as a treatment for stress urinary incontinence.(584, 613, 629-631) Elegant studies in humans using magnetic stimulation of brain and sacral nerve roots(632) have indicated that duloxetine increases the excitability of rhabdosphincter motor neurons to both supraspinal and segmental inputs to increase urethral pressures. Importantly, duloxetine’s ability to increase urethral rhabdosphincter activity did not interfere with the inhibition of sphincter activity during voiding (i.e. bladder-sphincter synergy was well-maintained).(584) Similar clinical results occurred after administration of S.S-reboxetine, a selective norepinephrine reuptake inhibitor,(633, 634) This approach of increasing synaptic levels of serotonin and/or norepinephrine is logical, since it has been shown that noradrenergic and serotonergic terminals associated with rhabdosphincter motor neurons show an age-dependent decrease in density in rats(324) that might explain the increased incidence of stress incontinence with aging.

Multiple adrenergic receptor subtypes play a role in control of rhabdosphincter motor neurons, and the results with norepinephrine reuptake inhibitors indicate that these receptors can be activated by endogenous norepinephrine. (585) Strong evidence exists that α1 adrenoceptors excite rhabdosphincter motor neurons.(585, 635) Patch clamp studies(577) have shown that norepinephrine produces a direct depolarizing effect, accompanied by an increase in input resistance and decreased rheobase (Figure 42D-G). These excitatory effects are largely mimicked by the α1 adrenoceptor agonist, phenylephrine, blocked by the α1 adrenoceptor antagonist, prazosin, but were resistant to apamin (Figure 42M-N), a small conductance Ca2+ activated K+ (SKCa) channel blocker. Excitatory effects of α1 adrenoceptor stimulation on
rhabdosphincter neurons are supported by clinical studies(635) where decreases in rhabdosphincter activity were seen after administration of prazosin to human subjects. On the other hand, strong evidence exists that $\alpha_2$ adrenoceptor stimulation has the opposite effect, i.e. inhibition, of rhabdosphincter activity.(585, 615, 636) Importantly, reflex activity in the sympathetic pathway to the urethral and anal smooth muscle (i.e. the hypogastric nerve) shows similar adrenergic pharmacology—an enhancement of activity by $\alpha_1$ adrenoceptors(585) and inhibition of activity by $\alpha_2$ adrenoceptors.(585, 637)

Multiple subtypes of serotonin (5-hydroxytryptamine, 5-HT) receptors are also involved in modulating rhabdosphincter motor neuron excitability. Strong evidence exists that 5-HT$_2$ receptors can excite sphincter motor neurons.(598) Indeed duloxetine’s facilitatory effects on rhabdosphincter activity in anesthetized cats are mediated in part through activation of 5-HT$_2$ receptors.(584) Both 5-HT$_2A$ and 5-HT$_2C$ receptor agonists increase rhabdosphincter EMG activity in dogs, guinea pigs, and rats.(586, 638, 639) Recent *in vitro* rat spinal cord slice patch clamp studies show that part of this effect may be directly on rhabdosphincter motor neurons, as opposed to interneurons,(640) since 5-HT induces a direct depolarization of rhabdosphincter motor neurons. The effect of 5-HT to enhance the bistable behavior, plateau potentials and persistent firing of motor neurons(641) very likely contributes to its facilitatory effect on sphincter reflexes and sphincter motor neuron firing.(597) Interestingly, substance P, a peptide transmitter co-localized with 5-HT in nerve terminals, also produces direct depolarization of rhabdosphincter motor neurons in rat spinal cord slices,(642) and thyrotropin releasing hormone (TRH), another peptide transmitter co-localized with 5-HT in nerve terminals, induces excitation of rat sphincter activity(643) *in vivo*.

Immunohistochemical and molecular studies in humans and dogs have shown that 5-HT$_{2A}$, 5-HT$_{2B}$, and 5-HT$_{2C}$ receptor subtypes are associated with Onuf’s nucleus motor neurons. In addition, 5-HT$_{2C}$ receptor mRNA has been localized to anal sphincter motor neurons in the rat.(644) On the other hand, another immunohistochemistry study with retrograde labeling of urethral rhabdosphincter motor neurons and ischiocavernous motor neurons in male rats indicates that the 5-HT$_{2A}$ receptor is associated with the rhabdosphincter motor neurons, while the 5-HT$_{2A}$ receptor is preferentially associated with the ischiocavernous motor neurons(171) and thus may be preferentially involved in sexual function.

As described above, supraspinal 5-HT$_{1A}$ receptor stimulation also enhances rhabdosphincter activity in cats.(607, 608) Importantly, the excitatory effects of 5-HT$_{1A}$ receptor agonists on the rhabdosphincter can still be “over ridden” by inhibitory mechanisms during voiding, i.e. bladder-sphincter synergy remains despite 8-OH-DPAT induced enhancement of rhabdosphincter activity.(607, 608, 645) The enhancement of sphincter activity by 8-OH-DPAT in cats is not seen following acute(645) or chronic(607) spinal cord transection, indicating the 5-HT$_{1A}$ receptors mediating these effects are located supraspinally. 5-HT$_{1A}$ receptor activation may inhibit supraspinal neurons that facilitate SUSRIC-mediated inhibition of sphincter reflexes and thereby facilitate URS activity through disinhibition.

In addition to amino acid and monoamine control of the rhabdosphincter motor neurons, peptides have also been shown to influence their activity. Onuf’s nucleus is densely innervated by the opioid peptides encephalin and dynorphin.(646, 647) In cats, the $\kappa_2$ opioid receptor agonist, ethylketocyclazocine, selectively inhibits spinal rhabdosphincter reflexes.(589) However, attempts to block sphincter inhibition during voiding with high doses of the opioid receptor antagonist, naloxone, were unsuccessful, indicating the enkephalins are not mediating physiological inhibition. In spinal intact rats, it was found that a $\kappa_2$ opioid receptor agonist inhibits the rhabdosphincter bursting pattern associated with micturition, leading to decreased voiding efficiency.(607) In these studies, $\kappa_2$ opioid receptor stimulation had no influence on the asynchronous rhabdosphincter activity that precedes and follows micturition-associated bursting, only on the bursting itself. Onuf’s nucleus is abundantly invested with other peptidergic terminals. Excitatory effects of peptides; vasopressin, thyrotropin-releasing hormone (TRH) and substance P (SP), on rhabdosphincter motor neurons have been demonstrated.(642)

8. LA AND RHABDOSPHINCTER NEUROPATHY

Childbirth is a risk factor for development of pelvic organ prolapse (POP).(648) Furthermore, various studies have indicated damage to the innervation of the pelvic floor muscles, which might be expected to initiate pelvic descent and prolapse.(649) Early studies using pudendal nerve terminal latency as a measure of nerve damage(650) were met with skepticism for many reasons, however with more sophisticated analyses using EMG interference patterns a more recent series of elegant studies(649, 651) have provided evidence that LA nerve damage accompanies parturition in about 25% of women with approximately 1/3 of those continuing to show evidence of nerve damage at 6 months after parturition.(651, 652) Importantly, women undergoing elective Caesarian section (i.e. without preceding labor) showed no signs of LA nerve damage.(649) Furthermore, changes in function of the urethral rhabdosphincter were also associated with pregnancy (i.e. before labor), and these remained evident at 6 months postpartum.(649, 652) In rabbits,(653) it has also been shown that multiparous females have thinner, longer, and weaker pubococcygeus muscles than nulliparous females, which
may indicate nerve damage also occurs in this species. A recent study comparing continent and incontinent women(654) also demonstrated that incontinent women showed evidence of poor neuromuscular function of the rhabdosphincter, and the authors indicated that there was a correlation with age.

Studies have indicated that neurotrophins such as brain derived neurotrophic factor or BDNF plays an important role in neural control of bladder storage and emptying. In addition, BDNF also is involved in neural regeneration after an injury. Recent evidence using a childbirth simulated injury model in rodents has revealed that electrical stimulation of the pudendal nerve significantly augments BDNF expression in injured motoneurons (Figure 44). This increase in trophic factors such as BDNF at the spinal cord level can accelerate axonal regeneration and improves continence.(655) While underlying mechanism has not been established, electrical stimulation of a cut or damaged peripheral nerve is likely independent of production of trophic factors by surrounding cells though is dependent upon stimulation of factors in the regenerating axons themselves (Figure 45).(656) Other studies have used administration of insulin like growth factor-1 to activate satellite cells in the rhabdosphincter, which, in turn induces regeneration and improves continence.(657) Thus, future research might focus on the changes in administration of trophic factors or extracellular matrix that occur with pregnancy, childbirth, and aging.

LA and pudendal nerves contribute to continence mechanisms during sneezing in rats and cats

Analysis of the urethral closure mechanisms during sneeze-induced stress conditions in anesthetized female rats and cats has revealed that pressure increases in the middle portion of the urethra are mediated by reflex contractions of the rhabdosphincter as well as the pelvic floor muscles.(594, 658) Transection of the pudendal nerves reduced sneeze-induced urethral reflex responses by 67% and transecting the

Figure 44: Relative expression of BDNF and βII-tubulin mRNA in Onuf’s nucleus. A: Images of Onuf’s nucleus from a laser dissection microscope. Purple coloration is from thioin staining of neuronal cell bodies. The circled group indicates Onuf’s nucleus, which was cut and collected using laser microdissection, and subsequently used for quantitative RT-PCR. Bar = 100µm. B: Relative expression of BDNF and βII-tubulin mRNA in Onuf’s nucleus after sham or simulated childbirth injury and pudendal nerve stimulation or sham stimulation. Each bar represents mean +/- standard error of the mean of data from 10 animals. The mean RQ in Onuf’s nucleus of the pudendal nerve receiving sham stimulation were normalized to 1. * indicates a significant difference compared to sham stimulation (p<0.05) in the same animals. (From Jiang et al., 2013)
nerves to the iliococcygeus and pubococcygeus muscles reduced urethral reflex responses by an additional 25%. Transecting the hypogastric nerves and visceral branches of the pelvic nerves did not affect the urethral reflexes indicating that sneeze-evoked urethral reflexes in normal rats were not mediated by these autonomic pathways. However, hypogastric nerve transection in conscious, chronic spinal cord injured, female rats reduced urethral baseline pressure, reduced post-void residual urine volumes, reduced maximal voiding pressure, and increased voiding efficiency. This indicates that sympathetic pathways to the bladder neck and proximal urethra contribute to urethral pressure and functional outlet obstruction and voiding dysfunction after spinal cord injury in unanesthetized animals, but not during sneezing.(659)

9. SUMMARY

Neural control of the pelvic floor (LA and coccygeus) is provided by the LA nerve, while the urethral and anal rhabdosphincters are controlled by the pudendal nerve. LA motor neurons are similar in morphology to other skeletal motor neurons, showing large α and small γ neuronal populations diffusely distributed in the sacral ventral horn. One distinguishing feature, however, is projections from LA motor neurons into Onuf’s nucleus, the location of rhabdosphincter motor neurons. Presumably these projections coordinate pelvic floor and rhabdosphincter function. This proposed coordination of visceral and rhabdosphincter activity with pelvic floor muscle activity is one important area for future research. Rhabdosphincter muscles and their innervation are remarkably different from skeletal muscles. The rhabdosphincter striated muscles do not have Golgi tendon organs and muscle spindles, which are common in skeletal muscles. In addition, the rhabdosphincters are intimately associated with the urethra and anal canal and participate extensively in voiding and sexual function. Thus it should not be surprising that rhabdosphincter motor neurons are quite distinctive from skeletal muscle motor neurons. In contrast to the diffuse distribution of LA motor neurons in the sacral ventral horn, the rhabdosphincter motor neurons are densely packed within Onuf’s nucleus (and homologous nuclei in other species). Finally, rhabdosphincter neurons exhibit a number of unique membrane properties that may contribute to simultaneous activation and which are distinctive from skeletal muscle motor neurons. Important species differences exist in the spinal localization of anal sphincter neurons. Other distinguishing characteristics of rhabdosphincter motor neurons are their unique morphology, their association with abundant neurotransmitters and receptors, a diverse physiology, and a rich pharmacology. These differences presumably reflect their integral role in coordinating somatic and visceral function during micturition, defecation, and copulation. Denervation of both the pelvic floor and the rhabdosphincters has been associated with childbirth and aging.

Figure 45: Low magnification images of two common fibular nerves are used to show the effects of electrical stimulation on regeneration of cut axons. Each nerve had been cut and surgically repaired 2 weeks earlier using a ca. 2 mm long graft from a wild type donor mouse. The boundaries of each graft are indicated by arrows. The overall image of each nerve is a montage, constructed from images from several microscope fields, each taken at the same confocal plane through whole mounts of the nerve. They represent a single optical section through the nerve from proximal to the lesion site to its muscle entry point. By 2 weeks after nerve repair, any residual fluorescence in the original distal stump (distal to the graft) due to degeneration of the host axons has disappeared. Fluoresence found in this region represents profiles of regenerating axons that have grown entirely through the grafts. The nerve on right (ES) was stimulated for 1 hr at the time of the nerve repair. The nerve on the left (US) was from a mouse that was unstimulated. Note that in US nerve, buildup and recurrent looppings of regenerating axons are found near the proximal and distal attachments of the host nerve to the graft (open arrows). No such effects were noted in electrically stimulated nerve and larger numbers of regenerating axon profiles are present. (From English et al., 2007)
1. BACKGROUND

This contribution to the International Consultation on Incontinence should be read in conjunction with the companion section on midbrain control of bladder function. Its aim is to present the clinical and experimental evidence for the role of the forebrain in bladder control, and to summarize our understanding, not just of the individual brain regions mediating specific aspects of bladder behaviour, but of how they work together to evoke bladder sensations and appropriate motor activity. An important goal will be to understand how lack of control (urgency incontinence) can arise and be treated.

The importance of the frontal cortex and brainstem in the control of voiding has long been recognized, but only in the past 2 or 3 decades has functional brain imaging come to dominate bladder control research. Most studies have been carried out using either positron emission tomography (PET) or functional magnetic resonance imaging (fMRI). A few have utilized single-photon emission computed tomography (SPECT) or near-infrared spectroscopy (NIRS). All these methods provide indirect measures of regional blood flow and assumed to be related to local neuronal activity. Each has advantages and disadvantages: PET is good for measuring long-lasting states of a system; fMRI is better for following relatively fast events, although resting-state fMRI measures long-lasting states; SPECT has rather poor temporal and spatial resolution; NIRS(660) requires no scanner but has limited penetration through the skull (10 mm) and modest spatial resolution: it has not become popular.

Normal human micturition is organized in 2 phases, storage and voiding, governed by reflexes involving the midbrain, brainstem and spinal cord. During storage (99.8% of the time in health) the urethral sphincter mechanism contracts tonically, preventing urine leakage, while the detrusor remains relaxed, so as to avoid developing a pressure that would expel urine.

During voluntary voiding, the urethral sphincter relaxes, facilitating urine flow, and the detrusor contracts so as to expel urine. This coordinated relaxation and contraction is driven by a long-loop, spino-bulbospinal, voiding reflex.(600) As the bladder fills, increasingly strong bladder afferents travel via the sacral cord to the brainstem and midbrain. If a certain trigger level is exceeded in the midbrain periaqueductal grey (PAG), a pontine nucleus (the pontine micturition centre, PMC) is excited, the voiding reflex is triggered and voiding occurs. Thus this spinobulbospinal voiding-reflex pathway functions like a switch, either “off” (for storage) or “on” (for voiding). (661)

In the absence of higher control, such switching behaviour would lead to involuntary bladder emptying (i.e. incontinence) whenever the bladder volume reached the critical level sufficient to trigger the brainstem switch. However underlying this apparently simple mode of behaviour are complex networks of cerebral neurons (Figure 46). During storage of urine the ascending afferent signals received by the midbrain periaqueductal grey (PAG) are relayed to higher regions of the brain, generating unconscious changes (for example, changes in connectivity)(662-664) as well as conscious bladder sensations which are factored into the assessment of whether voiding is appropriate. Crucially, motor output from these higher centres is able to suppress or promote voiding by manipulating the switch at brainstem level.

Figure 46: Working model showing forebrain part of bladder control network. Note that PAG and PMC form the link with the voiding reflex, of which they are the upper terminus. The PAG receives ascending afferents via spinal cord from bladder; passes signals on to circuits 1, 2 and 3; and receives input back from these circuits, which control the state of the PMC (storage or voiding). This model is not intended to be definitive but to serve as a stepping stone to more detailed understanding of bladder control.
This arrangement forms the substrate for the bladder behaviour characteristic of our species. Embarrassment caused by inappropriate voiding and feelings of shame about incontinence are deeply embedded in human behaviour. Voiding at a socially acceptable time and place is achieved by maintaining strict voluntary control of the voiding reflex. Knowledge of the extent to which one’s bladder content is ‘safe’ is central in this process. Thus, voluntary control of the bladder and urethra has two important aspects: registration of bladder filling sensations and manipulation of the voiding reflex switch. The PAG seems to play a pivotal role in both: as shown in Figure 46, on the one hand it receives bladder afferents and transmits them to higher brain centres and into the realm of conscious sensation; on the other hand it receives projections from those higher centres which thus provide critical input to the voiding reflex. (666) This input to the PAG, together with some direct input from the hypothalamus (Figure 46), normally suppresses excitation of the PMC during bladder filling, so preventing voiding or incontinence. Thus the net effect of higher control during the storage phase is tonic suppression of the voiding reflex. If voiding becomes necessary (bladder volume is large), and is judged (perhaps unconsciously) to be safe, and is consciously assessed to be socially acceptable, suppression can be voluntarily interrupted, allowing the brainstem switch to be turned on and voiding to occur. These social and emotional aspects of continence and voiding rely on the neural pathways discussed below.

Figure 47: In Andrew and Nathan’s series, regions where cortical lesions led to temporary incontinence (turquoise, in grey matter) or permanent incontinence (red, in white matter). Modified from Maurice-Williams 1974 and from a sketch made by Dr Nathan, kindly provided by Dr Clare Fowler (private communication).

3. FOREBRAIN CENTRES AND CONNECTING PATHWAYS INVOLVED IN BLADDER CONTROL

3.1. Centres versus pathways or neural networks

There is a long tradition of describing brain control of the bladder in terms of the activation of ‘reflexes’, ‘neural circuits’ or ‘loops’. (667, 668) Nevertheless, most early functional imaging studies were interpreted in terms of activation or deactivation of compact regions or centres. More recently, in a second wave of imaging studies, results have again been interpreted in terms of neural circuits or connecting pathways governing various aspects of bladder control.

Sections 3 and 4 describe the older evidence for the involvement of some of the regions of the brain that have proved to be the most important for bladder control or lack of control (urgency incontinence). The results are systematized with the help of the working model that comprises a number of neural circuits working together. Finally, in sections 5 and 6, the more recent imaging results, including studies of connectivity, white-matter pathways, and the cerebral effects of treatment of urgency incontinence, are described and placed in the same provisional framework.

3.2. Frontal Lobes

Although Andrew and Nathan(669) were not the first to describe disturbances of micturition resulting from a variety of causes of frontal lobe pathology, their celebrated 1964 paper reporting the syndrome of frequency, urgency and urinary incontinence (and in some patients faecal incontinence), is regarded as seminal in the field. Their description of these patients cannot be improved upon:

“They were not demented, indifferent or lacking in social awareness; they were much upset and embarrassed ... The acts of micturition and defaecation occur in a normal manner; what is disturbed ... is the higher control of these acts. The lesion causes frequency and extreme urgency of micturition when the patient is awake, incontinence when asleep. The sensation of gradual awareness of increasing fullness of the bladder and the sensation that micturition is imminent, are impaired. When the syndrome is less pronounced, the sensation underlying the desire to micturate is absent, whereas the sensation that micturition is imminent still occurs. Then the patient is waylaid by a sudden awareness that he is about to pass urine; when neither sensation is experienced, the patient is amazed to find that he has passed urine. The threshold of the micturition reflex is much lowered. In the most complete form of the syndrome, the patient cannot inhibit the detrusor contraction of the micturition reflex; he is thus forced to empty his bladder as...”
soon as the reflex occurs. When the syndrome is less pronounced, the patient can make a conscious effort to stop the act of micturition, and he may or he may not succeed …”

The cases of leucotomy in Andrew and Nathan’s series were regarded as the most useful for localizing the lesion causing the syndrome. The significant plane of the lesion lay immediately anterior to the tips of the ventricles and the genu of the corpus callosum. Such lesions involved grey matter, in particular the superomedial part of the frontal lobe (the turquoise blob in Figure 47); but they caused a permanent disorder of the control of micturition and of defaecation only when they involved some of the white matter lateral to the anterior horns of the lateral ventricle (red blobs in Figure 47).

Subsequently the same features were observed in 7 patients out of a series of 50 consecutive frontal tumours.(670) In an analysis of patients with acute hemispheric strokes the occurrence of disturbance of micturition was found to be more common in frontal than occipital lobe lesions and there was an association with hemiparesis.(671) In 3 cases, Andrew and Nathan observed that lesions in similar areas to those discussed above led to urinary retention rather than incontinence. Three further cases of frontal lesions with urinary retention have been reported. Successful treatment brought recovery of bladder function.(672, 673)

Early studies using PET(674-677) or fMRI (678, 679) were in agreement that, during bladder filling, storage or withholding of urine, there was activity in the right inferior frontal or dorsolateral prefrontal cortex, perhaps extending into the lateral part of the superior frontal cortex. There was some right-sided predominance. In contrast there was little evidence for activation of the medial parts of the frontal cortex during storage. An fMRI study showed abnormally weak activation in medial prefrontal cortex in subjects with urgency incontinence,(679) and further analysis suggested that, in these subjects, bladder filling tends to provoke deactivation in this region. Disappointingly, there is little overlap of this medial prefrontal cortex with the superomedial frontal region described by Andrew and Nathan.(669)

3.3. Anterior cingulate cortex (ACC), supplementary motor cortex (SMA) and insula

The anterior cingulate is an extensive area with parts serving varied functions. The cases of aneurysm in Andrew and Nathan’s series of frontal lobe pathologies were thought to have involved the anterior end of the cingulate gyrus.(669) Incontinence was observed as part of a complex behavioural disorder following bilateral infarction of the anterior cingulate gyril. (680) A more recent report of a patient in whom a glioma in the right posterior ACC and supplementary motor area was resected described how she experienced urgency incontinence and loss of bladder sensation following surgery.(681)

Many functional imaging studies have observed responses (mostly activations) in ACC to bladder filling, storage or withholding. (674, 677);(679, 682) The re-
ported locations trail from dorsal to ventral ACC. Figure 48, adapted from a review(683) of five PET studies, (675, 677, 684); indicates some of those locations. Response to bladder filling in the dorsal part of the anterior cingulate (dACC) is weak in Figure 48, but this cingulate region and the adjacent supplementary motor area (SMA) are often abnormally activated in patients with urgency incontinence.(679) (See Figure 50 upper left panel, for an example.) These patients, with full bladder but without any actual bladder contraction, experience the abnormal sensation of urgency (a compelling desire to void that is difficult to inhibit,(685) also associated with fear of leakage,(686) i.e. embarrassment). Thus urgency is a powerful homeostatic and social emotion that provides strong motivation to void, perhaps with motor output aimed at suppressing or delaying incontinence until a socially acceptable location can be reached. fMRI observations in rats confirm activation in the cingulate cortex during bladder filling, (687) although whether the region is homologous with the human dACC, and whether rats ever experience urgency or void voluntarily, are not known.

Co-activation of the insula with the ACC is frequently seen in functional brain imaging studies of other organ systems(688) and has been reported in almost all bladder experiments. The insula, an island of cortex deep beneath the operculum of the temporal and fronto-parietal lobes, is regarded as the seat of “interoception”, the sense of the physiological condition of the entire body, (689) including visceral sensation.(690, 691) A key feature of such sensations is an association with an affective, motivational aspect: hence their value in homeostasis. Consistent with this role, there is a correlation between the degree of bladder filling and insula activation in healthy controls with an exaggerated increase in activation at high volumes in women with poor bladder control. (679) The homolog of the insula in the rat responds to bladder filling,(687) although it is also activated during voiding.

Given these observations it is remarkable that there have not been more reported cases of bladder dysfunction from insular lesions. One patient in whom a glioma affecting the inferior frontal gyrus and the insula was excised experienced incontinence without loss of bladder sensation.(681)

Imaging studies during storage or withholding of urine show that regions reported as insula form a cluster near the expected location (see Figure 48)(674, 675, 679, 692, 693). There is slight right-sided predominance, barely visible in Figure 48. In healthy subjects, insular activation becomes stronger with increasing filling of the bladder, consistent with its postulated role in bladder sensation.(694) In normal elderly, the insular response to bladder filling decreases with age, consistent with age-associated loss of sensation. However, insula activity cannot by itself be responsible for conscious desire to void or urgency, because these sensations are lost following extensive frontal lesions,(669) suggesting that integrity of connecting pathways between insula and frontal cortex is essential for conscious sensation.

Voiding, as opposed to storage, is considered in section 4.

3.4. Periaqueductal grey (PAG)

The PAG must be mentioned here because of its presumed pivotal role in bladder control, even though it is part of the midbrain circuitry that is the topic of the companion chapter. A single case history describes a young man presenting with urinary retention in whom the only abnormality found was a small, presumed inflammatory lesion in the PAG.(695) Presumably in other cases the clinical picture was dominated by other symptoms and deficits that were more striking to a neurologist.

The brainstem/midbrain activations reported during the storage and voiding phases seem to cluster in 3 distinct regions (Figure 49), one of them being the PAG. PAG response to bladder filling is reported in 3 studies.(677, 679) This response may reflect increased afferent signals arriving at the PAG or increased inhibitory activity from the medial PFC, needed to prevent triggering of the voiding reflex (see pathway in Figure 46).

The PAG responded to imagined voiding in one fMRI study,(696) but not to real voiding.

3.5. Hypothalamus

Imaging studies have suggested hypothalamic involvement only sporadically. Correspondingly, lesions in the hypothalamus as a cause of bladder symptoms are rare but 3 cases of pituitary tumours, extending upwards into the hypothalamus, have been described with urgency incontinence or retention, weight loss, psychiatric disturbance and bitemporal field restriction.(697) Other instances include gliomas involving the hypothalamus(698) or vascular disturbances of the anterior hypothalamus. Andrew and Nathan also reported five patients with bladder symptoms appearing after a ruptured cerebral aneurysm and speculated that the site of lesion responsible was the anterior hypothalamus. (699)

Animal observations suggest that the anterior and caudal hypothalamus have monosynaptic projections to the PAG and PMC.(666) Correspondingly, two human brain imaging reports suggest response to bladder filling in a region near the caudal hypothalamus,(677, 694) and one near the preoptic area.(679) These connections may allow the hypothalamus to inhibit voiding until the situation is judged to be safe.

4. VOIDING

The preceding sections have been largely devoted to storage or withholding of urine (the filling phase), and
Imagined voiding. In a group of 11 healthy women, relaxation of the pelvic floor, as if intending to void but without actually voiding, evoked activations in many of the same regions as contraction of the pelvic floor muscles.(696) Thus this does not seem to be a good model of real voiding, although another group(662) using a similar protocol found a different result. Indeed, a pontine region that was found to be activated (696) may be the L-region or pontine storage centre activated when subjects tried but were unable to void in the PET scanner (see Figure 49).(700)

Purinergic signaling is involved in the voiding reflex, both at the peripheral and central nerve levels.(349) P2X1 and P2X3 receptors play an important role in the micturition reflex with altered purinergic receptor expression in patients with detrusor overactivity.(87, 193) Intravesical ATP has been shown (in awake rats) to stimulate overactivity and in patients with idiopathic detrusor instability there is an abnormal purinergic transmission.(184, 491)

Involuntary voiding. A preliminary fMRI study of involuntary voiding (detrusor overactivity, DO)(701) showed marked deactivation of the frontal cortex during DO, a finding that still awaits confirmation.

PET studies of voiding. Blok and Holstege used PET to show that a pontine region probably homologous with the PMC was activated during voluntary voiding in humans, suggesting that the voiding reflex had indeed been triggered.(674, 684) They showed also that the right inferior frontal gyrus (or lateral prefrontal cortex) was activated during voiding. The perigenual cingulate, close to the ventromedial prefrontal cortex, which during storage, is typically deactivated, was activated during voiding. This change may indicate that tonic inhibition of the voiding reflex exerted by the medial frontal cortex (Fig. 50) has been switched off, allowing voiding to take place. During voiding the PAG was activated, as were a number of other regions including the hypothalamus and right inferior frontal gyrus.

Nour et al.(684) using PET, demonstrated many regional activations during voiding, including the PAG and a pontine region close to the PMC. However, the perigenual region was not activated, while the SMA, dACC, and left insula, were unexpectedly active.

Some subjects who were unable to void in the scanner failed to show activation either in the perigenual region or in the PMC. They did however show activation of a different region in the pons, believed to be the L-region(702) or pontine continence centre (see Figure 49). This may suggest involuntary tightening of the urethral sphincter.

5. NEURAL CIRCUITS

We have seen that many brain regions respond with altered neuronal activity to bladder filling or voiding, and thus presumably form part of the brain-bladder control network. Such brain regions are believed to be organized in neural circuits that perform tasks related to homeostasis – i.e. maintenance of continence and appropriate timing of voiding – answering questions regarding the adequacy of bladder filling, and the safety and social appropriateness of voiding, as well as the mechanical aspects dealt with by the brainstem switch. In the simple model shown in Figure 46, the regions described above are provisionally organized in 3 neural circuits that govern bladder and urethral behaviour.

Circuit 2 is the most firmly established of these circuits. It comprises the dACC and midcingulate and the insula bilaterally (perhaps with slight right-sided predominance). Together these regions form a network known elsewhere as the salience network, responsible for salience or motivation as well as corresponding motor output.(703) This circuit is activated by bladder filling, markedly in some women with urgency incontinence but barely in normal controls. It seems to correspond therefore to the sensation of urgency, as defined by the International Continence Society.(685, 686) The working model suggests (by analogy with heart rate control)(704, 705) that the output from dACC bypasses the PAG and descends via pathways that are involved in sympathetic regulation of bladder and urethral smooth muscle, thus helping to control incontinence and possibly to modulate voiding. The dACC and adjacent sensorimotor areas, especially the supplementary motor area (SMA), seem to form a functional complex that is often co-activated. The SMA is also activated during purely voluntary contraction of the striated muscles of the pelvic floor and urethral sphincter.(696, 700, 706, 707) Thus SMA co-activation during urgency may reflect tightening of the striated urethral sphincter.

The lateral part of the prefrontal cortex, sometimes called the inferior frontal gyrus, is activated by bladder filling if the dACC, SMA and insula are strongly activated. It therefore fits naturally in circuit 2.
Circuit 1 has as key region the medial prefrontal cortex (mPFC), which in some women with urgency incontinence, is deactivated when the bladder is filled to the point of leakage. The concept of deactivation has caused some perplexity, and mPFC deactivation was initially but incorrectly classified as a deficit in activation. However, circuit 1 is part of the widely recognized default mode network (DMN) that is active at rest and deactivated if conscious attention to a task or event such as rapid bladder filling is required. mPFC deactivation may contribute to suppression of voiding at the PAG, presumably by directing conscious attention to the behaviour of the bladder and sphincter. The posterior cingulate and the occipital cortex are other parts of the DMN that are frequently observed to be deactivated, although this has been little remarked upon.

Circuit 3, often co-deactivated with circuit 1, includes the parahippocampal complex (the hippocampus and surrounding temporal area). These subcortical regions are sometimes classified as a sub-branch of the DMN (circuit 1). Regardless, deactivation on attention to the bladder presumably contributes to voiding suppression in a similar way to circuit 1.

The hypothalamus is sometimes activated by bladder filling in healthy individuals or urgency-incontinent women. It is believed to provide a ‘safe’ signal to the PMC or PAG, to allow or prevent voiding. Tentatively, this subcortical region may belong to circuit 3.

Other regions observed in some studies but not assigned to one of the 3 circuits are the thalamus, shown as a relay station to/from the cortex, with an array of connections based on what is known about a better-studied control system. The basal ganglia, specifically the putamen, are seen in some studies of connectivity. Parts of the cerebellum are often activated but its role in bladder control has been little studied.
5.1. Normal and Abnormal Function

In healthy individuals, as the bladder fills during urine storage it generates afferent signals that ascend to the brainstem switch but do not trigger it. If bladder volume is small then sensation of bladder filling carried by these afferents is weak or absent. Correspondingly, cerebral response to bladder filling is quite difficult to reveal when bladder volume is small, but there appears to be weak activation of circuit 3 (the parahippocampal region) that may reflect subconscious monitoring of the bladder and may help to maintain continence. (708) It should be remembered however that under these circumstances continence may be maintained principally at the spinal cord level, by spinal reflexes that are discussed in another section.

If the normal bladder is filled to capacity so as to evoke a strong desire to void, parts of circuit 2 – insula and dACC/SMA – are slightly activated, consistent with the salience of the sensation (Figure 50, lower left panel). (709) Such normal subjects never show incontinence, detrusor overactivity, or the urgency experienced by subjects with urgency incontinence; but if there is a strong desire to void, propagation of activity to the lateral and ultimately the medial prefrontal cortex probably enables a conscious decision about voiding and an assessment of social propriety and possible embarrassment. If voiding is desired, activation of the return pathway from mPFC to midbrain PAG may trigger the voiding reflex. If no voiding is planned, mPFC presumably remains deactivated, so helping to suppress voiding via this return pathway, part of the normal continence mechanism. During normal daily life however there is usually no conscious awareness of the bladder at all. The mechanism that monitors bladder behaviour in this situation may include the subcortical circuitry of circuit 3, involving the parahippocampal complex and hypothalamus.

In those suffering from urgency incontinence – and to a lesser extent in healthy people – the dACC and SMA in circuit 2 (the salience network) are frequently activated when the bladder is well filled, generating the sensation of urgency and presumably sending a descending signal that delays bladder contraction and tightens the urethral sphincter. It is suggested that this signal makes use of sympathetic pathways, so bypassing the PAG and the voiding reflex in its action on the lower urinary tract. This appears to be a normal mechanism that helps maintain homeostasis by generating sensation and motor output so as to address the threat of incontinence. It is exaggerated in those with urgency incontinence. One would expect that a lesion affecting this pathway would interfere with both sensation of bladder filling and continence.

5.1.1 Complete spinal cord injury

A spinal cord injury will interfere with the propagation of afferent signals from the bladder to the brainstem; a complete injury would be expected to abolish all such bladder signals, making bladder sensation and control impossible. Krhut et al. (710) showed however, in 14 patients with complete lesions at C7 to T5 sustained about 17 months previously, that bladder filling evoked activity in several regions, including the nucleus of the solitary tract and the parabrachial nucleus, nuclei which probably carry afferents via the vagal nerve, bypassing the normal afferent pathway. These afferents were able to excite several regions belonging to the circuits shown in Figure 46 (hypothalamus, thalamus, amygdala, insula, anterior cingulate, and prefrontal cortex), suggesting that the vagal nerve may play a role in the re-innervation of the bladder after spinal cord injury, so perhaps allowing a measure of bladder sensation to be regained.

5.2. Voiding

Referring to Figure 46, if voiding is voluntarily decided upon (in the prefrontal cortex) a series of stereotypical actions follows (finding a toilet, adjusting clothing, adopting the correct posture) and ultimately the deactivating pathway from mPFC to brainstem PAG is silenced or reversed, removing inhibition of the voiding reflex and allowing activation of the PMC – provided that input from the hypothalamus permits it.

6. RECENT DEVELOPMENTS IN FMRI AND RELATED STUDIES

Since the previous ICI, a number of imaging studies have been reported which add to our knowledge of the effect of treatment and the connectivity of the neural circuits outlined above, so further testing the working model and its interpretation.

6.1. Treatment of urgency incontinence

6.1.1 Behavioural treatment: biofeedback-assisted pelvic floor muscle training (BFB-PFMT)

BFB-PFMT is not just 'Kegel exercises'. As well as EMG or pressure feedback from the pelvic floor to help identify the correct muscles to exercise, it includes practice in the techniques of urge suppression, and this is the part of the treatment most valued by patients. (711) Urge suppression is the conscious attempt to control the bladder, overriding any automatic or reflex responses by using voluntary effort and attention to keep the sphincter shut.

In a group of neurologically normal older women with moderate to severe urgency incontinence, a 12-week course of biofeedback-assisted pelvic floor muscle training (BFB-PFMT) reduced the frequency of incontinence episodes from 3.5 to 1.9 per 24 hours (p <0.0001). (709) Not all patients responded to treatment (arbitrarily defined as 50% or greater reduction in incontinence frequency): 46% of all subjects were responders by this criterion. Functional brain imaging showed that, prior to treatment, not all patients responded in the same way to bladder filling (Figure 50); some activated circuit 2, including dACC/SMA;
others deactivated circuit 1, including the mPFC. Intriguingly, the mPFC deactivators tended to fail to respond to BFB therapy, while the dACC/SMA activators did respond. Moreover, those who responded tended to do so by deactivating the mPFC (Figure 50), suggesting that BFB-PFMT works by increasing conscious attention to the bladder (exactly as taught by urge suppression,(711) and consistent with Andrew and Nathan’s original description(669) of the importance of conscious attention). Furthermore, among responders, dACC/SMA activation decreased after treatment, consistent with reduced salience (less urgency), thereby showing that dACC/SMA activation is not the cause but the consequence of UUI improvement. It appears therefore that those who already, at baseline, exercise conscious control of the bladder cannot reduce incontinence by increasing that conscious control, while others who experience great urgency without much attempt at conscious control are able to improve the situation by increasing their conscious control, a skill that can be taught by urge suppression techniques.

These observations fit nicely into the circuits identified in the working model of bladder control. They show also that a trial of therapy, monitored with brain imaging, can yield a good deal of information about how the therapy works, although without a formal control arm it provides little information about the actual cause of the urgency incontinence.

The urge suppression used in this study was based on the use of quick pelvic floor muscle squeezes to control the bladder whenever urgency was experienced. BFB-aided instruction in pelvic floor exercises, particularly quick squeezes, was a helpful preliminary. Note that urge suppression is aimed at exerting voluntary control of the bladder. It is different from “the knack”, which is a technique for stress incontinence aimed at the pelvic floor muscles.

6.1.2 Pharmacological treatment of urgency incontinence

Antimuscarinics are widely used to treat urgency incontinence. They are believed to act peripherally, by reducing the activity of bladder afferents (and in turn, excitability of the bladder muscle) and thus the amplitude of the afferents ascending to the PAG and thence to the forebrain and circuits 1, 2, and 3. Manufacturers have attempted to reduce any direct central effect of their drugs by limiting penetration of the blood-brain barrier or by other means.

A pilot study(712) of the effect of a commonly used antimuscarinic agent, fesoterodine, showed that, in 8 older women with UUI, cortical activation was reduced after treatment, in regions that included dACC/SMA. This is consistent with the expected reduction of urgency after improvement of urgency incontinence, and tends to support the interpretation of circuit 2 in the working model. A similar study of the effect of a β3 adrenergic agonist, a non-antimuscarinic pharmacological treatment for overactive bladder, has not yet been reported.

6.1.3 Neuromodulation for treatment of neurogenic incontinence

Blok et al.(713) used PET to measure brain activity in 20 patients with urgency incontinence. 12 had had chronic sacral neuromodulation (SN) via an implanted unilateral S3 nerve neuro-stimulator for > 6 months. 8 underwent SN acutely for the first time in the scanner.

In the chronically implanted patients, switching on the stimulation caused significant decreases in brain activity in the middle part of the cingulate gyrus (circuit 2) and the ventromedial orbitofrontal cortex (circuit 1), suggesting deactivation of circuit 1 that leads to suppression of voiding at the PAG, with a consequent reduction in urgency (circuit 2). Other stimulation-dependent changes seen in midbrain, thalamus, and dorsolateral prefrontal cortex are more difficult to interpret. Nonetheless these observations imply that long-term neuromodulation does indeed alter the bladder control system.

In newly implanted patients, in contrast, acute sacral neuromodulation (SN) caused significant decrease in the activity of the medial cerebellum, and increase in the right postcentral gyrus cortex, the right insular cortex and the ventromedial orbitofrontal cortex. Some of these regions are similar to those in the chronic stimulation group, but the effects of chronic and acute SN showed significant differences in parts of the brain believed to be concerned with learning: the associative sensory cortex, the premotor cortex and the cerebellum.

These findings suggest that, acutely, SN predominantly modulates areas involved in sensorimotor learning. These areas become less active as SN is continued, revealing ultimately that chronic SN influences, via the spinal cord, brain areas of the working
model implicated in detrusor hyperactivity, awareness of bladder filling, the urge to void and the timing of micturition. Furthermore, SN affects areas involved in alertness and awareness.

6.1.4 Deep brain stimulation for treatment of Parkinson’s disease: effects on bladder function

Deep brain stimulation of the subthalamic nucleus (STN-DBS), part of the basal ganglia, has proved to be an effective therapy for off-period motor symptoms and dyskinesias in advanced Parkinson’s disease. Clinical studies have shown that STN-DBS also ameliorates urinary bladder function in Parkinson’s disease by delaying the first desire to void and increasing bladder capacity. (714, 715) Herzog et al performed a PET imaging study aimed at investigating the effect of STN-DBS on the neural mechanisms underlying cerebral bladder control. (714) In 11 patients with bilateral STN-DBS they observed a significant interaction between bladder state (full/empty) and STN-DBS in ACC and lateral frontal cortex. (714) During urodynamic bladder filling, with or without stimulation, a filled bladder led to a significant increase of activity in the anterior cingulate cortex, which was further enhanced with stimulation off. These authors suggested that STN-DBS ameliorates bladder dysfunction and that the mechanism may include facilitated processing of afferent bladder information.

In a second PET study of 9 such patients, (716) urinary bladder filling led to increased activity in the periaqueductal grey (PAG), the posterior thalamus, and the insular cortex, as well as in the right frontal cortex and the cerebellum bilaterally. A significant interaction between bladder filling and STN-DBS was observed in the posterior thalamus and the insular cortex, with enhanced modulation of these areas when stimulation was on. Furthermore, modulation of the neural activity in the thalamus and the insular cortex by PAG activity was observed only with stimulation on. These data suggest that STN-DBS facilitates the discrimination of different bodily states by supporting sensory perception and underlying neural mechanisms. Furthermore, the brain regions identified by DBS (except for the stimulation site itself) belong to the working model (Figure 46).

More recently it has been shown, (717) in humans and rodents, that deep brain stimulation in the PAG can rapidly and reversibly manipulate the voiding switch, so as to defer voiding and maintain urinary continence, even when the bladder is full. It appears therefore that manipulation of neural continence pathways by deep brain stimulation may offer new avenues for the treatment of urinary incontinence but, given the invasive nature of DBS, only those whose incontinence is of central origin as in Parkinson’s disease are likely to be considered for treatment.

6.1.5 Abnormal brain responses following radical prostatectomy

Seseke et al. (718) demonstrated brain responses to urethral sphincter contraction that involved expected regions (Figure 51); among other observations it revealed a trend to mPFC deactivation that supports the results shown in Figure 50 and elsewhere. These responses were similar to those found previously in a different group of males without urological abnormality, (719) except that they were smaller overall in the post-operative group. This was taken to imply a degree of iatrogenic sphincter damage caused by surgery.

6.2. Connectivity

Increased interest in neural circuits, as opposed to isolated centres of brain activity, has led to a proliferation of methods intended to quantify the connectivity that supports the integrity of the circuits. Many studies depend on correlation between the fMRI signals in different regions, known as "functional connectivity" and defined as statistical dependency among remote neurophysiological events. (718, 720) Functional connectivity conveys no information about the direction of the connection. Various methods have been devised to get around this limitation and thus measure "effective connectivity" – the influence that one neural system exerts over another.

6.2.1 Psycho- and physio-physiological interaction

Psycho- and physio-physiological interaction are methods intended – at least partially – to demonstrate effective connectivity. Tadic et al. (721) used physio-physiological interaction to study effective connectivity in women aged 26-85 years, 11 with urgency incontinence and 10 with normal bladder function. Regions of interest representing the right insula (RI) and anterior cingulate gyrus (ACG) were used as seed regions. Other regions effectively connected to them were identified by significant correlation between the local fMRI signal and the interaction RIxACG. Among normal subjects, many regions involved in bladder control were effectively connected with RI/ACG, including frontotemporal and sensorimotor cortex, forebrain, midbrain and pontine regions. Among urgency-incontinent subjects, the effective connectivity was shifted posteriorly to a parieto-temporal complex. Thus, the connectivity of the bladder control network appeared to differ in normal and UI subjects. A subsequent paper using the same method in 10 continent, healthy women aged 30-79 years revealed connectivity with RI and dACC in regions that included bilateral putamen (basal ganglia) and right pontine micturition center. Connectivity tended to become stronger with age in regions that included L insula, L paracentral lobule and PAG. Consistent with its putative role in maintaining continence (see Figure 46), medial prefrontal cortex (mPFC) showed a trend to deactivation on bladder infusion that became more prominent in old age, and connectivity that weakened significantly with age. Thus, with increasing age,
weaker signals in the bladder control network as a whole as well as changes in mPFC function or connecting pathways may contribute to the development of urgency incontinence.

Kuhtz-Buschbeck et al. (662) pointed out that, when the bladder is moderately full, the desire to void can be suppressed, but it can also be called forth deliberately. They studied brain activity during such intentional modulations of bladder sensation in healthy volunteers (17 women, 16 men). The supplementary motor area, midcingulate cortex, insula, frontal operculum, and right prefrontal cortex (regions of circuit 2; see Figure 46) were consistently more active when the desire to void was enhanced without allowing urine to pass (“attempted micturition”) than when bladder sensations were suppressed. Consistent with the above, the psychophysiological interaction method showed that the midcingulate cortex had stronger connectivity with the PAG and medial motor areas during attempted micturition than during suppression. The left and right insula however showed weaker connectivity with many other brain regions during “attempted micturition”. Therefore intentional modulations of the desire to void can change the effective connectivity of the brain regions involved in circuit 2, the salience network. Some but not all of the observations are in the direction of greater salience and stronger connectivity when desire to void is enhanced, as one would expect from the interpretation of the working model.

6.2.2 Resting-state functional connectivity

Study of resting-state functional connectivity has recently become popular because it provides information about connectivity in a given “resting” state without requiring use of an artificial protocol such as infusion/withdrawal or attempted micturition. Typically, a seed region is chosen a priori and parts of the brain are sought where, over a long period in a resting state, neural activity is correlated with activity in the seed region. High correlation implies strong functional connectivity, and experience in non-bladder fields has shown that it usually indicates an actual neural interconnection (not necessarily monosynap-

Figure 52: Resting state connectivity data: functional connections that are predictive of whether or not an individual had urgency incontinence. Each connection is a correlation between two regions of interest (ROIs, represented as spheres) that are functionally connected, indicated by having the same letter. The names of the ROIs and coordinates in Talairach Atlas space are indicated on the right.

Kuhtz-Buschbeck et al. (662) pointed out that, when the bladder is moderately full, the desire to void can be suppressed, but it can also be called forth deliberately. They studied brain activity during such intentional modulations of bladder sensation in healthy volunteers (17 women, 16 men). The supplementary motor area, midcingulate cortex, insula, frontal operculum, and right prefrontal cortex (regions of circuit 2; see Figure 46) were consistently more active when the desire to void was enhanced without allowing urine to pass (“attempted micturition”) than when bladder sensations were suppressed. Consistent with the above, the psychophysiological interaction method showed that the midcingulate cortex had stronger connectivity with the PAG and medial motor areas during attempted micturition than during suppression. The left and right insula however showed weaker connectivity with many other brain regions during “attempted micturition”. Therefore intentional modulations of the desire to void can change the effective connectivity of the brain regions involved in circuit 2, the salience network. Some but not all of the observations are in the direction of greater salience and stronger connectivity when desire to void is enhanced, as one would expect from the interpretation of the working model.

6.2.2 Resting-state functional connectivity

Study of resting-state functional connectivity has recently become popular because it provides information about connectivity in a given “resting” state without requiring use of an artificial protocol such as infusion/withdrawal or attempted micturition. Typically, a seed region is chosen a priori and parts of the brain are sought where, over a long period in a resting state, neural activity is correlated with activity in the seed region. High correlation implies strong functional connectivity, and experience in non-bladder fields has shown that it usually indicates an actual neural interconnection (not necessarily monosynap-
brain regions, and another on how these brain regions are functionally connected. This may be an important insight.

Jarrahi et al, (723) using a network variant of functional connectivity, found that bladder filling (to strong desire to void) changed the connectivity between insula and parahippocampal complex; insula and ventromedial prefrontal cortex; and ventromedial prefrontal cortex and temporal-parietal junction. These regions are again as expected from the working model.

Although not strictly a measure of connectivity, the parameter “regional homogeneity” (ReHo) is a measure of brain activity that evaluates the similarity between the fMRI signal for a given voxel and its nearest neighbors. Usually resting-state data is employed. ReHo is based on the hypothesis that intrinsic brain activity is manifested by clusters of voxels (high ReHo) rather than isolated single voxels (low ReHo). Recently, Gao et al (664) used this method to determine brain activity of healthy men and women with empty and full bladder, and the difference between these two bladder states. In contrast to the Nardos group,(722) they found that brain activity became stronger with full bladder, perhaps suggesting that this method is more sensitive than the functional connectivity method. Increased activity was observed in the prefrontal cortex, anterior cingulate, hypothalamus, temporal lobes and left caudate, broadly consistent with the working model.

6.2.3 White-matter integrity and tractography
Proper connectivity between regions of the brain requires intact white-matter pathways. Damage to critical pathways may cause permanent incontinence (see section 3.2). For example, disruption of the pathway from medial frontal cortex to brainstem may interfere with the signal that maintains continence by tonically inhibiting the voiding reflex (see Figure 46).

Indeed, studies have identified white-matter disease as the pathology underlying a triad of symptoms commonly seen in the elderly – incontinence, impairment of gait and cognitive disability. (724-726) The Kuchel group (724) used structural MRI to show that in elderly incontinent people, regional brain activations and deactivations of gait and cognitive disability. The Kuchel group (724) used structural MRI to demonstrate that increased effort is required to maintain homeostasis. (724)

Diffusion Tensor Imaging is a quite different method of assessing the integrity of white-matter pathways. Because white matter tracts have a fibrous structure, water molecules diffuse more rapidly in the direction aligned with the internal structure, and more slowly in the perpendicular direction. This difference can be detected by MRI. Expressed as a fraction of the mean (the “fractional anisotropy”) it measures the integrity of the structure, while the direction of fastest diffusion in each voxel can be used to track the white-matter pathways and hence visualize the connectivity of various brain regions (“tractography”). Detrusor-tensor imaging has not been used to its full potential in brain-bladder studies but initial results in women with urgency incontinence appear promising, since they suggest reduced white-matter integrity in pathways such as the fornix, that might not otherwise be revealed.

7. CONCLUSION

The fact that voiding and continence are under forebrain control is now well established by multiple lines of evidence. Brain-imaging protocols designed to excite bladder afferent signals lead to striking changes – activation or deactivation – in many brain regions. An obvious question is: what do these changes represent? Are they simply a side-effect of bladder manipulation or do they reveal the actual working of the bladder control system? This chapter takes the latter view. Some of the brain regions involved are known with reasonable certainty, although further investigations, particularly of normal behaviour, voiding, and different age groups of both genders, will be helpful. The specific functions of these regions and the pathways connecting them are less well known but speculatively they can be organized in a working model comprising a few neural circuits that perform tasks related to homeostasis and maintenance of continence. These tasks include reception of bladder afferents; generation of bladder sensation aimed at ensuring regular (but voluntary) voiding; and provision of motor output that acts on the voiding reflex, via the brainstem switch, to delay or advance the moment of voiding; a second output pathway bypasses the brainstem switch and so is not concerned with the timing of voiding.

Looked at in this way, it is clear that bladder function disorders such as urgency incontinence might in principle be facilitated by abnormalities in the voiding reflex itself (peripheral or spinal); or by abnormalities of cerebral control, the topic of this chapter; or by both. And indeed there is evidence that structural damage to critical connecting pathways can contribute causally to urgency incontinence. Treatment of such disorders leads to changes in brain activity that may be
simply a consequence of successful treatment, but can sometimes indicate a mechanism of therapy, thus helping to design improved therapies and guide new research.

Bladder dysfunction is encountered in both neurologically compromised and neurologically intact people. It is a characteristic feature of some diseases, such as Parkinson’s disease, which have a cerebral origin. In such diseases one would expect to find changes in brain function that could be a target for therapy or a marker of therapeutic success. Patients with such serious disease may be candidates for invasive therapies that interfere directly with brain function. For example deep brain stimulation of subcortical nuclei may improve bladder function as well as motor function in general. Other patients, for example women with overactive bladder, have no obvious neurological abnormality. In them one might expect to find a number of factors, cerebral, spinal or peripheral, that contribute to the dysfunction; any of them might be a target for therapy.

Deeper understanding of bladder control, by elucidating causal and therapeutic mechanisms, is expected to show the way to a new generation of treatments for otherwise intractable bladder dysfunction.

VI. PONTINE-MIDBRAIN CONTROL OF BLADDER FUNCTION

The coordinating role of the caudal brainstem in the urinary bladder control was demonstrated by the observation that micturition was abolished by precise lesions at the level of the inferior colliculus whereas lesions rostral to the colliculus facilitated micturition, presumably by removing inhibitory influences.(727, 728) (Anatomical and physiological studies in both rat and cat have delineated midbrain-pontine-spinal cord circuits in reflexes controlling filling and emptying of the bladder. The role of the so-called pontine micturition center (PMC) revealed by animal models translates well to humans as indicated by brain imaging during micturition and urine withholding(674, 729) and clinical cases showing that specific pontine lesions can result in either urinary retention or urinary incontinence.(671, 730, 731) This section will review the anatomical and physiological evidence for the caudal brainstem circuitry that regulates the autonomic and somatic motor innervation of the lower urinary tract.

1. AFFERENT PATHWAYS LINKING THE BLADDER AND URETHRA TO THE PONS AND MIDBRAIN

Sensations of bladder fullness are conveyed to the spinal cord by the pelvic and hypogastric nerves, while input from the bladder neck and urethra is carried in the pudendal and hypogastric nerves. Afferents arising from the bladder and urethra are mechanoreceptive (myelinated Aδ fibres) and nociceptive (unmyelinated C fibres). The main afferents for the

Figure 53: Schematic depicting information flow between the bladder, spinal cord and brain. In the cat spinal cord interneurons relay information about the bladder to the PAG. The pontine micturition center (or PMC) gets input from the PAG, lateral hypothalamus and medial preoptic nucleus. The PMC also gets input from the PAG, lateral hypothalamus and medial preoptic nucleus. PMC neurons project to the locus coeruleus (LC) and preganglionic parasympathetic neurons of the lumbar-sacral spinal cord that innervate the detrusor. There are also projections to premotor neurons in the dorsal gray commissure that innervate and inhibit Onuf’s nucleus which projects to the urethral sphincter. A pontine continence center (PCC) has been proposed in the cat and is localized to the L-region of the pons. Neurons here project to Onuf’s nucleus.
these interneurons make spinal connections that mediate segmentally organized reflex responses. However, a proportion of these spinal interneurons send ascending projections supraspinally to specific areas in the pons and midbrain that are involved in the micturition reflex (Figure 53). Other interneurons relay information to forebrain structures, including the thalamus and the hypothalamus, but these are though not to play a role in the basic micturition reflex. The circuitry through which information from the urinary bladder is conveyed to the brain varies somewhat depending on the species in which the anatomy was characterized. The main area in the caudal brainstem in the cat and presumably also in humans which receives this information is the periaqueductal gray (PAG), a region of the midbrain. In recent years it has become clear that this nucleus around the aqueduct of Sylvius is essential for many vital functions, like respiration, aggression, mating, defecation and micturition. The forebrain controls the PAG like a switch and complex behavior like micturition can be turned on or off instantly depending of the state of the individual.

In the cat anterogradely labeled fibers from the lumbosacral spinal cord form a dense terminal field particularly in the lateral PAG. Furthermore, bladder and pelvic nerve stimulation evokes activation of the PAG. The importance of the PAG in the cat is exemplified by the observation that electrical stimulation of the lateral PAG results in the cat in micturition that includes an initial relaxation of the external urethral sphincter (EUS) followed by a bladder contraction. Furthermore, the lateral and, to a lesser extent, the dorsal PAG projects specifically to the PMC. It has been proposed that the basic micturition reflex contains an ascending pathway from the lumbosacral cord to the PAG and PMC and a descending pathway from the PMC to the sacral cord. Lesioning between the PAG-PMC and the sacral spinal cord will result in a disruption of the normal micturition reflex. Lesions of rostral from the mesencephalic PAG will result in the loss of control of the timing of micturition, but the micturition reflex, with relaxation of the EUS followed by a contraction of the bladder muscle, remains intact.

Studies in the rat using retrograde tracing from the PMC and anterograde tracing from the spinal cord provided evidence for direct projections from spinal neurons to the PAG, but also to the PMC, which do not exist in the cat. This suggests that the role of the PAG in the micturition reflex of the rat is more modulatory than primary part of the reflex loop. Given the role of the PAG in nociception and defensive behavior it is likely that in rats the PAG exerts an influence on micturition through the PMC under specific conditions but that it is not necessary for micturition to occur with bladder filling. Although these putative circuits are based on animal models, a pivotal role for both the PAG and PMC has been confirmed.

Figure 54: Schematic depicting neuronal types (micturition or bladder contraction) versus inverse or bladder filling within the major midbrain and ponto-medullary regions involved in central neural regulation of bladder function. A major future aim must be to understand both the intra- and inter-nuclear connectivity of neurons involved in bladder contraction and filling. Who drives who and what terminates firing of neurones during bladder filling and contraction. Additionally, how are the volitional drives integrated with the automatic control circuitry of the lower brain. Abbreviations: P, parasympathetic neuron; PAG, periaqueductal grey; PMC, pontine micturition centre; PSC, pontine storage (continence) centre; RVMM, rostral ventromedial medulla; S, sympathetic neuron.
in man using positron emission tomography and functional magnetic imaging with and without a full bladder (see Figure 48). (674, 675, 679, 683, 692)

## 2. EFFERENT PATHWAYS FROM THE PONTINE MICTURITION CENTER (PMC OR BARRINGTON’S NUCLEUS)

In 1925 Barrington was the first to describe a pontine control center for micturition in the cat on the basis of bilateral lesion studies. (727, 728) This region was localized in the dorsal pons and is now termed pontine micturition center (PMC) or Barrington’s nucleus. Later studies used more discrete lesions that abolished micturition and caused urinary retention in cats and rats. (742, 743) Lesions in humans as a result of stroke or multiple sclerosis in an analogous region similarly result in urinary retention in man. (731, 744) (Figure 54)

The PMC is located in the dorsal pons ventromedial to the rostral pole of the locus coeruleus (LC) in the rat, but intermingled with neurons the LC in the cat. (745) Notably the LC in rats and cats differ substantially in that the LC is homogeneous in the rat with all neurons containing norepinephrine, whereas it is more heterogeneous in the cat, with norepinephrine neurons being interdigitated with non-norepinephrine neurons. (746) In humans, comparable regions in the pons have been described recently in the dorsal part of the pontine tegmentum, including the possible PMC. (747) Long descending axons from the PMC have been described to project to the intermediolateral cell column. (748) These axons have excitatory terminal boutons on parasympathetic preganglionic motoneurons innervating the bladder in the lumbosacral preganglionic cell column. (603) PMC neurons are antidromically activated from the dorsolateral funiculus of the first sacral segment, providing physiological confirmation of its spinal projections. (597, 749)

Physiological studies have confirmed the role of the PMC in micturition. Both electrical and chemical activation of the PMC in rats and cats initiates bladder contractions and relaxes the urethral sphincter mimicking normal micturition. (602, 702, 750) Single unit recordings in rat pons revealed 3 types of responses to bladder contraction, an excitation that occurred only prior to contraction (E1), an excitation that occurred prior to and was maintained during contraction (E2) and an inhibition during contraction. (751) Neurons that were activated just prior to contraction and that maintained activation during contraction were found in the PMC while the other two types of neurons were scattered throughout the pontine tegmentum. Similar results were reported in cats during cystometry. (752)

There are basically three micturition phases: 1. pre-micturition phase during realization of a safe environ-

2. relaxation phase during relaxation of the external urethral sphincter; and 2. contraction phase during contraction of the detrusor muscle. Without the onset of one of these phases normal micturition at the right time and place does not take place. These three micturition phases are controlled by three separated specific central pathways. The pre-micturition phase is controlled via a forebrain pathway to the PAG and PMC, (583) the relaxation phase is controlled via an excitatory PMC pathway to inhibitory sacral interneurons, (605) and the contraction phase via the already mentioned excitatory PMC pathway to sacral preganglionic bladder motoneurons. (603)

The forebrain pathway is important for the executive signal to initiate micturition. The inhibitory PMC pathway to the sacral spinal cord does not terminate directly on the motoneurons of the external urethral sphincter in the Onuf’s nucleus. The PMC sends long descending fibers to the intermediolateral cell column, also called dorsal grey commissure or lamina X, which make contact with inhibitory interneurons containing GABA and glycine. (605, 606) These inhibitory interneurons, in turn, project specifically to the motoneurons of the striated external urethral sphincter. (753) Stimulation of the sacral intermediolateral cell column of the cat results in a strong relaxation of the external urethral sphincter, mimicking the relaxation of the sphincter during micturition. (604)

Together, the anatomical and physiological findings described above point to the PMC as being the command center during micturition for both the relaxation phase involving the external urethral sphincter and the contraction phase involving the smooth detrusor muscle of the urinary bladder.

## 3. FOREBRAIN INPUTS TO THE PONTINE MICTURITION CENTER

As mentioned previously, the PAG and the PMC are both part of the basic micturition reflex. Afferents to the PAG and PMC are important to initiate or withhold micturition (pre-micturition phase) and could be targets for modulating bladder function. The most prominent afferents in the cat and rat are the lateral hypothalamus and medial preoptic area. (754-756)

The lateral hypothalamus, particularly, the perifornical region is a major source of afferents to the PMC. (755, 756) The lateral hypothalamus is involved in defensive responses and modulation of the PAG and PMC by the hypothalamic afferents likely plays a role in urination as a component of the defense response (757, 758). A second major afferent arises from the medial preoptic area. This pathway terminates directly on spinal-projecting PMC neurons. (759) Many of these neurons express estrogen receptor alpha, suggesting that this is an estrogen sensitive pathway. (760) The medial preoptic region has been suggested to provide an inhibitory influence during sleep and/or sexual activity to suppress micturition. (761)
4. COORDINATION OF BLADDER WITH OTHER PELVIC VISCERA BY THE PMC

Transneuronal tracing studies with pseudorabies virus injection into different pelvic viscera suggests that the PMC neurons are also positioned to regulate activity of multiple pelvic viscera, including bladder, distal colon and sex organs, and perhaps coordinate activity between viscera. Dual PRV labeling from colon and bladder results in a large population of Barrington’s nucleus neurons that are double labeled from both viscera, suggesting that their axons diverge to innervate both bladder and colonic parasympathetic efferent. PRV labeling from the penis, prostate and perineal muscles also suggests an overlap of central neurons and time course of labeling with bladder. Chemical stimulation of Barrington’s nucleus neurons increases distal colonic intraluminal pressure, which is abolished by muscarinic antagonists. Notably, most Barrington’s nucleus neurons are activated by increases in bladder pressure and many of these are also activated by increases in colonic intraluminal pressure indicating that these neurons receive convergent information from both viscera. Although these findings suggest a role for the PMC in coordinating bladder and colonic activity, currently there is no evidence that PMC impacts on ongoing distal colon activity. Furthermore, the activity of the distal colon is highly dependent on other factors such as pressure gradients and the enteric nervous system. Recently, PET scanning suggested that the PMC is also involved in the control of orgasm in both men and women.

5. THE PONTINE CONTINENCE CENTRE (PCC)

The bladder’s function of urine storage requires detrusor relaxation accompanied by urethral sphincter contraction. Studies in the cat identified a pontine continence center (PCC) also termed the L-region that is distinct from and lying ventrolateral to the micturition center. Neurons in this region project selectively to Onuf’s nucleus in the sacral cord, which contains the external urethral sphincter motoneurons. The majority of neurons in the PCC fire during the relaxation phase of bladder contractions and the onset of their firing can be prior to the initiation of bladder relaxation. Indeed, this would make sense if their prime function were to close the urethral sphincter. Another potential role for these neurons is in off-switching micturition. Supporting this, stimulation of this region stops micturition, excites the pelvic floor musculature and contracts the urethral sphincter. Conversely, bilateral lesions of the PCC cause incontinence, excessive detrusor activity, an inability to store urine and relaxation of the urethral sphincter. However, there is no anatomical evidence for connections between the PMC and the PCC and it has been suggested that the PMC and PCC function independently. Notably, the PCC has also been characterized by PET scanning in humans who try to start micturition or orgasm, but fail to do so.

Future challenges

Although advances have been made in our understanding of central control of lower urinary tract during the decades, many challenges remain. Especially, the patients with functional bladder problems did not benefit much from the better understanding of the central control of the urinary tract. The therapies, such as antimuscarinics and artificial urethral sphincter, which are used by clinicians are usually quite old fashioned and full of side effects. Remarkably, there has been an astounding technical and medical progress for the treatment of patients with cancer because of the focus of the scientists involved aimed at direct treatment. In contrast, the science involved in the dysfunctional control of the pelvic organs were mainly focused on mechanisms of action and not so much on improvement of the future of patients involved. Perhaps the necessary change will come in the near future due to the advance of new imaging techniques, like diffusion tractography and high field magnetic resonance imaging. Also new noninvasive electrophysiological recording technology and optogenetic methods of neuronal stimulation could lead to improvement of the quality of life in chronic patients with functional bladder problems.

THE OVERACTIVE BLADDER

1. INTRODUCTION

The International Continence Society defines urgency as "the complaint of a sudden compelling desire to pass urine, which is difficult to defer" [1]. The "overactive bladder" (OAB) is a symptom syndrome which is defined by the presence of urgency, with or without urge incontinence, but usually with frequency and nocturia in the absence of infection or other obvious etiology [1]. Therefore, urgency is the pivotal symptom of the OAB syndrome. A better understanding of the genesis of urgency and its relationship to other aspects of bladder function is required to unravel the pathophysiology of OAB and to develop more effective treatments [2].

OAB symptoms are suggestive of urodynamically demonstrable detrusor overactivity (DO; involuntary detrusor contractions) during the filling phase which may be spontaneous or provoked [1]. However, OAB is not interchangeable with DO regardless of whether they are associated with reported urgency. Only about half of all patients with DO experience urgency [3], whereas among patients with urgency 44–69% exhibit DO during cystometric studies [4-7].

The definition of urgency as a complaint implies that it can only be measured in cognitively intact patients [2, 8]. Quantifiable and objective demonstration of urgency is difficult, and thus surrogate measures are often used as outcome measures in OAB, leading to inconsistency between clinical trials. Urgency is a pathological sensation and does not necessarily involve the same mechanisms as those underlying the physiological urge to void upon bladder filling. Therefore, comparisons between urge in healthy people and urgency in patients may help our understanding of the mechanisms involved in the latter but, in fact, may be misleading [8].

The emphasis on urgency, rather than DO, as the defining element of OAB gives the condition a subjective foundation which renders derivation of basic science insights challenging. The subjective nature of urgency makes development of animal models impossible. Despite of these limitations, most studies on mechanisms related to urgency/OAB have employed the use of isolated tissues and experimental animals. Non-voiding contractions remains the most frequently used surrogate parameter in such experimental animal studies [8]. The pathophysiology of the OAB syndrome and DO is still incompletely known, but most probably multifactorial. Against the background mentioned above, this section focuses on pathophysiology of the OAB and reviews studies that have provided insight into the mechanisms underlying OAB symptoms and DO.

DO may be further characterized as neurogenic when there is a relevant neurological condition. The dependence of lower urinary tract (LUT) functions on complex central neural networks makes these functions susceptible to a variety of neurologic disorders. Non-neurogenic etiologies may be related to outflow obstruction, aging and female anatomical incontinence, but most cases are idiopathic. There may be two possible origins of OAB symptoms: 1) decreased capacity to handle the afferent signals in the brain, and 2) abnormally increased afferent signals from the bladder and/or urethra (Figure 1).

Two theories probably contribute in varying proportion to the complex mechanisms underlying the genesis of DO and the associated storage symptoms composing OAB, have been put forward (Figure 2):
The urothelium-based hypothesis: changes in urothelial receptor function and neurotransmitter release as well as in the sensitivity and coupling of the suburothelial interstitial cell network lead to enhancement of involuntary contractions [9, 10].

The myogenic hypothesis: changes to the excitability and coupling of smooth muscle cells with other myocytes or interstitial cells lead to the generation of uninhibited contractions [11, 12].

2.1. The Urothelium-based Hypothesis

There is increasing evidence that urothelial cells play an important role in modulation of bladder activity by responding to local chemical and mechanical stimuli and then sending chemical signals to bladder afferent nerves. It has been shown that urothelial cells express various “sensor molecules” such as receptors of bradykinin, neurotrophins, purines (P2X and P2Y), norepinephrine (NE) (α and β), ACh (nicotinic and muscarinic), epithelial Na + channels (ENaC), and a number of transient receptor potential (TRP) channels. These sensor molecules respond to mechanical as well as chemical stimuli and in turn release chemicals such as ATP, prostaglandins (PG), nerve growth factor (NGF), ACh, and NO. These transmitters are known to have excitatory or inhibitory actions on afferent nerves, which are located close to or in the urothelium [10].

The urothelium interacts closely with the underlying suburothelial layer, in particular the interstitial cell network contained within it, so that the whole structure can be regarded as a functional unit [9]. The suburothelium is an area composed of nerves, blood vessels, and connective tissue in intimate contact with the urothelium. The roles of the urothelium and suburothelial myofibroblasts in afferent activation have been emphasised with intense interest. The C-fibre afferents generally have endings in the suburothelial layer of the bladder wall, but in some cases, they also penetrate the urothelium [13].

ATP was the first neurotransmitter demonstrated to be released directly from the urothelium [14]. Non-vesicular ATP release is evoked by chemical stimuli or by stretch proportional to the extent of bladder distension [15-19]. Both P2X and P2Y purinergic receptor subtypes have been identified in the bladder urothelium. It is now thought that these purinergic receptors may respond to urothelial-derived ATP release in autocrine and paracrine signalling [15, 16, 20-23]. By acting on structures such as nerves [24] and interstitial cells in the suburothelial space, urothelial-derived ATP may trigger the underlying afferent signalling of bladder fullness and pain and possibly even the micturition reflex [25].

After successful treatment with botulinum toxin injection, a reduced P2X3-immunoactive suburothelial nerve fibres correlated with a reduction in urgency [26]. Pathologically increased amounts of urothelially released ATP in rats with spinal cord injury can be reduced on treatment with botulinum toxin [27]. Sugaya et al reported that improvement of OAB symptoms with antimuscarinic treatment was significantly correlated with a decrease in urinary ATP level in female patients with OAB [28].

The presence and localisation of muscarinic receptor protein and mRNA in the human [29-34] and mouse [35] urothelium have been studied. All five muscarinic subtypes are expressed throughout the urothelial layers with a specific localisation of the M2 subtype to the umbrella cells and M1 to the basal layer, with M3 receptors more generally distributed. Release of ACh from human urothelial and suburothelial sites increases with age, as well as during bladder stretch, and represents a functional, non-neuronal, alternative cholinergic system [31]. At therapeutic doses, antimuscarinics act mainly during the filling phase and exert little effect on detrusor contraction during emptying [36-38]. This lends support to the suggestion that urothelial muscarinic receptors might be involved in the generation of afferent impulses.

Urothelial cells express also both α and β adrenoceptor subtypes, stimulation of which has been shown to trigger the release of ATP and nitric oxide (NO), respectively [39, 40]. Stimulation of urothelial β adrenoceptors triggers also a urothelially-derived inhibitory factor [41]. Catecholamines could be released from nerves adjacent to the urothelium; however, neither a role of catecholamines nor an altered adrenoceptor profile has yet been shown in pathologic conditions.

In addition to the changes in ACh-release mentioned above, several specific alterations in urothelial function and ultrastructure have been demonstrated in OAB. Expression of the mechanosensitive ENaC is increased significantly in human obstructed bladders in comparison with unobstructed controls and correlates significantly with storage symptom scores [42]. It is possible that increased expression of mechanosensitive channels such as ENaC in the urothelium enhances substance release upon bladder stretch. Levels of PG, which are locally synthesized in bladder

---

**Figure 1:** Two possible origins of OAB symptoms: 1) decreased capacity to handle the afferent signals in the brain and, 2) abnormally increased afferent signals from the bladder and/or urethra.
muscle and mucosa, and levels of NGF are increased in subjects with OAB in comparison with controls; and in symptomatic patients, levels of PGE2 are positively correlated with OAB symptoms and maximum cystometric capacity [43, 44]. Bladder biopsies from patients with both idiopathic detrusor overactivity (IDO) [45] and neurogenic detrusor overactivity (NDO) [46] showed increased urothelial TRPV1 expression. This may be in accordance with the fact that intravesical vanilloids (resineferatoxin) have been shown to improve OAB symptoms in patients with (IDO) as well as with hypersensitivity disorders [47, 48].

This sensory process is more complex than originally thought. Suburothelial myofibroblasts (interstitial cells) in the bladder wall form a functional syncitium through connexin 43 gap junction [49, 50]. These myofibroblasts make close appositions to unmyelinated nerves (afferent C-fibre nerves) [51]. Studies investigating human myofibroblasts show that these cells can respond to ATP by generating an intracellular Ca2+ transient, which is mediated by a P2Y receptor, most likely including a P2Y6 [52]. On the basis of these observations, it has been hypothesized that the close relation between nerves and myofibroblasts allows an amplification of the afferent system in its response to stimulatory mediators such as ATP.

Overall, up-regulation of urothelial function and increased release of various chemical mediators and known neurotransmitters may influence afferent nerve activity to generate OAB symptoms, although the precise mechanism by which these processes interact with neural tissue to achieve signal transduction remains to be clarified.

2.2. Myogenic Hypothesis

Brading and Turner [11, 12] have emphasised that myogenic changes (regardless of aetiology) may contribute to the pathophysiology of (IDO). On the basis of observation that denervation is consistently found in detrusor biopsy specimen from patients with various forms of non- (NDO), it has been proposed that partial denervation of the detrusor may alter the properties of smooth muscle, leading to increased excitability and increased coupling between cells [53]. Thus, local contraction (activity) that occurs somewhere in the detrusor will spread throughout the bladder wall, resulting in coordinated myogenic contraction of the whole bladder. In addition, this local contraction in the bladder wall has been shown to generate afferent discharge [54, 55]. Localized bladder activity was assessed by the micromotion detection method, demonstrating that women with increased bladder sensation on filling cystometry had a significantly higher prevalence of localized activity than the control group [56]. This observation suggests that localized distortion of the bladder wall simulates afferent activity, which would precipitate a feeling of urgency and (DO) [57, 58] (Figure 3).

Although the relationships between intercellular communication and spontaneous mechanical activity and the degree of involvement of different types of connexins (Cx) need further study, Cx45 and Cx43 appear to be the most prominent Cx expressed in human detrusor smooth muscle tissue and cultured cells. Observations in tissue biopsies from patients with NDO and urgency symptoms clearly demonstrated an increase in the presence of Cx43-derived gap junction channels in detrusor muscle [59].

In addition, another population of cells in the bladder known as interstitial cells has been proposed for a pacemaking role in spontaneous activity of the bladder [60, 61]. Because it has been reported that the number of interstitial cells is increased in a guinea-pig model of bladder outlet obstruction (BOO) [62] and that c-kit tyrosine kinase inhibitors, which inhibit interstitial cell activity, decreased the amplitude of spontaneous contractions in the guinea-pig and human bladder [63, 64], interstitial cells may also be involved in the emergence of (DO) because of enhanced autonomous detrusor muscle activity.

Figure 2: Mechanisms involved in increased afferent input from the bladder: the urothelium-based and myogenic theories.

Figure 3: The myogenic hypothesis of the mechanisms involved in increased afferent input from the bladder.
2.3. Other Factors

Aside from the two main hypothesis in the genesis of DO, several other processes may factor in development of DO/OAB. This includes the process of ageing, BOO, bladder ischaemia and mucosal injury. Ageing and BOO may have a common pathway in contribution to DO/OAB development. Remodelling of the micturition circuits caused by ageing and BOO both involve a) ischaemia/reperfusion, and subject to oxidative stress, and b) chronic inflammation (Figure 4). In addition, there is an increasing amount of evidence for the potential role of the urinary microbiome in correlation to DO/OAB (See section: B. THE ROLE OF URINARY MICROBIOTA IN INCONTINENCE AND PELVIC FLOOR DYSFUNCTIONS).

2.3.1 Process of ischaemia and reperfusion

Ischaemia/reperfusion has been proposed as a pathophysiological factor of DO/OAB. Recent studies suggest that arterial obstructive disease, such as atherosclerosis, may cause OAB in both men and women via ischemia, hypoxia and oxidative stress in the bladder [65-68]. DO associated mitochondrial stress may have a central role in epithelial damage, smooth muscle cell injury and neurodegeneration. Superoxide dismutase and aldose reductase up-regulation in the OAB imply intrinsic defensive reaction against free radicals that apparently fails to prevent oxidative damage and neurodegeneration [67]. Up-regulation of HIF, TGF-β, VEGF and NGF in the ischemic bladder was accompanied by the loss of mitochondrial structural integrity, fibrosis, and the degeneration of microvasculature and nerve fibres [69]. These observations may suggest the role of ischaemia in OAB with impaired contraction, as reported in elderly patients without obstruction. Ischaemia may be a key factor in aging associated LUTS.

2.3.2 Inflammation

Recent studies have noted signs of inflammation in bladder biopsy specimens from OAB patients [69, 70]. Increases in cytokines, chemokines, and growth factors have been reported in the urine of OAB patients [71]. Consistent association of increasing serum CRP levels and OAB has been demonstrated in the literature [72-74]. Moreover, a recent study demonstrated increased levels of serum adipokines (adipose tissue secreted cytochines), including IL-1β, IL-6, IL-8, and TNF-α, in patients with OAB refractory to antimuscarinic therapy compared to the control subjects [74]. In this study, no significant difference was found in adipokine levels between OAB-dry and OAB-wet, while serum CRP and NGF levels were significantly higher in OAB-wet, compared to controls. The prevalence of OAB increased with increasing CRP levels in both men and women, supporting the hypothesis for the role of inflammation in the development of OAB. These findings suggest that some OAB patients might have pathophysiology linked to urinary or systemic inflammatory conditions.

Serum MCP-1 levels have shown to be significantly higher only in OAB-dry compared to controls [74]. This may imply that more systemic inflammatory disorders exist among OAB-dry patients, as MCP-1 provokes mast cell activation and has chemotactic activity for monocytes that mature into macrophages at the site of inflammation. Age-associated biochemical changes may accentuate the inflammation associated with OAB. A study on urinary chemokines in OAB patients showed an age-associated elevation of NGF, suggesting a homeostatic response to counter the senescence of bladder nerves and arrest the progression of OAB into detrusor hyperactivity with impaired contractility [75]. All together, these findings support the hypothesis for the role of chronic inflammation at the local and systemic levels in the development of OAB.

3. MECHANISM INVOLVED IN ABNORMAL HANDLING OF THE AFFERENT SIGNALS IN THE BRAIN

3.1. Functional Brain Imaging in Patients with Idiopatic Urgency Urinary Incontinence

Recent advances in functional brain imaging have made it possible to study directly the supraspinal control system operating during bladder filling. Comparisons between brain response in subjects with normal bladder function and those with urgency urinary incontinence (UUI) may give insight neural circuit involvement and the relation to symptomatology [79-81].

The 'neurogenic hypothesis' suggests that abnormal handling of the afferent signals in the brain leads to urgency/Urgency Urinary Incontinence (UUI). Recent functional Magnetic Resonance Imaging (fMRI) data suggested that the PAG is not relatively overactivated.
in UUI patients. On the contrary, the elderly show reduced sensory feedback from the LUT, suggesting alterations at the brain level are involved in DO/OAB [82]. Women with UUI showed weaker activity in the prefrontal cortex (PFC) and exaggerated activity in the anterior cingulate cortex (ACC) and supplementary motor area (SMA) compared with normal controls [83-86]. Responders to pelvic floor muscle training (PFMT) showed exaggerated activity in the ACC and SMA before PFMT, which diminished after successful PFMT. The medial PFC was deactivated in non-responders and only showed minor change in activity after PFMT [86].

Reductions in ACC activity after PFMT with biofeedback in women with SUI were also reported [87]. The anterior cingulate cortex initially was considered to be responsible for monitoring bladder volume. However, the ACC additionally appears to play a role in integrating afferent information and internal motivational states, and management and evaluation of bladder filling information [88].

### 3.2. Neurogenic Detrusor Overactivity

Damage to the central inhibitory pathways, or sensitisation of afferent nerves, may lead to the unmasking of primitive voiding reflexes, which may trigger involuntary detrusor contractions [89,90]. In addition, increased release of nerve growth factor in DO has been reported, which may alter the neural regulation of detrusor muscle [91-93]. Plasticity in peripheral innervation and within the central nervous system (CNS) may both play a pathophysiological role in DO [94]. Peripherally, neurological diseases might cause a sensitisation of C-fibers that are silent under normal circumstances, thereby leading to the emergence of a C-fibre-mediated reflex.

While many neurologic diseases predispose patients to NDO, the only populations that have been systematically studied are adults with multiple sclerosis, adults with spinal cord injury (SCI) and children and young adults with myelodysplasia [90].

#### 3.2.1 Suprapontine lesions

It is generally accepted that suprapontine lesions such as cerebrovascular disease and Parkinson’s disease produce DO. The patient with a suprapontine lesion loses voluntary inhibition of micturition, which corresponds to uninhibited overactive bladder according to a classification by Fall et al [95, 96].

Higher brain centres provide an additional level of urinary control, which is responsible for conscious sensation, volition and emotional response. Key higher centres include the prefrontal cortex, insular cortex and anterior cingulate gyrus, and functional brain imaging has shown changes in higher CNS activity in OAB [79, 80, 90]. Although such observations have been made infrequently, they do point to some key areas for consideration. For example, the participation of several brain areas in urinary control may explain why brain diseases and senile cerebral atrophy are risk factors for lower urinary tract dysfunction [90]. Variation in observations between individuals indicates a diversity of processes in the mechanisms that underlie OAB, although these are expressed clinically in the common manifestation of OAB. The increased activity observed in certain regions of the brain in patients with OAB may actually be compensatory, to counteract urgency, rather than being responsible for the symptom [90]. This confounds interpretation of function, and there are many questions that still need to be answered.

Brain transection studies in animals with an intact neuroaxis showed that suprapontine areas generally exert a tonic inhibitory influence on the pontine micturition center (PMC) [97,98]. In humans, the cerebral cortex (medial frontal lobes) and the basal ganglia are thought to suppress the micturition reflex. Thus, damage to the brain induces DO by reducing suprapontine inhibition.

#### 3.2.1.1 Stroke Cerebral Infarction

The mechanism of DO induced by cerebral infarction or Parkinson’s disease has been further studied using animal models [99, 100]. In the central nervous system, a glutamatergic pathway is known to play a role in both excitatory and inhibitory regulation of micturition [100-102]. It has been demonstrated that in the rat cerebral infarction model, bladder overactivity is mediated by NMDA glutamatergic and D2 dopaminergic excitatory mechanisms [100], suggesting that cerebral infarction may alter a balance between the facilitatory and inhibitory mechanism that results in up-regulation of an excitatory pathway and down-regulation of a tonic inhibitory pathway.

#### 3.2.1.2 Parkinson’s Disease

Parkinson’s disease (PD) is characterised by the degeneration of dopamine-producing cells in the substantia nigra of the midbrain and Lowy body formation. PD is the most common cause of parkinsonism which is the neurological syndrome bearing the hallmarks, hypokinesia and postural instability. Urgency occurs in 33-54% of patients with PD. Neurogenic DO was seen in 45-93% of PD patients [103]. The most widely accepted theory of pathophysiology of DO in PD is that basal ganglia inhibits the micturition reflex in the normal situation via D1 receptors, and that cell depletion in the substantia nigra in PD results in loss of D1-mediated inhibition and consequently DO [103, 104]. The absence of dopaminergic tone via D1 receptors may cause a dysfunction in GABA regulation in the periaqueductal grey (PAG) and DO [105]. Kitta et al [106] demonstrated an increased activation in the PAG, supplementary motor area, cerebellar vermis, insula, putamen and thalamus during DO in male patients with PD. Compared with previous results in healthy volunteers the periaqueductal grey, insula, putamen and thalamus were common activation sites responding to bladder filling, while the pons was not activated during DO, suggesting alteration in brain activation sites in response to bladder filling.
may be related to the pathophysiology of DO in patients with PD.

### 3.2.2 Spinal cord lesions

A spinal cord lesion above the lumbosacral level eliminates voluntary and supraspinal control of micturition, leading to DO mediated by spinal reflex pathways [107]. Disruption below the level of the pons leads to sustained and uncoordinated detrusor contractions often associated with uncoordinated sphincter overactivity (detrusor-sphincter dyssynergy, DSD). Impairment or loss of bladder sensation is a typical feature.

Electrophysiological studies of the effect of capsaicin on voiding reflexes have shown that the afferent limb of the micturition reflex in chronic spinal cats, consists of unmyelinated C-fibre afferents, whereas in normal cats it consists of myelinated A-delta afferents [97, 107, 108]. Since C-fiber bladder afferents in the cat do not usually respond to bladder distension [109], a considerable reorganisation of reflex connections takes place in the spinal cord following the interruption of descending pathways from the brain. In humans with spinal cord lesions, NDO is likely to be mediated by capsaicin-sensitive C-fibre afferents. Clinical experience with capsaicin supports the role of these C-fibre afferents in the pathophysiology of NDO. Capsaicin has been used for the treatment of NDO in patients with spinal cord injury or multiple sclerosis. When administered intravesically, capsaicin increases bladder capacity, reduces micturition contraction pressure, decreases autonomic dysreflexia and reduces the frequency of incontinence [110-112]. More recently, resiniferatoxin, an ultra-potent analogue of capsaicin, has been also used [113-115].

Increased TRPV1, P2X3 and pan-neuronal marker (PGP9.5) staining in suburothelial nerves and increased TRPV1 staining in the basal layer of the urothelium have been observed in patients with neurogenic bladder due to SCI and multiple sclerosis [26]. Treatment of NDO patients with intravesical capsaicin or resiniferatoxin reduces the density of TRPV1, P2X3 and PGP9.5 immunoreactive nerve fibres and urothelial TRPV1 immunoreactivity in those patients exhibiting symptomatic improvement [116]. Injections into the bladder wall of botulinum neurotoxin type A (BoNTA), an agent that blocks the release of neurotransmitters from afferent and efferent nerves, and from urothelial cells, also reduces NDO and the density of TRPV1- and P2X3-immunoreactive nerves [117]. These results indicate that an abnormality of the C-fibre afferent innervation contributes to NDO.

Uregulation of TRPA1 protein and mRNA levels, in bladder and in dorsal root ganglion (DRG; L6-S1) has been reported in rats with SCI. Moreover, HC-030031 (TRPA1 antagonist) treatment decreased the number and the amplitude of DO, suggesting that the TRPA1 activation and upregulation seem to exert an important role in DO following SCI [118].

Following SCI changes in the electrophysiological properties of bladder afferent neurons have also been observed consisting in multiple action potentials (tonic firing) in response to long depolarizing current pulses [119]. In addition, A-type K+ channels are suppressed in parallel with an increased expression of TTX-sensitive Na+ currents, thereby increasing excitability of C-fibre bladder afferent neurons [120]. These electrophysiological changes contribute to the emergence of the C-fibre-mediated spinal micturition reflex following SCI.

**II. THE ROLE OF URINARY MICROBIOTA IN INCONTINENCE AND PELVIC FLOOR DYSFUNCTIONS**

### 1. INTRODUCTION

Historically urine was considered to be sterile and it has only recently been appreciated that the bladder contains its own microbiome. With that understanding a whole new field of research within urology has been opened up with regard to the physiological role of the lower urinary tract microbiome and the pathophysiology of microbiota in lower urinary tract dysfunctions and urinary tract infections (UTIs). Over 50% of women will experience at least one UTI during their life, with a yearly prevalence of 11% [121]. In addition, UTIs are responsible for substantial morbidity in the group of frail elderly patients. Amongst community dwelling elderly women, UTIs compromise the second most common cause of infection. In long-term care facilities and hospitalised subjects, UTIs represent the most common cause of infection [122]. Aside from the patient’s burden this results in a significant increase in health care expenses. UTIs are estimated to be responsible for more than 100.000 hospital visits and costs of 3.5 billion dollar annually in the United States of America [123]. A sample analysis on UTI prevalence of 456.586 German patients with type 2 DM showed a prevalence of 48.337 UTI episodes over a mean observation period of 665 days. Additional multivariable cost analysis in this group showed a UTI cost-increasing effect of 3.916 euro per patient year [124]. These UTI related additional costs might be even higher in a group of frail elderly UTIs in this group lead more often to hospitalisation [125]. During a 90-day follow-up period Turner et al. showed that in-hospital treatment leads to significantly more costs during treatment but also at 90 days post-treatment follow-up [125].
1.1. Terminology

**Microbiome**: The microbiome represents the genes and genomes of the microbiota. In addition, it represents the products of microbiota and the host environment. The microbiome incorporates biotic and abiotic factors (including archaea, viruses and fungi and products of microbiota) [144].

**Metagenome**: The metagenome refers to the genes and genomes of the microbiota and highlight the genetic potential of a population.

**Microbiota**: Identification of the microorganisms in an environment by the use of molecular techniques (such as 16S ribosomal RNA sequencing). The term microbiota refers to the microbial taxa associated with an environment [144, 145].

2. MICROBIOTA AND URINARY TRACT HOMEOSTASIS

The significance of microbiome in maintenance of health and development has been extensively explored in organ systems other than the urinary tract and it has only been recently accepted that most of the human body is colonised with bacteria. The Human Microbiome Project (HMP) is a large mapping study of the human microbiome sampling 300 individuals at five body sites (gastrointestinal tract, mouth, vagina, skin and nasal cavity) using culture independent methods [146]. In addition, specific microbial sites have been linked to diseases. For example, gastrointestinal imbalance in microbiota has been related to brain abnormalities [147], problems in the musculoskeletal system [148] and linked to metabolic processes [149].

In addition to the Human Microbiome Project multiple studies have suggested that the lower urinary tract contains a unique set of microbiota that is vastly different from gastrointestinal and vaginal colonisation (Table 1) [132, 135, 150]. In contrast to traditional bacterial culturing of urine which only allow identification of fast-growing pathogens, recent progress has been made possible by advanced culture and molecular techniques (PCR and 16S ribosomal RNA sequencing). The initial disadvantage of the molecular techniques was that they were not able to distinguish life from death bacteria. However, by combining RNA sequencing with expanded cultures Hill et al. were able to show that indeed most bacteria in the bladder were alive [135].

Is there a ‘core set’ of bladder microbiota? In 2013 Lewis et al presented a catalogue of bacterial DNA from a small cross-sectional sample of healthy adults. In addition, they proposed the concept of a set of bacteria that exist across different age groups but may fluctuate in abundance with age [133]. However, with regard to the variations in detected microbiota amongst the different studies presented in Table 1, larger longitudinal studies will be needed to confirm the existence of core set of microbiota in the bladder. Moreover, evolution of the bladder’s microbiome over time and factors influencing these specific microbiota need further investigation.

The specific role of microbiota and the microbiome in the urinary tract still needs to be sorted out. In contrast to other organ systems the homeostatic role of bacteria in the lower urinary tract has only received minimal research attention. However, specific key roles of the urinary tract’s microbiome have been suggested based on research in other organ systems: 1) Regulation and maintenance of barrier function of the bladder wall and functioning as prime urothelial defence mechanism. For example through competition of commensal microbiota with pathogens for common resources. This is true for other sites of the body such as the gut and vagina [151, 152]. 2) Products of microbiota may kill pathogens and degrade certain harmful compounds. 3) Involvement of microbiota in the development of the urinary tract, including the connected peripheral nervous system. There is only little known about the link between microbiota and development of the nervous system. Through production of neurotransmitters microbiota might be needed for the correct development of bladder’s signalling system. Incorrect development of these signalling systems might be related to lower urinary tract dysfunctions such as OAB or detrusor underactivity (DUA). Gastrointestinal studies on germ-free mice show that absence of microbes correlated with behavioural and neurological disorders [147]. However, the exact role of microbiota in the bladder and its relation to signalling systems in the bladder-brain axis is still unknown due to the lack of studies in this specific area of research.

3. THE PATHOPHYSIOLOGICAL ROLE OF MICROBIOTA IN THE URINARY TRACT

Acknowledgement of the suggested physiological role of the urinary tract microbiome does raise questions about the pathophysiological role of microbiota in different urological entities. For example, microbiota have suggested to be involved in development of urolithiasis and as treatment for recurrent superficial bladder cancer. However, both of these topics go beyond the scope of this chapter. In this section the link between microbiota and functional lower urinary tract disorders will be further elaborated.

3.1. Stress Urinary Incontinence

To date there is only one study available on the relationship between urinary microbiota and the characteristics of women with stress urinary incontinence. This cross-sectional study in 197 women showed no associations between stress urinary incontinence symptoms and the bacterial diversity. Based only on these results, the involvement of the urinary microbiome in SUI seems of less importance compared to...
other lower urinary tract dysfunctions. However, more research is needed to conform these initial conclusions.

3.2. Urgency Urinary Incontinence

Urgency Urinary Incontinence is a widespread disorder affecting many adult women. It is only recently that the potential role of the microbiome has been explored. In 2014 Pearce et al compared microbiota of women with and without UUI using molecular sequencing. Results showed that women with UUI had decreased Lactobacillus taxa and higher Gardnerella presence. In addition, Actinobaculum, Actinomyces, Aerococcus, Arthrobacter, Corynebacterium, Oligella, Staphylococcus and Streptococcus were found more frequently in the UUI group [136]. However, no difference was found in microbial diversity. One of studies describing the variability in female microbiota in patients with UUI, an association between certain microbial characteristics (i.e. taxa and variety of microbes) and symptom severity was found. An increase in UUI symptom severity may be associated with a loss of microbial diversity in women with UUI [141]. In a follow-up study Pearce et al compared sequencing positive and negative UUI groups before oral drug treatment for UUI. They found that positive sequencing was associated with more severe UUI and better response to treatment.

In 2016 Thomas-White et al reported a 12 week anticholinergic follow-up study in women with UUI suggesting that less diversity tended to be associated with fewer UUI symptoms and with better treatment response to an anticholinergic drug [142]. Non-responders had a more diverse microbial population that was different from the population found in responders. An additional study in women with stress urinary incontinence, gave consistent results. Increased microbial diversity was associated with a higher urge index score [143]. In addition to the finding of differences between women with UUI and healthy controls several studies have shown a relationship between urinary microbiota and response to oral drug treatment. The variations in outcome between the studies might be related to the sampling method. However, in general the results highlight the potential clinical importance of the urinary microbiome in UUI [138].

Hence, recent research gives clues regarding the potential role of urinary microbiota diversity in the aetiology and treatment of women with UUI. However, a major flaw still is the variability in sampling methods between the different studies. This makes replication and clinical utility difficult, at least for now [153].

3.3. Urological Pain Syndromes

The role of microbiota in different urological pain syndromes has been explored, for example in PBS/IC and CPPS. Saddiqi et al collected urine samples from women with interstitial cystitis and compared this with healthy volunteers. They were able to show that IC patients had lower bacterial diversity and an increase in Lactobacillus compared to healthy volunteers (92 vs 57%) [131]. Reduction of bacterial diversity in general is seen in chronic inflammatory states such as in inflammatory bowel disease [154]. The relative abundance of Lactobacilli however is yet to be confirmed in other studies and the question is whether or not this is truly associated with IC in women.

The Multidisciplinary Approach to the Study of Chronic Pelvic Pain (MAPP) research network compared female patients with Urological Chronic Pelvic Pain Syndrome (UCPPS) who reported symptom flare vs those who did not report a flare, to examine differences in microbiota. The results revealed no difference in bacterial prevalence in the urine samples. However, the group with flare had a significantly greater prevalence of fungi (Candida and Saccharomyces sp.) [140]. This is in concordance with an earlier study from the same group in which they performed a two year follow-up of IC/PBS patients to identify bacterial culture status using only standard culture techniques [155]. The same MAPP research network studied male UCPPS (PBS/IC/chronic prostatitis) patients and compared the microbiota with aged-matched controls. The study group showed higher presence of Burkholderia Cenocepcacia in the UCPPS group of patients in the initial urinary stream urine [139]. However, these differences were not reproducible for the midstream urine samples or after prostate massage.

A recent study examining stool samples of women UCPPS patients identified potential stool-based microbial and metabolome markers for UCPPS, with specific interest for Colisella aerofaciens and metabolite glyceraldehyde. These biomarkers were, amongst several others, altered in the gut compared to healthy controls in this pilot study consisting of a total of 34 women (16 healthy controls vs. 18 women with UCPPS) [156]. Shoskes et al analysed gut microbiota in men with UCPPS and showed a decreased microbial diversity in the gut in men with UCPPS compared to controls [157].

In theory the urinary microbiome might be involved in aetiology or development of IC/PBS/UCPPS, however different studies show largely varying results. Up until now there is no compelling evidence to support the specific role of the microbiome in patients with urological pain syndromes and more research is needed in this specific area.

The presented strains are highlighted by the authors of the original studies as predominant or more prevalent than other populations. The microbiota are listed as genera unless otherwise specified. STI: sexually transmitted infection, NBD: neurogenic bladder dysfunction, IC: interstitial cystitis, POP: pelvic organ prolapse, OAB: overactive bladder, UUI: urgency urinary incontinence, UTI: urinary tract infection, UCPPS: urological chronic pelvic pain syndrome, SUI: Stress Urinary Incontinence.
Despite the great achievements made in modern obstetric practice in developed countries during the last 100 years, delivery remains the most stressful and dangerous event the female pelvic diaphragm is submitted to during a woman's lifespan.

Reduction in both perinatal and maternal mortality rates in recent decades has allowed us to focus increasingly on maternal morbidity and the long-term sequelae of childbirth. Due to improved investigative techniques available over the past decade, the incidence and mechanisms of obstetric injury to the pelvic floor have come under scrutiny.

However, the controversial debate on whether and how pregnancy and vaginal delivery are responsible for pelvic floor morbidity is still wide open.

During pregnancy, muscular, connective and nervous pelvic structures are subjected to anatomical, morphological, functional and hormonal changes. During vaginal delivery, the pelvic floor undergoes an enormous amount of stretching to allow the passage of the newborn through it.

Through pregnancy and just after delivery, the functions sustained by the pelvic floor (urinary and faecal continence, pelvic organ containment and sexual function) often begin to fail. Evident or hidden injuries to the pelvic floor may manifest themselves through urinary and faecal incontinence, prolapse symptoms or sexual dysfunction, with a considerable impact on quality of life.

Several mechanisms of birth trauma have already been investigated, but a lot needs to be understood regarding the role of pregnancy on the pelvic floor.

The growing knowledge of the consequences of childbirth and pregnancy on the pelvic floor offers the chance to develop prevention and treatment strategies. It is important that contributing obstetric factors are identified and their occurrence minimised, in order to focus efforts on preventable risk factors.

1. DAMAGE TO FUNCTIONS SUSTAINED BY THE PELVIC FLOOR

1.1. Postpartum Urinary Incontinence

A systematic review of 33 studies reported a 33% prevalence of any type of postpartum urinary incontinence (UI) in the first 3 months postpartum, with a prevalence of weekly and daily incontinence of 12% and 3% respectively. The prevalence in the vaginal delivery group (31%) was double that of the caesarean section group (15%). Long-term studies in the first year postpartum showed small changes in prevalence over time [158]. Caesarean section seems to decrease the risk of postpartum UI [159, 160], but its protective effect seems to diminish over time and disappears after multiple deliveries [160, 161].

In a recent cohort study extracted by the national Swedish Medical Birth Registry between 1973 and 1982, two groups were identified: 30,880 women who had their first and all subsequent deliveries by caesarean vs. an age-matched sample of 60,122 women who delivered vaginally only. Stress urinary incontinence (SUI) surgery was observed in 0.4% of the caesarean group and 1.2% of the vaginal group (follow-up time 26.9 years), and the risk of SUI is estimated to be 2.9 times higher after vaginal delivery compared with women after caesarean section. Among women with vaginal deliveries, rates of SUI surgery increased with the number of births, whereas in the caesarean delivery cohort it slightly decreased with a higher number of births. Compared with caesarean delivery, the risk of SUI was more than doubled for vaginal delivery with vacuum extraction and tripled for a vaginal non-instrumental delivery, but this lower risk for a vacuum extraction delivery has been in part explained by an overall lower birth rate in this subset of patients. After vaginal delivery, the incidence rates for SUI surgery steadily increased, reaching a peak close to three decades after the first delivery. For caesarean delivery, the incidence of SUI...
increased more slowly and started to diverge from the curve for vaginal delivery very early during follow-up (Figure 5) [162].

After the first delivery, women who delivered vaginally seem to have at least a two-fold greater risk of UI than those delivered by caesarean. However, data for the rates of incontinence after elective and emergency caesarean section are mixed; we therefore lack the information as to whether caesarean carried out before labour confers greater protection than caesarean done after labour is established.

To understand the true impact of caesarean delivery on UI, future studies must compare incontinence by planned mode of delivery, consider a woman’s entire reproductive career, focus on leakage severe enough to be problematic, consider other bladder symptoms as well as incontinence, and take into account other risk factors, particularly antepartum UI [163].

1.2. Postpartum Anal Incontinence

De-novo anal incontinence (AI) symptoms after childbirth are described as up to 26-38% between 6 weeks-6 months postpartum [164-169].

In a population-based survey estimating the postpartum incidence of faecal incontinence (FI), Guise et al. [165] reported that 29% of 8,774 women reported FI (defined as recurring episodes of involuntary loss of stool or flatus since delivery) within 3-6 months postpartum: almost half (46%) of them reported incontinence of stool, and 38% reported incontinence of flatus only. Approximately 46% reported the onset of incontinence after the delivery of their first child. Higher body mass index, longer pushing, forceps-assisted delivery, third or fourth-degree laceration and smoking were associated with severe FI. The authors conclude that in this population-based study, more than one in four women reported FI within 6 months of childbirth, with almost half reporting the onset of symptoms after delivery of their first child. Four in ten women reported loss of flatus or stool during intercourse. Given the burden of this condition, both in number and social impact, coupled with the hesitancy of women in initiating this conversation, providers should ask women about symptoms of FI during postpartum examinations. Additionally, these data suggest that there may be a benefit to extending postpartum follow-up visits beyond the typical 6-8 weeks to provide surveillance for potential incontinence.

LEVEL OF EVIDENCE: II.

In comparison with caesarean section, vaginal delivery seems to be associated with an increased risk of AI. In a population-based study, Guise et al. [164], reported that vaginal delivery has a greater risk of FI compared to caesarean (OR 1.45; 95%CI: 1.29-1.64) 3-6 months postpartum. However, a vaginal delivery without laceration or instrument assistance did not create a higher risk of FI than the risk with caesarean delivery. Being overweight (body mass index >30 kg/m²), pushing for greater than two hours, and constipation were independently associated with postpartum FI (p < 0.05) regardless of route of delivery.

A self-administered survey of FI symptoms and delivery events administered to 50 women at six weeks postpartum, showed that vaginal delivery was associated with an increased risk of any FI symptom in comparison with caesarean section (43% vs. 20%) [166].

1.3. Pelvic Organ Prolapse

The occurrence rate of pelvic organ prolapse (POP) stage ≥2 in the first 3-6 months postpartum has been described in literature between 18.1-56% [170-172].

In a cross-sectional study of 382 primigravid women, pelvic organ support was explored 6 months postpartum: POP-Q stage ≥II was present in 7.7%, 18.1% and 29% of women who delivered by caesarean section, spontaneous and instrumental vaginal delivery, respectively. Spontaneous vaginal delivery increased the risk by more than three times (OR 3.19) while instrumental vaginal delivery increased it more than five-fold (OR 5.52) in comparison with caesarean section. Instrument-assisted delivery did not increase the risk of prolapse in women who delivered vaginally. The authors concluded that caesarean section is associated with a lower prevalence of POP after delivery and instrument assisted delivery is not associated with an increased risk of postpartum prolapse among women who delivered vaginally [170].

In the cohort study extracted by the nationwide Swedish Medical Birth Registry [162], POP surgery was observed in 2.2% of vaginal deliveries and 0.2% of caesarean sections (follow-up time 25.9 years). Among women only having had vaginal deliveries, rates of POP surgery increased with number of childbirths. In the caesarean delivery cohort, rates of POP surgery slightly decreased with increasing parity number. Compared with a caesarean delivery, the risk of POP surgery was increased nine-fold both after non-instrumental vaginal delivery and after vacuum extraction, whereas among women with forceps delivery a twenty-fold increase in risk was observed. The incidence rate of POP in women with caesarean deliveries showed very little variation over time, but started to diverge more notably from the vaginal delivery cohort 10 years after the first birth (Figure 5B).

The association between caesarean section and POP was investigated by Larsson et al. [173]: the Swedish Hospital Discharge Registry was used to identify women with an inpatient diagnosis of POP, and the data were linked to the Swedish Medical Birth Registry. A total of 1.4 million women were investigated. A strong and statistically significant association between caesarean section and POP was found (Adjusted OR 0.18 [95% CI: 0.16-0.20] and overall hazard ratio=0.20 [95% CI: 0.18-0.22]). The authors concluded that caesarean section is associated with a lower risk of POP than vaginal delivery.
A registry-based national cohort study carried out by Gyhagen et al. [174], demonstrated that the prevalence of symptomatic POP (sPOP) was doubled after vaginal delivery compared with caesarean section, two decades after one birth. Infant birthweight and current BMI were risk factors for sPOP after vaginal delivery. The same authors demonstrated that the prevalence of SUI, UUI and mixed UI was higher and moderate to severe UI and bothersome UI were reported more often after vaginal delivery than caesarean section 20 years after one delivery [175]. Moreover, the late prevalence of UI, sPOP, and FI were almost identical between vacuum extraction (VE) and spontaneous vaginal delivery (SVD). VE almost tripled the rate of obstetric anal sphincter injury (OASI) compared with SVD (6.3 vs. 2.4 %, p < 0.001). FI rate after an OASI was similar for both VE and SVD (30.2 vs. 27.8 %, adjusted odds ratio (aOR) 1.12; 95 % confidence interval (CI) 0.49-2.56). Comparing VE without laceration, VE complicated by OASI increased the rate of FI (from 15.4 to 30.2 %, aOR 2.55; 95 % CI 1.26-5.15) and UI (from 39.0 to 61.4 %, aOR 2.28; 95 % CI 1.19-4.34), but the rate of sPOP was almost unaltered (from 15.0 to 15.9 %).

The incidence rate of UI and AI during pregnancy in previously continent women has been reported as 39.1% and 10.3% respectively. Age, baseline body mass index, and family history of UI were significantly associated with the occurrence of UI during pregnancy, while age and excess weight gain during pregnancy were associated with the occurrence of AI during pregnancy. The identified risk factors for both incontinences postpartum were incontinence during pregnancy and vaginal delivery. LEVEL OF EVIDENCE II [176].

About half of all women develop transient UI during pregnancy [163], SUI in pregnancy was a significant predictor for postpartum incontinence. The weight of the women and duration of their labor were also significantly associated with the development of SUI postpartum [177]. Women with incontinence before pregnancy were nearly three times more likely to have postpartum incontinence [178].

Among 272 eligible women attending a follow-up visit at two years postpartum, 26 (9.5%) women reported persistent SUI since pregnancy. A higher BMI in pregnant women at term was recognized as an independent risk factor for the persistence of SUI from pregnancy to two years post-partum [179].

Fear of birth is a frequent indication for caesareans demanded by the patient [180, 181]. A cross-sectional study based on the Norwegian Mother and Child Cohort Study (n=58,881), reported that 6% of the sample preferred caesarean over vaginal delivery in week 30 of pregnancy; 16% reported “fear of giving birth” as the reason for caesarean preference [182]. A general fear of pelvic floor trauma was cited as the most common reason for this choice [183]. Despite being based on incomplete prognostic data, this feeling may be echoed increasingly among obstetric patients and may lead to an unsought, and even misguided, increase in caesarean delivery rates.

However, so far, there is no evidence from randomised controlled trials, upon which to base any practice recommendations regarding planned caesarean section for non-medical reasons at term in order to avoid pelvic floor symptoms in a woman without previous disorders. This has been demonstrated by Lavender et al. [184]; their aim was to find out, from randomized trials, the effects on perinatal and maternal morbidity and mortality, and on maternal psychological morbidity, of planned caesarean delivery versus planned vaginal birth in women with no clear clinical indication for caesarean section. A search of the Cochrane Pregnancy and Childbirth Group’s Trials Register (December 2005), MEDLINE (1974 to April 2005), EMBASE (1974 to April 2005), CINAHL (1982 to April 2005) and PsycINFO (1887 to April 2005) was carried out. The selection criteria were the following: comparisons of intention to perform caesarean section and intention for women to give birth vaginally; random allocation to treatment and control groups; adequate allocation concealment; women at term with single foetuses with cephalic presentations and no clear medical indication for caesarean section. No studies were identified that met the inclusion criteria [184].

To our knowledge, scientific data are insufficient to justify an elective caesarean section in order to avoid pelvic floor symptoms in a woman without previous disorders [185], considering that pregnancy itself may be involved in the development of such dysfunctions.

A systematic review of Cochrane assessed the ability of caesarean delivery (CD), in comparison to vaginal delivery (VD), to preserve anal continence: 21 reports have been found eligible for inclusion, encompassing 31,698 women having had 6,028 CDs and 25,170 VDs, as the index event prior to anal continence assessment. Only one report randomised women (with breech presentation) to CD or VD, but because of extensive cross-over, 52.1% after randomization, it was analysed along with the other 20 studies as treated, i.e. as a non-randomised trial. Only one of these reports demonstrated a significant benefit of CD in the preservation of anal continence, a report in which incontinence incidence was extremely high, 39% in CD and 48% in VD, questioning, relative to other reports, the timing and nature of continence assessment. The authors did not find any difference in continence in women who had an emergency versus elective CD. They concluded that, without demonstrable benefit, preservation of anal continence should not be used as a criterion for choosing elective primary CD [186].

PREGNANCY, CHILDBIRTH AND THE PELVIC FLOOR | 377
2. EFFECTS OF PREGNANCY ON PELVIC FLOOR FUNCTION

2.1. Effect on Collagen

Despite the great advances that have been made in many areas of obstetric care, the effect of pregnancy on the morphology and function of the pelvic floor is still mostly unknown. Prospective data assessing the severity of urinary and anal incontinence during pregnancy are scarce.

During pregnancy, hormones affect the biochemical composition of the solid matrix and hydration phases constituting each pelvic floor tissue. Remodelling mechanisms lead to changes in the organisation, orientation, and diameter of the collagen fibres as well as the crimp structure of the collagen fibrils reinforcing each tissue. Such effects can significantly affect the short and long-term viscoelastic properties of the vaginal wall, the pubovisceral muscles, and the perineal body, for example. They will largely determine (a) the extent and rate at which these structures can be stretched by an expulsive force acting cyclically on the foetal head, and (b) the resistance to stretch provided by those structures. The more a tissue exhibits creep behaviour, the further it will stretch under a constant load. And the more it exhibits relaxation behaviour, the more the stress in a tissue will decrease over time when held at a constant length, thereby helping to lower the risk of rupture in the next loading cycle. Were a tissue to exhibit viscoplasticity, it would behave as a solid below a critical level of stress, but above that level, it would flow like a viscous liquid. There is evidence that tensile failure in some soft tissues can be predicted by the product of the stress times the strain extent in the tissue, so mechanisms that lower one or both these variables will reduce the risk of rupture. Pregnancy is known to significantly affect the instantaneous stiffness and relaxation behaviour of vaginal tissues in rats. However, accurate data are lacking for pregnant human pelvic floor tissues, and the effects of pregnancy on injury at any tissue level, and on structural failure, are as yet largely unknown [187].

Changes in collagen may result in greater mobility of the bladder neck resulting in stress incontinence. In a study of 116 primigravidae, perineal ultrasound was used to assess bladder neck mobility. Women with antenatal bladder neck mobility of more than 5mm on linear movement (equivalent to >108° rotation) were found to be at higher risk of developing postpartum stress incontinence. Approximately 50% of this group reported stress incontinence at 3 months postpartum [188].

There may be a group of women at an inherent increased risk of developing incontinence due to abnormalities in collagen [189], as the collagenous component of the connective tissue contributes to structural support of the bladder neck. In pregnancy, the tensile properties of the connective tissue are reduced, with a reduction in total collagen tissue and increase in glycosaminoglycans [190].

2.2. Natural History

Distinguishing the time of onset, severity, and persistence of urinary and anal incontinences during and after pregnancy may provide an insight into the natural history of incontinence, and hence in the differences between transient incontinence due to the hormonal and mechanical effects of pregnancy and the damage that may occur as a result of delivery [176].

Solans-Domenech et al. [176] have brought to light the high incidence of UI and AI over the three trimesters of pregnancy, and particularly in the second trimester. In this cohort study, an incidence rate of UI during pregnancy of 39.1% and 10.3% of AI was found.

Figure 6: Evolution of the severity of urinary incontinence symptoms by time of data collection. From: Solans-Domenech. Incontinence During Pregnancy and Postpartum. Obstet Gynecol 2010 [176].

Figure 6 shows the evolution of severity of UI by data collection time, as well as the changes in trends between slight and moderate UI, with a tendency for slight to become moderate UI. The correlation between the severity of UI and level of interference in daily living was moderate but statistically significant in all periods of data collection with correlation coefficients of 0.35, 0.13, 0.46, and 0.47 for the first, second, and third trimesters and postpartum, respectively.

The same authors [191] showed in a cohort study of healthy, nulliparous, continent pregnant women, that symptoms of double incontinence are prevalent during first pregnancy; age and other intrinsic factors may favour the occurrence of double incontinence throughout gestation, while instrumental delivery and episiotomy increase the risk of double incontinence in the postpartum period.

Huebner et al [192] confirmed that pregnancy itself may influence pelvic floor function in a different way compared with vaginal delivery: in 411 pregnant women, the prevalence of UI increased significantly in the second half of pregnancy (26.3%, P<0.001).
Although the overall number of women who reported UI within 6 weeks after delivery was almost the same as the number reporting UI in the second half of pregnancy, approximately every second woman changed from being continent to incontinent and vice versa.

Ten percent of women presented with AI at some point during pregnancy: the prevalence of AI in this study cohort is 2.3%, 6.8% and 7.4% in the first, second and third trimesters. The presence of AI was characterised by loss of flatus in more than 90% of cases and common to all periods. LEVEL OF EVIDENCE: II [176].

In a prospective population-based cohort study, Johannessen et al [193], involving 1571 pregnant women, one in four primiparæ experienced AI in late pregnancy; one year later, one in five still suffered from incontinence. Sphincter injury predicted incontinence of stool and flatus, whereas greater age and operative delivery predicted urgency. The authors suggest that identification and adequate follow-up of pregnant women with AI may reduce postpartum AI.

The prevalence of urinary and anal incontinence in a subgroup of pregnant women, constituted of African American adolescents (age: 14-19 years) in the third trimester, resulted in: 44% of patients complaining of UUI and 43% of SUI; 12% complained of faecal and flatal incontinence [194].

Incontinence during pregnancy has been linked to age [195], body mass index [196], strenuous physical exercise [197] and smoking history [196].

The risk of UI increases in pregnant women aged more than 35 years, in women who are overweight or obese at baseline, and in those with a family history of UI, while the risk of AI rises with age and excessive weight gain during pregnancy [176]. Weight gain greater than the 50th percentile during weeks 0–15 of pregnancy was weakly associated with higher incidence of UI at week 30 compared with weight gain less than or equal to the 50th percentile [198].

The data regarding the relationship between UI during pregnancy and its persistence or worsening condition postpartum are controversial: the results of Solans-Domenech et al. [176] showed that the occurrence of UI and AI during pregnancy is related to the presence of incontinence in the postpartum period, and vaginal delivery increases the risk of persistent incontinence. On the other hand Wesnes et al [199] concluded that the association between incontinence postpartum and mode of delivery is not substantially influenced by incontinence status in pregnancy and the prediction of a group with high risk of incontinence according to mode of delivery cannot be based on continence status in pregnancy.

2.3. Familial Predisposition

A familial predisposition in the aetiology of UI has also been considered, but the results are still controversial. Buchsbaum et al. [200] investigated the role of vaginal delivery and familial factors in the development of UI by comparing the prevalence of this condition in nulliparous women and their parous sisters. Among this sample of biological sisters, UI was reported by 47.6% of nulliparous women and by 49.7% of parous women (P =0.782). Considering the high concordance in continence status between sister pairs, and considering that the majority of parous women are continent, an underlying familial predisposition toward the development of UI may be present. LEVEL OF EVIDENCE II-2.

Nguyen et al. [201] analysed a large population comprising 1530 identical and 234 non-identical female twins (mean age 41.3 years), who answered a specific questionnaire focusing on symptoms of UI. The two groups were comparable in terms of age, race, parity, BMI, menopausal status, tobacco use, mode of delivery and prior pelvic surgery. The authors demonstrated that environmental factors contributed significantly to the occurrence of SUI (shared environmental factors contribute 77.6% of the variance, unique environmental factors contribute to 20.9% of the variance; p<0.001). The heritability of SUI was not statistically significant for the contribution of the phenotypic variance (1.49%; p=0.46). Additional analyses were performed on the subgroup of women without prior incontinence or prolapse surgery (638 twin pairs) and in the subgroup of twins with “pure stress urinary incontinence” (458 twin pairs): the results in this cohort of patients showed no genetic influence. The authors point out that environmental factors (in particular obstetrical events) play a dominant role in middle-aged women; genetics contributed more toward the development of SUI in elderly women, as reported by Rohr et al. [202]; “nurture” before menopause and “nature” during aging. LEVEL OF EVIDENCE II.

3. PATHOPHYSIOLOGIC MECHANISM OF BIRTH INJURY TO THE PELVIC FLOOR

Strong epidemiological evidence links vaginal childbirth and the development of postpartum incontinence and prolapse.

There would seem to exist four major mechanisms by which vaginal delivery might contribute to the pelvic floor trauma: a) muscle trauma, b) connective tissue damage, c) nerve injury, d) vascular damage.

3.1. Muscle Trauma

The effect of delivery on muscular structure has been widely investigated, either with computer models, MRI and ultrasound. In a three-dimensional computer model Lien et al. [203] predicted levator ani muscle (LAM) stretch during vaginal birth. Serial magnetic resonance images from a healthy nulliparous 34-year-old woman, and engineering graphics software,
were used to construct a structural model of the levator ani muscles along with related passive tissues. The model was used to quantify pelvic floor muscle stretch induced during the second stage of labor as a model in which the foetal head progressively engaged and then stretched the iliococcygeus, pubococygeus and puborectalis muscles. The largest tissue strain reached a stretch ratio (tissue length under stretch/original tissue length) of 3.26 in the medial pubococcygeus muscle, the shortest, most medial and ventral LAM. Regions of the ileococcygeus, pubococcygeus, and puborectalis muscles reached a maximal stretch ratio of 2.73, 2.50, and 2.28, respectively. Tissue stretch ratios were proportional to foetal head size: for example, increasing foetal head diameter by 9% increased medial pubococcygeus stretch by the same amount. The authors demonstrated that the medial pubococcygeus muscles undergo the largest stretch of any levator ani muscles during vaginal birth and it is therefore at the greatest risk of stretch-related injury [203] (Figure 7).

Svabik et al. [204] showed that the area of the levator hiatus needs a distension of between 25% and 245% to allow the passage of the foetal head, considering as average a cross-sectional foetal head area of 68 cm², based on Caucasian biometric data.

The occurrence rate of postpartum levator avulsion in primiparae, diagnosed with 3D-4D ultrasound between 24 hours and 9 months after vaginal delivery, is reported between 15-39.5% [205-211]. The incidence of levator trauma evaluated with MRI is reported between 17.7%-19.1% 6-12 months postpartum [212-215].

A study published by Novellas et al. [212], reported an occurrence of 19.1% levator abnormalities diagnosed with MRI in primiparae submitted to caesarean section and they found that patients who underwent emergency caesarean sections had 2.7 times more abnormalities than patients who underwent elective caesarean. Only one study in literature reported 4 cases of levator defect diagnosed with 3D ultrasound following emergency caesarean section [210].

Avulsion of the pubovisceral muscle seems to occur more frequently after forceps delivery than after spontaneous vaginal delivery: 1-12 months postpartum the occurrence rate of levator avulsion after forceps reaches the incidence rate of 59-72% [205, 216]. Kearney et al. [217] compared LAM injury rates in primiparous women who had a forceps delivery owing to foetal distress, with women delivered by forceps for second stage arrest; they compared these injury rates with a historical control group of women who delivered spontaneously. The major defect rates were 42% for women who delivered by forceps with a short second stage; 63% for women who delivered by forceps and had a prolonged second stage; and 6% for spontaneous delivery. The odds ratios for major injury were: 11.0 for forceps and short second stage compared with spontaneous delivery; 25.9 for forceps and second stage arrest compared with spontaneous delivery; and 2.3 for forceps and second stage arrest compared with spontaneous delivery; and 2.3 for forceps and second stage arrest compared with spontaneous delivery (p=0.07). These authors also confirmed that women delivered by forceps have a higher rate of levator ani injury compared with spontaneous delivery controls, but the length of the second stage of labor does not influence the effect of the forceps on the LAM.

Several obstetric factors associated with the occurrence of levator avulsion have been investigated: Valsky et al. [207] reported that a foetal head circumference ≥35.5 cm and a second stage of labour ≥110 min, increased odds of LAM trauma by a factor of 5.32. DeLancey’s group [215] demonstrated that injuries to the levator ani muscles in women after their first vaginal delivery are associated with forceps use.
Apical support led to an increase in anterior wall prolapse: a 90% impairment of the pubovisceral muscle, the larger the genital hiatus opened and a prolapse developed; the authors stated that once a cer-
cerative levator ani deficiency had 6.4 times the odds of prolapse compared with patients with a minimal defect; and no patients with stage 3 prolapse had less than moderate levator ani deficiency, and no patients with stage 4 prolapse had less than mild levator ani deficiency, and no patients with stage 4 prolapse had less than moderate levator ani deficiency. In patients with prolapse, those with moderate levator ani deficiency had 3.2 times the odds of POP compared with patients with a minimal defect; those with severe levator ani deficiency had 6.4 times the odds of prolapse than those with minimal def-
cency severity is associated with clinically significant prolapse: no patients with stage 3 prolapse had less than mild levator ani deficiency, and no patients with stage 4 prolapse had less than moderate levator ani deficiency. In patients with prolapse, those with moderate levator ani deficiency had 3.2 times the odds of POP compared with patients with a minimal defect; those with severe levator ani deficiency had 6.4 times the odds of prolapse than those with minimal def-
cency. (LEVEL OF EVIDENCE: II)

The aetiological role of LAM integrity in bladder dys-
function is still not completely clear. A weakly signifi-
cant association between levator avulsion and wors-
ening or de novo UI has been reported 3 months post-
partum, through the use of ultrasound [209]. Recent evidence questions this link, reporting that women with major levator defect diagnosed by MRI are less likely to experience SUI [222], and that puborectalis trauma evaluated by ultrasound is not associated with an increased risk of SUI or urodynamic stress inconti-
tence [223].

The involvement of urethral function in the presence of levator avulsion has been approached recently, considering that it is often assumed that SUI may be due to abnormal pelvic floor muscle function or anatomy. Brincat et al [224], found no significant associa-
tion between maximal urethral closure pressure (MUCP) and urethral closure pressure with a pelvic floor contraction or Kegel (KUCP) in women with or without LAM defects (p = 0.94, p = 0.95). Additionally, there was no correlation between MUCP and vaginal closure force (r = 0.06, p = 0.41), and there was a weak correlation between KUCP and vaginal closure force (r = 0.20, p = 0.01). They conclude that urethral pressure profiles are unrelated to LAM defect status after vaginal birth, indicating that the mechanism re-
sponsible for LAM damage spares the urethra. Shek et al. [211], demonstrated that except at the bladder neck, there was no significant association between urethral mobility and avulsion.

In regard to anorectal function, Heilbrun et al. [213] showed a weak trend towards more FI in women with LAM avulsion and anal sphincter tears, but the interpre-
tation of these results must take into account that this is a rather select group, with a special set of risk factors.

One might speculate as to how 85–90% of first time mothers can undergo vaginal birth without the foetal head overstretching and rupturing the U-shaped loop of pubovisceral muscle tissue. One possibility is that the structure that lies in series with this muscle could protect it by stretching more than the muscle itself, just as a fusible link protects the wiring harness of an automobile against an electrical short. That structure, the perineal body, located between the vagina and rectum and comprised of relatively soft connective tis-
sue, has material properties that do appear to change in late pregnancy, but these remain to be quantified [187].

3.2. Nerve Injury

A geometric model has been used to predict the stretch ratios in the nerves innervating the levator ani, urethra, and anal sphincter during the second stage of vaginal labour [225]. The results showed that the inferior rectal branch exhibited the maximum strain, 35%, and this strain varied by 15% from the scenario with the least perineal descent to that with the most perineal descent. The strain in the perineal nerve branch innervating the anal sphincter reached 33%, whereas the branches innervating the posterior labia and urethral sphincter reached values of 15% and 13%, respectively. It was concluded that during the second stage (a) nerves innervating the anal spincter are stretched beyond the 15% strain threshold known to cause permanent damage in the non-preg-
nant appendicular nerve, and (b) the degree of perineal descent is shown to influence pudendal nerve strain.

Pudendal nerve lesions usually result in demyelination of the fibres; axonal breaks may occur in severe cases where there is no recovery of the tissues [226]. c-Fos expression (an early reactive nerve injury marker) in the L6 to S1 spinal cord segments was observed in rats after simulated birth trauma, indicating acute nerve injury or irritation in spinal neurons. Also, histological studies have revealed a marked decrease of ganglion cells in the neural plexuses posterior to the vagina in rats after simulated birth [227].

Neuromuscular abnormal pelvic floor activation patterns may also contribute to the development of postpartum pelvic floor disorders [228-230]. Electroneurography studies have shown that 80% of primigravidae developed evidence of partial denervation with signs of reinnervation and increase in the density of nerve fibres in the postpartum period after vaginal delivery [231, 232]. The latency time of pudendal nerve motor fibres increased after two to threedays following vaginal delivery, but values normalised after six months in 66% [232]. Most nerve lesions spontaneously recover within a year by regenerative processes [226]. However, pudendal nerve damage, even with partial reinnervation of the external anal sphincter muscle, may persist and become more marked in the long term [233]. Neurophysiological tests revealed nerve damage in 36% of women with persistent SUI at 3 months postpartum. Compared with nulliparous control subjects, patients with SUI and POP had changes in the levator ani and external anal sphincter consistent with either motor unit loss or failure of central activation, or both [234].

4. PERINEAL TRAUMA

4.1. Epidural Analgesia During Labour

Regional anaesthesia for the relief of labour pain has become more popular during the past 20 years. Despite interest in its possible obstetric consequences, little attention has been paid to its potential effects on the pelvic floor and perineal injury.

The available published data describe controversial results. Some studies suggest that epidural analgesia, by enabling relaxation of the pelvic floor, leads to greater control of crowning of the foetal head and consequently fewer perineal lacerations [235], but prolongation of the second stage may also increase the incidence of pudendal nerve damage [236, 237].

Robinson et al. [238] examined whether epidural analgesia is associated with differences in rates of severe perineal trauma during vaginal deliveries. Among women who had epidurals, 16.1% (221/1376) had severe perineal lacerations compared with 9.7% (55/566) women who did not have epidurals (P < 0.001; OR 1.8, 95% CI: 1.3-2.4). When controlling for birth weight, use of oxytocin, and maternal age in logistic regression analysis, epidural remained a significant predictor of severe perineal injury (OR 1.4, 95% CI: 1.0-2.0). Epidural use is consistently associated with increased operative vaginal deliveries and consequent episiotomies, so the authors constructed a logistic regression model to evaluate whether the higher rates of those procedures were responsible for the effect of epidurals on severe perineal trauma. With operative vaginal delivery and episiotomy in the model, epidural was no longer an independent predictor of perineal injury (OR 0.9, 95% CI: 0.6-1.3). They concluded that epidural analgesia is associated with an increase in the rate of severe perineal trauma because of the more frequent use of operative vaginal delivery and episiotomy.

Carroll et al. [239], evaluated whether epidural analgesia was an independent risk factor for severe perineal laceration. Among women who had epidural analgesia, 10.25% (65 of 634) had severe perineal lacerations compared with 5.22% (111 of 2,125) of the women who did not have epidural analgesia. After controlling for major variables in a logistic regression analysis, epidural analgesia remained a significant predictor of severe perineal injury (OR 1.5, 95% CI = 1.0-2.1). A logistic regression model examining predictors of instrument use found that epidural analgesia does significantly predict instrument use (OR 3.01, 95% CI: 2.2-4.0). The author concluded that epidural analgesia is associated with an increase in severe perineal trauma as a result of an associated three-fold increased risk of instrument use. Instrument use in vaginal delivery more than triples the risk of severe perineal laceration.

No significant association between anal sphincter injury and the use of epidural anaesthesia was observed in 91 women in the retrospective study published by Christianson et al. [240]. On the other hand, Fitzgerald et al. [241] demonstrated that epidural was significantly associated with anal sphincter tear when the analysis was adjusted for maternal age, race, and gestational age.

In a study of 82 women, Meyer et al. [242] assessed the effects of epidural analgesia on pelvic floor function. Eighty-two primiparous women (consisting of 41 given an epidural and 41 not given an epidural) were investigated during pregnancy and at 2 and 10 months after delivery by a questionnaire, clinical examination, and assessment of bladder neck behaviour, urethral sphincter function and intravaginal/intra-anal pressures. Ten months after spontaneous delivery, there were no significant differences in the prevalence of SUI and decreased sexual vaginal response, or in bladder neck behaviour, urethral sphincter function and pelvic floor muscle strength between women who had or had not had epidural analgesia.

Sartore et al. [243] concluded that the use of epidural analgesia is not associated with symptoms related to
In a prospective observational study of 488 primiparae, Shek et al. [244], demonstrated with 3D ultrasound that intrapartum epidural appeared to have a protective effect (P=0.03; OR 0.42; 95% CI: 0.19-0.93) against levator trauma at the time of first delivery. Also Kearney et al. [215], using MRI, confirmed that epidural reduce the risk of developing a levator defect during vaginal delivery.

4.2. Role of Episiotomy

The episiotomy, a surgical incision in the perineum made to enlarge the vaginal opening and facilitate delivery, was originally introduced as a method assumed to improve maternal and neonatal outcomes and rapidly became a part of standard obstetric care. However, since the 1980s, routine use of episiotomy has been challenged, based on the lack of evidence of benefits of the procedure [245] and the publication of multiple studies reporting increased blood loss at delivery, perineal scar breakdown and infection, postpartum pelvic pain, and dyspareunia [246-249].

Nowadays routine episiotomy is not recommended any more. Various types of episiotomy have been described in the past (median, modified median, J-shaped episiotomy, mediolateral, lateral, radical lateral and anterior) in papers and textbooks (Figure 8). The description of mediolateral episiotomy (the most frequently used in Europe) in standard obstetrics textbooks differs widely; some publications provide only descriptive terms, the angle of incision varies between 31° and 63°, suggesting the wide potential variation in the practice of episiotomy worldwide.

Some studies deal with the different use of various episiotomies in different countries (e.g. UK, Finland and Greece) [251-254]. However randomised trials comparing alternative methods or position of episiotomy are lacking, resulting in Level 2b or Level 3 of evidence, only. To ensure Level 1 evidence from randomised trials, it needs a standardisation of the practice and reporting of the episiotomy incision. However, a standardized classification system has not been introduced yet, making it difficult to compare the various techniques. Even in the last Cochrane review of episiotomy, an exact classification or definition of episiotomies is lacking [255].

Some studies have demonstrated increased incidence of third and fourth-degree lacerations associated with the use of midline episiotomy [256, 257]. The resulting damage to the internal and external anal sphincters can lead to devastating long-term sequelae, including FI and rectovaginal fistulae [258].

To support the benefits of episiotomy, some clinicians have claimed that meticulous repair of a surgical episiotomy yields improved wound healing when compared with an unpredictable spontaneous laceration [246]. This assertion, however, has not been substantiated by evidence [259].

Kalis et al. [260] evaluated the results of mediolateral episiotomy with incision angle of 60°: the study group comprised 60 consecutively recruited primiparous women who required episiotomy during delivery. The results showed that the angles differed significantly among the incision (60°), repair (45°), and 6-month (48°) measurements (P < 0.001). There was a poor correlation between the suture angle and the angle measured at 6 months postpartum. No severe perineal tear was diagnosed in the cohort. At 6 months postpartum, only one woman reported mild symptoms of de novo AI, whereas 7 women reported perineal pain related to episiotomy.

Many institutions and individual obstetric practitioners have decreased their performance of episiotomy over the past 20 years, most likely as a result of practicing evidence-based medicine.

An electronic audit of the medical procedures database at Thomas Jefferson University Hospital from 1983 to 2000 was completed to determine if practice patterns have been altered by the large body of literature strongly advocating the selective use of episiotomy. Overall episiotomy rates in 34,048 vaginal births showed a significant reduction from 69.6% in 1983 to 19.4% in 2000. Significantly decreased risk of episiotomy was seen based upon year of childbirth (OR 0.87, 95% CI: 0.86-0.87), black race (OR 0.29, 95% CI: 0.28-0.31), and spontaneous vaginal delivery (OR 0.40, 95% CI: 0.36-0.45). Increased association with
episiotomy was seen in forceps deliveries (OR 4.04, 95% CI: 3.46-4.72), and with third or fourth-degree lacerations (OR 4.87, 95% CI: 4.38-5.41). This study demonstrates a statistically significant reduction in the overall episiotomy rate between 1983 and 2000. White women consistently underwent episiotomy more frequently than black women, even when controlling for age, parity, insurance status, and operative vaginal delivery [249].

A population-based register of 514,741 women with singleton vaginal deliveries recorded in the Finnish Medical Birth Register was reviewed. Primiparous and multiparous women who had undergone episiotomy were compared to women who had not undergone episiotomy, for possible risk factors. The occurrence of episiotomy decreased from 71.5% in 1997-1999 to 54.9% in 2006-2007 among primiparous women, and from 21.5% in 1997-2001 to 9.2% in 2006-2007 among multiparous women. The use of episiotomy decreased in not only low-risk but also high-risk women who had operative vaginal or breech deliveries, macrosomic newborns, and oxytocin augmentation. The ratio of episiotomy use remained relatively unchanged in different subgroups even though episiotomy policy became increasingly restrictive over time. The authors concluded that the spectrum of episiotomy indications has not changed over time, and use of episiotomy has declined arbitrarily to a similar extent among high and low-risk women [261].

To identify the risk factors for obstetric anal sphincter rupture (OASR), a retrospective population-based register study was carried out. A total of 514,741 women with singleton pregnancy and vaginal delivery between 1997 and 2007 in Finland were recruited. Episiotomy decreased the likelihood of OASR for the primiparous [OR 0.83, 95% CI: 0.75-0.92], but not the multiparous women (OR 2.01, 95% CI: 1.67-2.44). Episiotomy was associated with decreased risks for obstetric anal sphincter rupture in vacuum assisted deliveries (OR 0.70, 95% CI: 0.57-0.85). These results support the restrictive use of episiotomy, since 909 episiotomies appear to be needed to prevent one OASR among primiparous women. The equivalent estimate in vacuum assisted deliveries among primiparous women was 66, favoring routine use of episiotomy in such cases [253].

Robinson et al. [262], carried out a study to identify factors associated with the use of episiotomy at spontaneous vaginal delivery. They studied 1576 consecutive term, singleton, spontaneous vaginal deliveries; the association of demographic variables and obstetric factors with the rate of episiotomy use were examined. The overall rate of episiotomy was 40.6% (640 of 1576). Midwives performed episiotomies at a lower rate (21.4%) than faculty (33.3%) and private providers (55.6%) (P = 0.001). After controlling for confounding factors with logistic regression, private practice provider was the strongest predictor of episiotomy use (OR 4.1, 95% CI: 3.1-5.4) followed by faculty provider (OR 1.7; 95% CI:1.1-2.5), prolonged second stage of labour (OR 1.8; 95% CI: 1.2-2.7), foetal macrosomia (OR 1.6; 95% CI: 1.1-2.5), and epidural analgesia (OR 1.4 95% CI: 1.1-1.8). The authors conclude that the strongest factor associated with episiotomy at delivery was the category of obstetric provider. Obstetric and demographic factors evaluated did not readily explain this association.

A study was carried out to lower the episiotomy rate through physician education and to document the indication when episiotomy was performed. The intervention consisted of an evidence-based lecture recommending limited usage of episiotomy and requesting documentation of any indication for episiotomy. Data 3 months prior to the intervention were compared to those of the following year. For all vaginal deliveries, there was a 17% decrease in the rate of episiotomy, from 46.9% to 38.8%. For spontaneous vaginal deliveries, there was a 25% decrease in the episiotomy rate, from 40.8% to 30.8%. The most common indications for episiotomy reported were routine/elective, 41.0%; vacuum, 18.6%; forceps, 16.4%; and non-reassuring foetal heart tracing, 10.9% [263].

A review was conducted of women with consecutive vaginal deliveries at Magee-Women’s Hospital between 1995 and 2005 to evaluate the episiotomy exposure at first vaginal delivery. A total of 6,052 patients were included, of whom 47.8% had episiotomy at first delivery. Spontaneous second-degree lacerations at the time of second delivery occurred in 51.3% of women with history of episiotomy at first delivery, compared with 26.7% without history of episiotomy (P<0.001). Severe lacerations (third or fourth-degree) occurred in 4.8% of women with history of episiotomy at first delivery compared with 1.7% without history of episiotomy (P<0.001). Prior episiotomy remained a significant risk factor for second-degree (OR 4.47, 95% CI: 3.78-5.30) and severe obstetric lacerations (OR 5.25, 95% CI: 2.96-9.32) in the second vaginal delivery after controlling for confounders. Based on these findings, for every four episiotomies not performed, one second-degree laceration would be prevented. To prevent one severe laceration, performing 32 fewer episiotomies is required. Episiotomy at first vaginal delivery increases the risk of spontaneous obstetric laceration in the subsequent delivery. This finding should encourage obstetric providers to further restrict the use of episiotomy. LEVEL OF EVIDENCE II [264].

In a recent study of Bø et al [265], aiming to compare vaginal resting pressure, pelvic floor muscle strength and endurance and prevalence of UI at 6 weeks postpartum in women with and without episiotomy, the authors conclude that pelvic floor muscle function and prevalence of postpartum UI were not affected by a lateral or mediolateral episiotomy.

In a biomechanical analysis on the impact of episiotomy during childbirth, Oliveira et al. [266] demonstrated that a mediolateral episiotomy has a protective effect, reducing the stress on the muscles, and the force required to delivery successfully up to
52.2%. The intervention also has benefits on muscle injury, reducing the damage to a small zone.

5. CONCLUSIONS AND RECOMMENDATIONS

a) Prevalence of UI after vaginal delivery is double than after caesarean section [158]. Caesarean section seems to decrease the risk of postpartum UI [159, 160], but its protective effect seems to diminish over time and disappears after multiple deliveries [160, 161]. Risk of SUI is estimated to be 2.9 times higher after vaginal delivery compared with women after caesarean section [162]. Information as to whether caesarean done before labour confers greater protection than caesarean done after labour is lacking. To understand the true impact of caesarean delivery on UI, future studies must compare incontinence by planned delivery modes.

b) De-novo AI symptoms after child-birth are described as up to 26-38% between 6 weeks-6 months postpartum [164-169]. Vaginal delivery has a greater risk of FI compared to caesarean 3-6 months postpartum [164] [166]. It is recommended extending postpartum follow-up visits beyond the typical 6-8 weeks to provide surveillance for potential incontinence. LEVEL OF EVIDENCE: II.

c) POP rate in the first 3-6 months postpartum is reported between 18.1-56% [170-172]. Spontaneous vaginal delivery increased the risk by more than three times while instrumental vaginal delivery increased it more than five-fold in comparison with caesarean section [170]. Caesarean section has a protective effect on occurrence of POP [173].

d) The occurrence of UI and AI during the postpartum period is related to the presence of incontinence in pregnancy, and vaginal delivery increases the risk of persistent incontinence. LEVEL OF EVIDENCE II [176].

e) So far, there is no evidence from randomized controlled trials, upon which to base any practice recommendations regarding planned caesarean section for non-medical reasons at term or to avoid pelvic floor symptoms in a woman without previous disorders, considering that pregnancy itself may be involved in the development of such dysfunctions [184-186].

f) Obstetrics factors associated with the occurrence of LAM trauma postpartum: forceps use, foetal head circumference ≥ 35.5 cm, second stage of labour ≥110 min, anal sphincter rupture, episiotomy. LEVEL OF EVIDENCE II-3. Levator ani avulsion is associated with the occurrence of pelvic organ prolapse later in life, but the role of LAM integrity in bladder and anorectal dysfunctions are still not completely clear.

g) Epidural analgesia during labour: controversial results regarding its potential effect on the pelvic floor and perineal injury. There is a lack of prospective, randomised trials, requiring further research and development in order to draw recommendations.

h) Randomized trials comparing alternative methods or position of episiotomy are lacking, resulting in Level IIb or Level III of evidence, only. To ensure Level 1 evidence from randomized trials, it needs a standardisation of the practice and reporting of the episiotomy incision. The actual evidence shows that episiotomy is associated with 3rd-4th degree of perineal laceration and with an increased risk of spontaneous obstetrics laceration in the subsequent delivery. These findings encourage restriction of routine use of episiotomy. LEVEL OF EVIDENCE II.

IV. PATHOPHYSIOLOGY OF STRESS INCONTINENCE IN WOMEN: URETHRAL STRUCTURE, SUPPORT AND FUNCTION

The factors necessary for the urethra to remain closed at rest and during increased abdominal pressure have been well characterised, but their functional inter-relationships are still not fully understood. These factors include: 1) healthy, functioning striated sphincter controlled by pudendal innervation, 2) well vascularised urethral urothelium and sub-mucosa, 3) properly aligned and functioning intrinsic urethral smooth muscle, and 4) intact vaginal wall support.

1. THE FEMALE UROGENITAL DIAPHRAGM: URETHRAL SPHINCTER LOCATION

Detailed descriptions of the striated urogenital sphincter muscle have been made by Max Brodel working with Howard Kelly [267], Oelrich [268] and further expanded by DeLancey [269]. These reports have provided clear descriptions of the urethral rhabdosphincter. The location of the sphincter elements can be understood by dividing the urethral lumen into 5 equal segments. The first 20% is surrounded by the bladder muscle and detrusor loop, the next 40% is surrounded by a sleeve of striated muscle that forms the sphincteric portion of the striated sphincter. Next, from 60 to 80% two arch shaped bands of muscle diverge from the wall of the urethra to surround the vagina (urethrovaginal sphincter) and
perineal membrane (compressor urethrae). Manometric and electrophysiological recordings from the mid-urethra have shown that it generates the highest level of resting pressure and electromyographic activity.

This portion of the urethra is an intra-pelvic structure located immediately posterior to the pubic bone. In the past, much has been made of the loss of this intra-pelvic position in stress incontinence. It had been suggested that when the urethra descended away from its intra-abdominal position, intra-abdominal forces no longer constricted it during straining. This concept has survived and been modified into the “hammock hypothesis” [270] which suggests that the anterior vaginal wall provides a backboard against which increasing intra-abdominal forces compress the urethra. The anterior vaginal wall is stabilized by its lateral attachments to the arcus tendineus fascia pelvis and levator ani muscle. Data supporting this hypothesis are drawn from urethral pressure transmission studies showing that continent patients experience an increase in intra-urethral pressures during coughing. This pressure increase is lost in stress incontinence and may be restored following successful operations designed to stabilize or elevate the sub-urethral vaginal wall [271-280].

The urethra is supported by the anterior vaginal wall. The superior vaginal sulcus, most clearly found in nullipara, exists at this junction of the lower and middle third of the vaginal wall. This point represents the two lateral insertion points of the vaginal “hammock”. Portions of the pubococcygeus muscle attach to these sulci within the pelvis and can produce elevation during voluntary contraction.

Immediately anterior to the proximal urethra are found the reflections of the endopelvic fascia. The most prominent of these, the attachments of the arcus tendineus fascia pelvis (sometimes referred to clinically as “pubo-urethral ligaments”), are sufficiently condensed to form distinct and recognisable ligaments on either side of the pubis where they attach to the pubic bone about 1 cm from the midline and 1 cm above the bottom of the pubis. These structures are continuous with a complex of tissues including the perineal membrane and levator ani. The arcus tendineus fascia pelvis, which can be seen at the time of retropubic surgery, is the more familiar of these.

This is a strong fascial condensation which most likely maintain their characteristics throughout life. Previous investigators have suggested that elongation of this structure may be responsible for the loss of urethral support seen in stress incontinence, yet objective evidence for this is lacking.

Different authors have described the striated urogenital sphincter (SUS) that has also been called the external urethral sphincter (EUS) by some authors, both in foetuses [281, 282] and adults [283] as a superior horseshoe structure covering the urethra and an inferior one surrounding the anterolateral aspect of the urethra and the lateral part of the vagina.

The LAM is involved in urethral support. Wallner et al. [284] investigated the topographical relationship between the EUS and the LAM (Figure 9, 10), showing that in female foetuses, but not in male, the inferior part of the EUS is firmly attached to the LAM by a tendinous connection. This determines an anterior bending of the midurethral zone when a simultaneous contraction of the LAM and EUS occurs, closing the urethra.

Figure 9: EUS in 18 weeks foetus: A anterior view, B lateral view, C oblique view, D superior view, E inferior view - From Wallner et al., Eur Urol 2009 [284].

Figure 10: The anatomical relationship of the EUS to the LAM in adults. Panels (A) through (D) show transverse sections through the EUS and the LAM of an adult female (54 yr): (A) superior part of the EUS (arrowheads), section stained immunohistochemically for striated muscle; (B) sequential section stained with sirius red for connective tissue; (C) inferior part of the EUS (arrowheads), section stained immunohistochemically for striated muscle; (D) sequential section stained with sirius red for connective tissue. Note in (C) that in the adult, the anatomical relationship between the inferior part of the EUS and the LAM is still maintained. The contrast of images (A) and (C) was increased digitally. L = levator ani muscle; U = urethra; V = vagina. From Wallner et al Eur Urol 2009 [284].
urethral lumen and maintaining continence. The functional integrity of this connection between the EUS and the LAM is therefore crucial to avoid UI.

The striated EUS, both in foetuses and adults, has a superior horseshoe structure covering the urethra and an inferior one surrounding the anterolateral aspect of the urethra and the lateral part of the vagina.

Moreover, while the lower one-third of the vagina is oriented more vertically in the nullipara, the upper two-thirds of the vagina deviate horizontally [285]. This orientation is due: 1) to the posterior attachments of the cervix by the cardinal and utero-sacral ligaments and 2) to the anterior position of the levator hiatus. Barium vaginograms have demonstrated this horizontal angulation of the upper two-thirds of the vagina, and show that during coughing and stressful manoeuvres, the levator hiatus is shortened in an anterior direction by the contraction of the pubococcygeus muscles. Thus, the pelvic organs receive support from the shape and active contraction of the levator muscles.

Modifications of the genital hiatus determining an increase in the genitohiatal distance can be associated with urodynamic stress incontinence (USI). In a retrospective study of 396 women with USI [286], pelvic floor ultrasound revealed a small but statistically significant negative association of the genitohiatal distance to urodynamic functional urethral parameters such as the functional profile length, the maximum urethral closure pressure and a low Valsalva leak point pressure (r = -0.148, P = 0.018 and r = -0.227, P = 0.009, r = -0.199, P = 0.02 respectively), that would explain about 5% of the observed variation.

2. EFFECT OF CHILDBIRTH, VAGINAL PROLAPSE AND URETHRAL POSITION ON URINARY CONTINENCE

Labour and delivery alter vaginal and pelvic anatomy and innervation in several ways as has been discussed in other sections of this chapter. Each of these may contribute to the eventual development of UI:

Direct crushing or traction on the pudendal nerve has been discussed above and has previously been suggested as a primary cause of sphincter incompetence in stress incontinence. The pudendal nerve, which projects from Onuf's nucleus and traverses Alcock's canal before entering the ischiorectal fossa and innervating the EUS, can be injured during vaginal delivery, particularly in the area between the sacrospinous and sacrotuberous ligaments. Two different mechanisms of pudendal nerve damage during delivery have been described: 1) nerve compression and stretching which may cause an elongation of the 13% of its motor branch innervating the EUS [287]; 2) a reduced at 8% stretch and complete ischemia at 15% stretch of the nerve as shown in a tibial nerve rat model [288]. Thus, pudendal nerve ischemia likely occurs during vaginal delivery as a result of both stretch and compression [289].

The vagina itself may be torn away from its intrapelvic attachments; some believe there is also subsequent loss of the superior vaginal sulcus. There may be direct attenuation of the vaginal wall itself, manifested by loss of vaginal rugae and a thin appearance. Cullen Richardson has suggested four distinct kinds of vaginal injuries: paravaginal, central, distal, and cervical, the first two being the most commonly seen in women with stress incontinence. These defects have been identified by sonographic examination [290].

Finally, detachment of the pubococcygeal (sometimes called pubovisceral) portion of the LAM [291], often described as stretching, tearing and avulsion of the levator muscles, result in a longer and wider levator hiatus. This is not due to nerve injury or muscle compression as sometimes suggested. Studies that are designed to evaluate differences between possible injury mechanisms to include muscle detachment from their origin, neuropathic atrophy and compression injury show evidence of direct injury but not compression or nerve damage as a cause for this injury [292]. Consequently, the perineum is displaced caudally and posteriorly under stress and temporarily fails to support the pelvic organs. These changes in the levator hiatus with or without associated relaxation of cervical support result in chronic anterior displacement of pelvic organs with a loss of both active and passive organ support during rest and especially during straining.

In the patient with USI these changes typically give rise to a rotational descent of the proximal urethra away from its retropubic position. Radiographic images of USI in women have noted this and generated our earliest concepts of this condition. Jeffcoate and Roberts [293], using lateral cystourethromgrams, concluded: "...the most common characteristic anatomical change, present in four out of five cases of incontinence, is loss of the posterior urethro-vesical angle so that the urethra and trigone tend to come into line."

In 2002, fifty years later, perineal sonographic studies of urethrovessical angle differences in incontinent and normal patients have found excellent correlation identified between angle and degree of incontinence, supporting these original observations [294].

The history of urethrovessical support involves many studies focusing on the use of barium paste placed in the bladder and in the urethra [295, 296], but they are outdated and covered in prior editions of this book.

These kinds of radiographic studies, however, cannot distinguish between lateral or central defects in vaginal wall support. Therefore, while urethral movement can be identified as an important finding in stress incontinence, one cannot determine the exact location of the vaginal defect. Because the proximal urethra
rotates out of the focal plane of ultrasonographic probes or MRI, coronal images of vaginal relaxation have not yet shown anatomical detail at the moment of incontinence. They cannot distinguish central from paravaginal defects. For this, an examination of the patient is required. 3D stress MRI, however, has made this possible and reveals that the dominant factor in loss of anterior vaginal wall support comes from paravaginal separation and apical descent that are highly correlated with one another [297].

Although we have considerable knowledge about anatomical defects in the majority of patients USI, less is understood about the exact effect of these defects, and indeed, vaginal position itself, on urethral closure. Early experience with operations for stress incontinence showed that not all women with USI had vaginal prolapse, that correction of vaginal relaxation did not always correct stress incontinence, and that women who redeveloped stress incontinence symptoms after apparently successful surgery did not necessarily show a recurrence of their prolapse [298].

The effect on the urethral mechanism of anatomical defects induced by vaginal delivery has been recently investigated. In a rat model birth trauma has been simulated by inducing vaginal distension by balloon catheter inflation [299]. Sneeze induced SUI was caused by decreased active closure mechanisms at the mid-urethra without affecting the passive transmission of abdominal pressure in the proximal urethra.

The greater involvement of the urethral mechanism in the occurrence of post-partum stress incontinence was confirmed in a case control study evaluating urethral closure pressure and bladder neck movement assessed with ultrasound [300]. Eighty primiparous women complaining of de-novo stress incontinence 9-12 months after delivery were compared with 80 primiparous continent and 80 nulliparous continent women. Lower maximal urethral closure pressure was the closest association with de novo stress incontinence after first vaginal birth followed by vesical neck mobility and was as strong a predictor of incontinence as were changes in connective tissue in women with SUI [301-303]; moreover, in SUI a defect in endopelvic fascia is also likely to be of functional significance given that the urethra is indirectly attached to the levators by endopelvic fascia and an intact arrangement assists in urethral positioning [304]. Stress incontinence may be acquired through conditions causing changes in connective tissue:

3. ROLE OF CONNECTIVE TISSUE

Collagen and smooth muscle are the main constituents of endopelvic fascia and abnormalities in the quantity, type and quality of collagen have been observed in women with stress incontinence. Several studies have reported a decrease in the total collagen content in women with SUI [301-303]; moreover, in SUI a defect in endopelvic fascia is also likely to be of functional significance given that the urethra is indirectly attached to the levators by endopelvic fascia and an intact arrangement assists in urethral positioning [304]. Stress incontinence may be acquired through conditions causing changes in connective tissue:

The incidence of SUI is more common with increasing age. In postmenopausal women, connective tissue to muscle ratio is reduced, and although the formation of collagen cross-links stabilizes the molecule it prevents remodelling and flexibility [305].

It is well known that stress incontinence is more common in multiparous women. There is evidence to suggest that trauma during childbirth may cause neuromuscular injury. However, changes in connective tissue also occur during pregnancy. Fascia becomes more elastic and vulnerable and women who have antenatal stress incontinence might have a greater degree of fascial weakness compared with those who remain continent [306]. Women, who develop antenatal stress incontinence, even when it resolves in the postnatal period, are twice as likely to develop it again in the future compared with those without antenatal stress incontinence [307]. Whether this is due to pregnancy unmasking women with congenitally weak sphincter mechanisms or changes due to the pregnancy remains to be determined. The hormonal changes during pregnancy or abnormal remodelling of collagen may be important in the development of these conditions so this is plausible though not proven.

4. EMERGING CONCEPTS OF URETHRA WEAKNESS AND ISD

The idea that primary urethral weakness could cause SUI was first proposed by Howard Kelly in 1914 [308] and its relationship to problems with urethral support emphasized in a proposed classification by Blaivas et al. [309]. In their classification, they named this Type III incontinence to distinguish it from Types I and II, each of which showed movement, while Type III did not. This term still remains in the contemporary literature, although it has now been largely replaced by the term intrinsic sphincter deficiency (ISD), focusing attention on urethral elements which appear to be independent of vaginal position and mobility. These elements include pudendal innervation, striated sphincter mass and function, and urethral smooth muscle, mucosa and submucosal cushions.

When ISD was first introduced as a concept to explain surgical failures and the presence of stress incontinence in the absence of vaginal mobility, the diagnostic tendency was to consider the cause of stress incontinence as a dichotomy, due either to hypermobility (displacement, or prolapse of the vaginal wall) or ISD. The typical patient with ISD was described as having low urethral closure pressures, a “stovepipe” appearance on cystoscopy, and opening or funnelling of the urethra under resting or minimal increases in intra-abdominal pressures on radiographic images. The common causes were thought to be surgical injury, ischemia following previous pelvic or vaginal surgery or radiation damage.
5. HYPERMOBILITY VS. ISD: FROM DICHOTOMY TO CONTINUUM

Currently, it appears to be a shift away from this simple categorisation of stress incontinence as being due either to hypermobility or ISD. This has arisen in part because of the development of the concept of Valsalva Leak Point Pressure (VLPP) [310, 311] and more recent analyses of long term results of stress incontinence surgery [312].

VLPP emerged as an alternative method to study urethral closure during stress for studies of urethral bulking with collagen. Investigators recognised that improvements in continence following urethral bulking did not correlate with urethral closure pressures, but did correlate with the amount of pressure required to produce leakage in the absence of intrinsic detrusor contraction. Although VLPP still lacks specific anatomic or theoretical grounding and many uncertainties related to standardisation of recording methods and associated prolapse remain, low VLPP (without specified or established values) has been widely embraced as an indicator of ISD.

Just as the concept of VLPP blurred the previous distinction between simple ISD and simple hypermobility, long term outcome studies of correction of hypermobility have suggested that there may be more urethral weakness among patients with hypermobility than had been previously considered.

Long term outcome studies of stress incontinence surgery have shown that there is a much greater failure rate of many of the commonly performed stress incontinence operations than had been generally appreciated, and that slings providing direct sub-urethral support seemed to give the greatest long term protection against recurrence of incontinence [312]. Since slings had traditionally been the procedure of choice for recurrent incontinence or “Type III” (now ISD) incontinence, the possibility that ISD was more common than previously thought was more widely considered. Recently, Horbach and Ostergaard have found that age is a significant, independent predictor of ISD in the setting of USI [313], suggesting that age-related reduction in muscle mass, slowed reflexes or repeated episodes of prolapse may all contribute to the condition.

In two interesting studies Perucchini et al. [314, 315] showed that aging can cause a decrease in the number and density of urethral striated muscle fibres at the bladder neck and along the ventral wall of the urethra [315]. These changes were also associated with a loss of nerves within the urethra [316]. Whether the muscle loss leads to reduced numbers and size of nerves or vice versa is difficult to say. These two developments have led to a growing clinical impression that some degree of ISD may exist in many patients who, until recently, were thought to have only hypermobility as the cause of their incontinence. Atypical expression of this approach can be found in the conclusion of Kayigil et al. [317] following examination of 50 patients; “The high rate of intrinsic sphincter deficiency in patients with urethral hypermobility indicates that the incidence with stress incontinence may be greater than previously believed, and may influence the apparently higher failure rates after bladder neck suspension.” In contemporary clinical practice, this impression has given rise to a growing tendency to recommend suburethral sling surgery as a form of primary surgical treatment for all women with stress incontinence, whereas formerly this approach was reserved almost exclusively for patients with recurrent stress incontinence or significant ISD [318, 319].

5.1. Direct Studies of Urethral Function

As recognition of the importance of urethral function has increased, so too have the number of investigations of urethral position, urethral closure and transmission pressure profiles, Valsalva leak point pressure measurements and electromyographic examinations of the pudendal nerve and the striated sphincter.

5.1.1. Studies of urethral position

Stress incontinence is frequently associated with loss of urethral position. This has been the primary pathophysiological paradigm since the observations of Hodgkinson and Jeffcoate and Roberts. Similar observations are still reported today [320, 321]. Even when some displacement is seen in continent nulliparous females, incontinent women show a greater degree of mobility [260]. This pathophysiological mechanism has been supported by different authors [227, 323, 324] using a rat model. Induced trauma on structures supporting the urethra (such as the pubourethral ligaments) and urethrylosis resulted in SUI in short and long term because of increased urethral mobility.

Successful suspensory operations, whether by sling or paraurethral suspension stabilise urethral position [298] and, when studied, increase pressure transmission during stress. It is not clear if the active contraction of urethral support seen in the female is restored after surgery, nor is it known if it is necessary for continence. It has been suggested that passive support alone is what restores continence after suspension.

Direct comparison of urethral sphincter function and urethral support in women with clinical SUI and asymptomatic volunteers who were of similar age and parity allows the relative contributions of both factors to be compared. In such a study [325], the difference between incontinent and continent women was far greater for maximal urethral closure pressure (effect size 1.6) than for any of several parameters of urethral support (largest effect size 0.6). Because of
concern that the measures of urethral support might not be adequately capturing the some aspect of urethral support, the authors had individuals with published expertise in assessing urethral support on ultrasound review recordings of the women blinded to their status to see if they could discern continence status [326]. The raters were only 7% better than random chance supporting the idea that urethral support is not as important as previously thought.

5.1.2 Studies of urethral pressure and resistance

Stress incontinence is generally thought to be characterised by a decrease in urethral transmission profiles and resting closure pressure. The correlation between low resting pressures and low leak point pressures is still controversial. With a bladder filled up to 200 ml Almeida et al. [327] reported a significant correlation between MUCP and LPP. Patients with a LPP of 60 cm H2O or less also had shorter urethral functional length and lower sphincter activity. Moreover Sinha et al. [328] showed that women with USI were more likely to leak at cough leak point pressure than the Valsalva manoeuvre, with the opposite happening for women with DO. On the contrary Martan et al. [329] could not find any significant correlation between MUCP and VLPP.

Different urodynamic parameters have also been considered to assess urethral function and to correlate with women with stress incontinence. Digesu et al. [330] showed that urethral resistance pressure (URP) and pressure flow parameters were reduced in women with stress incontinence. Salvatore et al. [331] found that the opening vesical pressure is significantly correlated with ISD.

Sonographic studies have recently shown a relationship between low urethral resistance and decreased urethral smooth and skeletal muscle layers [332].

Improvement in transmission pressures is associated with successful outcomes after suspensory operations for SUI [271, 275, 278, 279, 333, 334]. The exact mechanism for this increase in transmission is not clear. Increased exposure to intra-abdominal forces has been suggested [280, 335, 336]. Compression against the pubis by the pelvic viscera has also been suggested [337]. The final position of the urethra, however, may not be the key variable [271].

5.1.3 Electrophysiological studies of urethral function

Snooks and Swash [338, 339] first brought attention to the importance of urethral denervation after its possible contribution to urinary and faecal incontinence. Stress incontinence is frequently associated with a decline in the electrophysiological function of the pudendal nerve [340], the striated urethral sphincter [341], and the pelvic floor muscles [229, 234]. Most recent studies continue to support the finding of prolonged pudendal nerve terminal motor latency in SUI [342].

With the use of animal models simulating intrinsic urethra deficit through periurethral cauterisation, urethral sphincterectomy or pudendal nerve transection, different authors reported a decrease of LPP lasting for weeks [343–345]. Injury of the pudendal nerve determined a dramatic decrease of urethral resistance causing urinary loss during an intrabdominal pressure increase.

Electromyographic studies of normal sphincter function show that in continent women, pressures begin to rise in the urethra before rising in the bladder, suggesting an active muscular component [346].

Women with stress incontinence have an altered pattern of pelvic floor muscle response during successive coughing efforts [347] with a sharp decrease in MUCP after repeated coughs [348]. EMG studies have also shown that women with persistent stress incontinence after previous surgery have poorer urethral neuromuscular function than naive stress incontinent women [349]. Experimental studies of urethral function and the role of Onuf’s nucleus in the sacral spinal cord have led to recent practical innovations in the development of serotonin uptake inhibitor agents in the treatment of stress incontinence [350]. Most electrophysiological studies have concentrated on motor rather than sensory innervation, however, and the role of urethral sensation in USI is unknown.

Needle electromyographic studies to assess urethral sphincter function have been performed by Takahashi et al. [351] to determine the electromyographic features of the striated urethral sphincter due to intrinsic sphincter deficiency. Myogenic dominant damages of the striated sphincter were suggested to contribute to the etiology of ISD [352]. Heesakkers et al. proposed circumferential sphincter surface electromyography (CSS-EMG), a less invasive and, therefore more patient friendly procedure, of the urethral sphincter and to identify CSS-EMG parameters for diagnosing ISD [353]. The authors found that the Average Rectified Value of the Motor Unit Action Potential, a measure of strength of the urethral rhabdosphincter, at 12 o’clock at 100% squeeze of the urethral sphincter, could discriminate between ISD and non ISD.

5.1.4 Genetic factors

Recent research is now focusing on the identification of factors related to stress incontinence which might be genetically determined. Chen et al. [354] reported that genes involved in elastin metabolism were differentially expressed in vaginal tissue from women with stress incontinence, suggesting that elastin remodeling may be important in the molecular aetiology of stress incontinence. Wen et al. [355] recently reported a decreased expression of alpha2-M mRNA and protein and protease inhibitor activity in the vaginal wall tissues of women with stress incontinence.
There is a need for a hypothesis which would integrate these various observations regarding hypermobility, ISD and pudendal nerve function, place them within the context of an abnormal pelvic floor and provide a model to guide research and studies of the natural history of the condition.

5.2. Role of Advanced Imaging in Understanding Pathophysiology

Many imaging modalities have been used to improve our knowledge on pelvic floor dysfunction, such as: radiographic imaging, ultrasound, computed tomography and magnetic resonance imaging (MRI).

Radiographic imaging has provided considerable insight into the pathophysiology of stress incontinence, ever since the advent of bead chain cystograms and simple static and straining lateral cystograms.

MRI and real time ultrasonography, in addition to showing the events of stress incontinence on both a global pelvic and local urethral scale, have suggested a relationship between the proximal urethra to vaginal wall movement.

5.2.1 Magnetic resonance imaging

Dynamic fastscan MRI can visualise all compartments of the female pelvis during increased intraabdominal straining [356]. MRI is comparable to standard cystography in demonstrating cystocele defects [357].

Using the pubococcygeal line as a reference marker, the normal displacement of bladder base, cervix or cervical cuff, and the rectum can be identified and compared to women with prolapse. The urethra is shown in the context of global pelvic relaxation [358]. Although most MRI studies have been descriptive rather than quantitative, they still show far more soft tissue detail than earlier radiographic studies and continue to offer promising research opportunities. Recent studies have utilised an endovaginal coil to obtain higher resolution images of the urethra [359].

Dynamic MRI with cine-loop reconstruction produces vivid, intuitively appealing images which can show movement of all compartments of the relaxed pelvis during straining [358]. Static MRI shows details of urethral and peri-urethral anatomy and the striated sphincter can be clearly seen [360]. Pending further improvements in resolution, MRI remains a most promising tool for studying details of urethral movement [361].

Functional MRI has recently been evaluated to assess the efficacy of pelvic floor muscle training with EMG-biofeedback in women with stress incontinence. After a 12-week training period a more focused activation in the primary motor and somatosenory cortical representation sites of the lower urogenital tract was found [362].

Madill et al. have recently proposed another clinically promising application of MRI. They hypothesized that the Pelvic Floor Muscle (PFM) rehabilitation program would also exercise the striated urethral sphincter and that this would be demonstrated by hypertrophy of the sphincter on MRI [363]. Their results appears to demonstrate that MRI is able to show that PFM training for SUI also trains the striated urethral sphincter and that improvement in incontinence signs and symptoms is associated with sphincter hypertrophy in older women with SUI. These findings support previous ultrasound (US) data showing an increase in urethral cross-sectional area following PFM training and extend the previous findings by more specifically assessing the area of hypertrophy and by demonstrating that older women present the same changes as younger women when assessed using MRI data. Similar data on the role of hypertrophy of the urethral sphincters after an effective PFM training, and therefore in the pathophysiology of SUI, were observed also by McLean et al, using a two- and three-dimensional ultrasound imaging of the pelvic structures [364].

Very recently, Macura et al., combining in women with SUI, the urodynamic findings with eight different MRI parameters, stated that MRI might play an important role in assessing the contribution of hypermobility and sphincter dysfunction to the SUI in women when considering treatment options. However the authors included a small study population [365].

Ultrasonography is simpler and less expensive in comparison with MRI, and, for now, provides better visualisation of moving structures.

5.2.2 Real time ultrasonography

Several sonographic approaches have been used for the study of stress incontinence: suprapubic, translabial, transvaginal and transperineal.

As resolution of sonographic probes has improved, the detail previously best seen with the transrectal approach may now be seen by a transperineal approach. Earlier studies with a transrectal approach have shown that funnelling of the proximal urethra was the sonographic sign most-frequently associated with loss of urine [366].

In about half the patients with stress incontinence in the study of Schaer et al. [367], funnelling was seen only with straining. In the other half, some degree of funnelling was already present at rest, increasing with straining and present with actual leakage. Enhanced views of the urethra are possible with sonographic contrast material.

Most recently, 3-D reconstruction from translabial views of the urethra has been used to compare findings in normal volunteers and those with ISD [368].

The most recent sonographic study of women with SUI found funnelling at rest in 109 of 330 patients, and found that the degree of vaginal relaxation as well as the parameters of intrinsic urethral function, including VLPP and urethral closure pressures, were worse
in patients with funnelling than without. The authors of this study concluded that: “In primary genuine stress incontinence, bladder neck funnelling on ultrasound cystourethrography implies the potential coexistence of poor anatomic support and an intrinsic sphincter defect [369].” Ghoniem et al. [370] also found that urethral funnelling was more likely to be associated with low closure pressures, low VLPPs, and a higher incidence of ISD in patients with SUI. However, recently, Tunn et al. [371] could not find an association between the ultrasound findings of urethral funnelling with stress incontinence using an intra-intestinal approach, demonstrating it only in 59% of the patients with SUI.

Ultrasound has been used to identify paravaginal defects prior to Burch colposuspension to guide surgical modification, and then repeated after surgery to show correction of the defects [372].

Urethral movement and funnelling seen by ultrasound resemble the rotational descent previously described by Nichols and Randall [373]. It is also consistent with the previously cited descriptions of Jeffcoate and Roberts, and that of Hodgkinson. Improved soft tissue detail seen with ultrasound has permitted an extension of these original observations. The anterior and posterior walls of the proximal urethra appear to move differently during increases in intra-abdominal pressure. At first, they appear to move together; the urethra begins its descent as a single unit. At some point, however, the anterior urethra becomes arrested in its rotational movement and appears to move more slowly. The posterior portion of the urethra continues to descend along with the vaginal wall [366, 374].

This difference in movement suggests a shearing apart of the two walls, leading to the appearance of funnelling, which can be seen as urine leaks out of the urethra.

On Valsalva, the proximal urethra rotates in a posteroinferior direction approximating to the symphysis pubis. This movement can be measured by comparing the angle of inclination between the proximal urethra and any other fixed axis. No normal values of bladder neck descent have been defined but cutoffs of 20, 25 and 30 mm have been reported to classify urethral hypermobility [375, 376]. The anatomical and functional integrity of PFM have been suggested as having an important role in the urethral support system and, therefore, in the continence mechanism. It has been shown that women with UI, compared to continent subjects, have less effective PFM in terms of: strength, reduced endurance, reduced thickness, coordination of PFM and lower abdominal muscles, and altered electromyographic activity [377-379]. This does not, however, appear to be due to visible damage to the levator ani muscle because direct comparison of women with stress incontinence to those who were stress continent do not show a difference in visible levator damage [325]. With transperineal ultrasound it is possible to evaluate the urethral displacement towards the pubic bone caused by PFM contractions [380]. This mechanism is involved in maintaining urinary continence by determining good efficacy in intraurethral pressure transmission [381].

Anatomic correlation suggests that what clinicians have called pubourethral ligaments, that in standardized anatomical terms are called the arcus tendineus fascia pelvis, may restrict the movement of the anterior urethral wall, facilitating downward traction by the prolapsing vagina during stress, contributing to the shear. At the level of the pubis, a body a connective tissue (the posterior portion of the pubourethral ligament) travels beneath the pubis to form an anterior portion, which supports the clitoris in women, and the corpora cavernosa in men. Both Milley and Nichols [382], and Zacharin [383, 384] and Mostwin [385] have previously suggested that the posterior pubourethral ligaments might support the urethra, and their laxity might contribute to the descent of the urethra in stress incontinence. These studies, however, suggest a different interpretation. Longitudinal and cross-sectional views of the proximal urethra show that the ligaments travel along only the anterior portion of the urethra as they pass beneath the pubis to emerge as the anterior pubourethral ligaments. The vagina and its bilateral attachments forming the lateral sulcus support the posterior part of the urethra. It is more likely that the vaginal wall and its attachments become weaker than the strong condensations of endopelvic fascia forming these ligaments. Therefore, the pubourethral complex, even if attenuated, probably remains stronger than the underlying vaginal wall. Sonographic examination of the prolapsing urethra therefore suggests arrest of anterior urethral wall movement by the pubourethral complex, while the vaginal wall continues to rotate, pulling the posterior wall of the urethra along with it.

These anatomical considerations, combined with current knowledge about pudendal nerve activity in normal, prolapse or stress incontinence, suggest an inter-relationship regarding urethral closure and vaginal movement. As intra-abdominal pressure increases, the proximal urethra experiences two kinds of forces, which may lead to opening. The first of these is a shearing force produced by the unequal separation of the anterior and posterior urethral walls from the pubis during straining. This is the effect of vaginal mobility on urethral closure. The second is an expulsive force, produced by the transmission of intra-abdominal forces to the bladder, which must be resisted by the urethra if opening is to be prevented.

The urethra resists this primarily by intrinsic closure of the pudendally innervated striated sphincter, aided by vaginal support.

3D ultrasound has recently introduced new insights into the image of urethral sphincters. Athanasiou et al. [386], using a transvaginal approach, reported a close correlation between the urethral sphincter volume and the degree of incontinence assessed on videocystourethrography (r = -.65; P <0.001).

COMMITTEE 4. PATHOPHYSIOLOGY OF URINARY INCONTINENCE, FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE

392
With the use of three-dimensional ultrasound Athanasiou et al. [324] quantitatively evaluated the urethra and the urethral sphincter in women with stress incontinence. These authors reported that this group of women have urethral sphincters that are shorter, thinner, and smaller in volume compared to controls.

Urethral vasculature has also been postulated to play a role in the continence mechanism and different Doppler parameters have been studied to evaluate correlation with SUI and experimental studies suggest that vascular factors contribute about 1/3 of MUCP [387].

However, Tsai et al. [388] reported that urethral vasculature, and in particular the anterior branch of the middle urethral vessels is less likely to be seen after the menopause (89.1% vs. 79.2% pre- and postmenopause, P = 0.030). In the postmenopausal women hormone replacement therapy did not affect the appearance of the urethral vessels.

However, results are controversial since some authors [360] reported less periurethral vessels and flow in women suffering from SUI whereas others [389] could not find any difference in the appearance of the urethral vasculature in subjects with or without SUI.

It is likely that these shearing and expulsive forces are generated simultaneously as intra-abdominal pressure rises. One can easily imagine that the urethra can be brought to a continence threshold beyond which urethral closure cannot be maintained. One can further imagine that repeated episodes of prolapse may eventually stretch, tear or attenuate sphincter mass and contribute to a chronically weakened urethra manifested by low VLPP or low urethral closure pressures, characteristic of ISD. After severe or prolonged untreated prolapse and stress incontinence, vaginal support alone may not be sufficient to correct the deficiencies of an exhausted sphincter. Although theoretical rather than evidence-based, such considerations may direct future research efforts towards a more integrated hypothesis regarding stress incontinence in women. The relative contributions of abnormal vaginal mobility and intrinsic urethral function should be considered as part of a continuum rather than a dichotomy. Current research and interest has concentrated mostly on ISD as the primary cause of SUI in women, but the relationship of the many factors affecting urethral support and function should remain a perspective in interpreting emerging findings.

6. THE LAST PATHOPHYSIOLOGICAL MODELS

Reviewing all the available evidences on the pathogenesis of SUI, DeLancey proposed a new conceptual model to describe the interaction between the different possible mechanisms. Considerable progress has been made to date, yet the author concluded that our understanding is far from complete. The urethra is a dynamic structure with variations in closure from second to second, minute-to-minute, day to day and year to year. The role of the submucosal vascular plexus is still poorly understood; also, the complex neural control mechanisms that allow for temporary and total relaxation during voiding, that somehow know when to re-establish normal muscle function are still not entirely understood. In addition, although it is clear that urethral support is not as important as previously thought, it is one of the major contributing factors for stress incontinence. Understanding what it is about urethral support that lessens continence is vital. However, the finding that maximal urethral closure pressure, and not urethral support, is the factor most strongly associated with stress incontinence implies that improving urethral function may have therapeutic promise. Racial disparities exist in incontinence, and the biological basis for these differences should help our understanding [390, 325].

7. CONCLUSIONS

We are approaching a new classification of stress incontinence which will integrate hypermobility and urethral dysfunction as inter-related elements on a spectrum of change. Certain concepts have stood the test of time, and they are included below, along with conclusions:

Sphincter insufficiency is related to a decline in striated sphincter muscle mass and function as measured by electrophysiological studies of pudendal nerve and sphincter function, and MRI and sonographic estimates of muscle mass (Level 1). If repeated episodes of vaginal traction can be shown to enhance sphincter damage, then the effect of early treatment of stress incontinence and prolapse on future development of ISD should be investigated, since advanced ISD remains difficult to treat.

Many patients with urodynamic stress incontinence show urethral mobility (Level 2), though it is not yet known what is about that mobility which permits urethral opening during stress.

Some patients who present with minimal mobility or who have recurrent after successful surgery have primary or residual sphincter insufficiency.

Successful operations can restore urethral position but probably do not restore urethral function. A good surgical outcome probably requires a certain reserve of urethral function. It is in the area of functional understanding of urethral anatomy that the greatest progress is likely to be made.
Anatomical support of pelvic viscera is mainly provided by the levator ani muscle complex and connective tissue attachments of the pelvic organs: vaginal support arises from the connective tissue attachments between the vagina and the pelvic sidewall, the vaginal wall, and the levator ani muscles [391, 392].

Two mechanical principles explain how the uterus and vagina are normally held in place. First, the uterus and vagina are attached to the walls of the pelvis by the endopelvic fascia that suspends the organs from the pelvic sidewalls. Second, the levator ani muscles costrict the lumen of these organs closed, forming an occlusive layer on which the pelvic organs may rest [393].

The levator ani complex consists of the pubococcygeus, the puborectalis, and the iliococcygeus muscles [394]. These muscles are tonically contracted at rest and act to close the genital hiatus, providing a stable platform for the pelvic viscera. Decline of normal levator ani tone by denervation or direct muscle trauma, results in an open urogenital hiatus, weakening of the horizontal orientation of the levator plate, and a bowl-like configuration [395, 396].

The supportive connective tissues are a continuous, highly interdependent sheet in which all members interact to achieve support of the vagina and, therefore, of the pelvic organs. DeLancey has introduced the concept of dividing the connective tissue support of the pelvis into three levels, with level I, II and III representing apical, midvaginal and distal support respectively. The upper portion of the paracolpium (Level I) consists of a relatively long sheet of tissue that suspends the vagina by attaching it to the pelvic wall, and it is responsible for suspending the apex of the vagina after hysterectomy. In the middle third of the vagina, the paracolpium attaches the vagina laterally, to the arcus tendineus and fascia of the levator ani muscles (Level II). This attachment stretches the vagina transversely between the bladder and the rectum. The structural layer that supports the bladder (pubocervical fascia) is composed of the anterior vaginal wall and its attachment through the endopelvic fascia to the pelvic wall. Similarly, the posterior vaginal wall and endopelvic fascia (rectovaginal fascia) form the restraining layer that prevents the rectum from protruding forward. The vagina’s lower third (Level III) fuses with the perineal membrane, levator ani muscles and perineal body, without any intervening paracolpium (Figure 11) [393, 397]. Damage to the upper suspensory fibres of the paracolpium causes a different type of prolapse from damage to the mid-level supports of the vagina. Defects in the support provided by the mid-level vaginal supports (pubocervical and rectovaginal fascia) result in cystocele and rectocele, while loss of the upper suspensory fibers of the paracolpium and parametrium is responsible for the development of vaginal and uterine prolapse. These defects usually occur in varying combinations and this is responsible for the diversity of clinical problems encountered within the overall spectrum of pelvic organ prolapse [393].

For conceptual purposes the supportive connective tissue has been related with structural elements of the pelvic floor: the uterosacral ligaments (level I); the paravaginal attachments (endopelvic fascia) that connect the lateral vaginal walls to the arcus tendineus fascia pelvis (ATFP) and the fascia of the levator ani muscles (level II); the perineal membrane and the perineal body (level III) [397]. Table 2 lists the structural elements of pelvic organ support, their possible damage and subsequent site of pelvic organ prolapse.
Table 2: Structural elements of pelvic organ support, their possible damage and subsequent site of pelvic organ prolapse. The levels of support and anatomical defects are derived from the anatomical studies of DeLancey [393, 397].

</thead>
</table>
| Level 1 | Uterosacral ligaments | - Disruption  
- Overdistension  
- Elongation | - Uterine prolapse  
- Vault prolapse |
| Level 2 | Anterior endopelvic fascia (pubocervical fascia)  
Posterior endopelvic fascia (rectovaginal fascia) | - Central impairment of fascia  
- Lateral detachment of fascia from ATF  
- Impairment of fascia | - Midline cystocele  
- Paravaginal defect-cystocele  
- Rectocele |
| Level 3 | Perineum | - Disruption from endopelvic fascia  
- Disruption of bulbocavernosus muscles | - Excessive perineal descent  
- Rectocele |

Table 3: Determinants of normal pelvic organ support. Possible sites of failure and possible causes, established and theoretical risk factors. LE = LEVEL OF EVIDENCE
The integrity of muscular, connective and nerve structures is essential to guarantee a normal pelvic organ support. If one of these factors fails, the other might be able to compensate to a certain degree.

In an American gynaecology clinic population (18-83 years), approximately 3-6% of women had pelvic organ descent and urinary incontinence sometime in their lifespan [400]. Therefore, vaginal delivery does not totally explain the origin and progression of pelvic organ prolapse [161, 400, 404-407]. However, if it is true that all women undergo pelvic floor stretch during vaginal delivery, not all of them develop a further prolapse; moreover, pelvic floor dysfunctions have also been described in women who gave birth by caesarean section only [161, 402] and in nulliparous women [408]. Therefore, vaginal delivery does not totally explain the origin and progression of pelvic floor descent in all women. This supports the hypothesis that other causes, besides obstetrics, are involved in the aetiology of pelvic organ prolapse: connective tissue deficiencies, genetic predisposition, sexual hormones, pregnancy, ageing, menopause, obesity, neuropathies, ethnicity and family history.

Miedel et al [409] showed that age and parity are the dominating risk factors for symptomatic pelvic organ prolapse, but significant independent associations with markers suggestive of congenital susceptibility (family history and conditions signaling weak connective tissue) and nonobstetric strain on the pelvic floor (overweight/obesity, heavy lifting, and constipation) imply that individual predisposition and lifestyle/environment also may play an important role. (LEVEL OF EVIDENCE: II)

In the last decade, attention has increasingly focused on understanding of the molecular basis of POP and the recognition of the potential molecular markers and their modulators in pelvic floor supportive tissues in order to identify the women predisposed to develop POP.

Table 3 lists anatomical and functional determinants of normal pelvic organ support. It also summarises the possible nature of failure and its potential causes as well as the established and theoretical risk factors.

Vaginal delivery has been considered the main causal factor in the development of pelvic organ prolapse for some years [161, 400, 404-407]. However, if it is true that all women undergo pelvic floor stretching during vaginal delivery, not all of them develop a further prolapse; moreover, pelvic floor dysfunctions have also been described in women who gave birth by caesarean section only [161, 402] and in nulliparous women [408]. Therefore, vaginal delivery does not totally explain the origin and progression of pelvic floor descent in all women. This supports the hypothesis that other causes, besides obstetrics, are involved in the aetiology of pelvic organ prolapse: connective tissue deficiencies, genetic predisposition, sexual hormones, pregnancy, ageing, menopause, obesity, neuropathies, ethnicity and family history.

In an American gynaecology clinic population (18-83 years), approximately 3-6% of women had pelvic organ prolapse descending beyond the vaginal opening on routine pelvic examination [399]; an estimated 11% of women will undergo surgery for pelvic organ descent and urinary incontinence sometime in their lifespan [400]. Therefore, vaginal delivery does not totally explain the origin and progression of pelvic organ prolapse [161, 400, 404-407]. However, if it is true that all women undergo pelvic floor stretch during vaginal delivery, not all of them develop a further prolapse; moreover, pelvic floor dysfunctions have also been described in women who gave birth by caesarean section only [161, 402] and in nulliparous women [408]. Therefore, vaginal delivery does not totally explain the origin and progression of pelvic floor descent in all women. This supports the hypothesis that other causes, besides obstetrics, are involved in the aetiology of pelvic organ prolapse: connective tissue deficiencies, genetic predisposition, sexual hormones, pregnancy, ageing, menopause, obesity, neuropathies, ethnicity and family history.

Miedel et al [409] showed that age and parity are the dominating risk factors for symptomatic pelvic organ prolapse, but significant independent associations with markers suggestive of congenital susceptibility (family history and conditions signaling weak connective tissue) and nonobstetric strain on the pelvic floor (overweight/obesity, heavy lifting, and constipation) imply that individual predisposition and lifestyle/environment also may play an important role. (LEVEL OF EVIDENCE: II)

In the last decade, attention has increasingly focused on understanding of the molecular basis of POP and the recognition of the potential molecular markers and their modulators in pelvic floor supportive tissues in order to identify the women predisposed to develop POP.

1.1. Inheritance, Genetic and Ethnic Predisposition

Several studies have recently focused their attention on the inheritable predisposition for pelvic organ prolapse.

In the large case-control study carried out by Chi-affarino et al. [410], a higher risk of prolapse was reported in women whose mother (OR: 3.2; 95% CI: 1.1-7.6) or sister (OR: 2.4; 95% CI: 1.0-5.6) were affected by the same condition; their data support that first-degree family history of prolapse is a risk factor for POP.

Jack et al. [411] demonstrated that the risk of POP among siblings of young women (average age: 37 years) with stage III and IV POP was five times higher than in the general population. Genetic analysis of the inheritance pattern within these families showed that pelvic organ prolapse segregated in a dominant fashion with incomplete penetrance.

Positive family history has been recently identified as independent risk factor (OR 8.016) for prolapse [412].

The findings of high concordance in the POP stage between nulliparous women and their parous sisters strongly support the hypothesis of a familial basis for POP. Buchsbaum et al. [413] investigated the role of familial factors in the development of pelvic organ prolapse by comparing the prevalence of this condition in nulliparous postmenopausal women and their parous sisters. By compartment, there was a 74.3% to 91.1% concordance in prolapse stage within sister pairs. In discordant sister pairs, the parous sister was found to have the more advanced prolapse 88% of the time. Based on these results, the authors conclude that a high concordance of pelvic organ prolapse in nulliparous and parous sister pairs suggests a familial predisposition toward developing this condition. However, vaginal delivery appeared to confer a risk for more advanced pelvic organ prolapse. LEVEL OF EVIDENCE: II-2.

Some studies have drawn attention to the incidence of pelvic organ prolapse amongst identical twins.

In the large Swedish twin registry of 3,376 monozygotic and 5,067 dizygotic female twin pairs, a greater twin similarity among the monozygotic twins was found, indicating the influence of a genetic component to the aetiology of pelvic organ prolapse. Genetic and non-shared environmental factors seemed to contribute equally to the development of pelvic floor disorders in these women, about 40% for each factor [414].

Buchsbaum et al. [415] even reported that vaginal delivery was not associated with clinically relevant differences in relaxation of the pelvic support system within four sets of postmenopausal identical twins with different parity status.
Genetic variants that run in families with an increased incidence of pelvic organ prolapse have been documented.

A recent trial provides strong scientific evidence for a genetic contribution to pelvic organ prolapse: using a genome-wide association study, Allen-Brady et al. [416], demonstrated that 6 single-nucleotide polymorphisms (SNPs) are significantly associated with POP in high-risk familial case group participants. LEVEL OF EVIDENCE: II. Their results showed that two of the six SNPs are located within the genes ZFAT and COL18A1, both with Mendelian inheritance in man. The ZFAT has been found to play a transcriptional regulator role for immune regulation and apoptosis and, hence, may affect development of the muscle and connective tissue of the pelvic floor. The COL18A1 gene (precursor of the collagen XVIII) may play a role in the structural organization of basement membranes. The other four SNPs identified are intergenic, but one of them is close to the ANTXR2 gene, which binds intravenously to collagen and laminin, suggesting that it may be involved in extracellular matrix adhesion. The authors identified at least three strong candidate genes for POP that warrant follow-up.

A recent genomewide linkage analysis to identify pelvic organ prolapse predisposition genes using a resource of high-risk POP pedigrees, provided evidence that loci on the chromosomes 10q and 17q may contribute to POP aetiology [417].

Further data suggest a role of genetic influence in early onset of POP. In a family in which three generations of female relatives suffered from prolapse at a very young age, a polymorphism in the promoter of LAMC1 gene has been found that seems to increase the susceptibility to early onset pelvic organ prolapse, as an autosomal dominant transmission [418].

A metanalysis of genetic association studies provided moderate epidemiological credibility for association of variation of COL1A1 gene with prolapse [419]. However, the authors suggested that clinical testing for these polymorphisms cannot be recommended based on current evidence.

One study examined gene expression of structural proteins that are related to actin and myosin in five women with, and five women without, pelvic organ prolapse in the pubococcygeal muscle. Several genetic differences between subjects and controls with gene under- and overexpression were found [420].

In mice, HOXA11 has been identified as an essential gene for the development of the uterosacral ligaments [421]. In HOXA11-null mice, the uterosacral ligaments were absent. Women with POP might have weakened connective tissue due to changes in a signalling pathway involving HOXA11 [421].

Increasing evidence supports a genetic aetiology of POP, also with respect to abnormal extracellular matrix remodelling [422]. A genetic predisposition to POP specific to elastin metabolism was noted in the rodent model, in which genetic mutation of the LOXL1 or the fibulin-5 gene in mice are involved in the altered elastic fibre assembly and then in the pathogenesis of the pelvic prolapse [423]. Altered gene expression of elastin has also been described in women with POP [424].

The study carried out by Wang et al [425] supported the view that the polymorphism of the matrix metalloproteinase-10 (MMP-10) gene may be associated with an increased risk of POP.

A genetic screening may be a future tool for identifying the woman at risk for POP and for refining the counseling of women deemed to be at elevated risk; the following consequences will be the prevention of this condition and a targeted treatment. The primary prevention tool could be the adaptation of the delivery mode in at-risk groups. These patients could also benefit from changing the management treatment, such as whether surgery should be considered early or late in the woman’s lifespan.

Race is another demographic factor that seems to be associated with the development of POP. Some studies reported that Hispanic and European women appear to be at higher risk for POP than those of African, Asian or other descent [399, 402, 406, 426, 427]. This is also supported by evidence suggesting that women of Asian descent have reduced inherent pelvic organ mobility. In a cadaveric study, Zacharin [428] reported that Chinese women have stronger and thicker pubourethral ligaments, endopelvic fascia and endopelvic attachment to the obturator fascia compared to Caucasian women. More recently, Dietz et al. [427] confirmed these results using pelvic floor ultrasound, showing that Asian women have significantly less pelvic organ mobility than Caucasian women both antepartum and postpartum.

In cohort analysis of 27,342 women, Hendrix et al. [406], confirmed previously reported differences between white and African-American women. Hispanic women had the highest rate of uterine prolapse (OR: 1.24, 95% CI: 1.01-1.54) and an increased risk for cystocele (OR: 1.20, 95% CI: 1.05-1.36) but not rectocele (OR: 0.95, 95% CI: 0.82-1.11). The reasons for these ethnic differences are unclear; however, some evidence indicates that African-American women have smaller pelvic outlets than those of European descent [429].

Other connective tissue deficiencies such as hernias may share common pathophysiological mechanisms with POP. In a group of 60 women with advanced prolapse, the total prevalence of hiatal and inguinal hernias was significantly higher than in a control group of 60 women with mild or no prolapse (31.6% vs. 5%, p<0.001) [430].

A population-based, cross-sectional study of 5,489 Stockholm women found an OR of 1.8 for a positive association with symptomatic prolapse in women with
a history of conditions suggestive of deficient connective tissue (varicose veins/hernia/haemorrhoids) [409].

McLennan et al. [431] demonstrated that the risk of prolapse was 1.4 (95% CI 1.2-1.8) times higher in women with a family history of prolapse and/or hernia, after adjusting for vaginal deliveries, hysterectomy and incontinence. The authors confirm that heredity is a risk factor for prolapse and suggest that history taking should include both male and female family members.

Taken together, this evidence suggests that exists a familial or genetic basis for POP in some women, and that heritable or genetic factor plays a role in its development.

1.2. Alteration of Collagen, Elastin and Smooth Muscle of Vaginal and Supportive Tissue

It has been demonstrated that young women with POP are more likely to have connective or neurological tissue diseases and congenital abnormalities [432].

Women with Marfan or Ehlers-Danlos syndrome have high rates of POP. Intrinsic joint hypermobility is another well recognised connective tissue disease that is associated with pelvic descent [433-436]. This finding supports the hypothesised aetiological role of connective tissue disorders as a factor in the pathogenesis of this conditions [437].

The vaginal wall is comprised of four layers: a superficial layer of non-keratinised stratified squamous epithelium; a subepithelial dense connective tissue layer composed primarily of collagen and elastin; a layer of smooth muscle referred to as the muscularis; and a layer of adventitia, composed of loose connective tissue. The subepithelium and muscularis together are thought to confer the greatest tensile strength to the vaginal wall. In the normally supported vagina, the supportive connective tissues pull the vagina up and back away from the vaginal introitus over the levator ani muscles. A normally supported vagina, in turn, provides support to the bladder, urethra, uterus and rectum. Disruptions of - or damage to - these connective tissue structures and injury to the vaginal wall are thought to be two important mechanisms causing prolapse.

The connective tissue of the vagina and supportive tissues contains a fibrillar component (collagen and elastin) and a non-fibrillar component (non-collagenous glycoproteins, hyaluronan, and proteoglycans). In addition, and with the exception of the arcus tendineus, these tissues contain a significant amount of smooth muscle. The fibrillar component is thought to contribute the most to the biomechanical behaviour of these tissues. The quantity and quality of collagen and elastin are maintained through a precise balance between synthesis, post-translational modification, and degradation.

Therefore, the integrity of the vagina and its supportive connective tissues are essential for keeping the pelvic organs in their normal anatomic position. Evaluation of these tissues from a biochemical perspective enables us to better discern the complex interplay between structural composition and supportive capacity.

Collagen types I, III and V are the main structural components of vaginal epithelium and endopelvic fascia and they are thought to be the principal determinants of tissue strength. Type I collagen confers strength to tissues while type III contributes to elasticity. Type III collagen is the primary collagen subtype in the vagina and its supportive structures. The ratio of collagen I to III is an indicator of tensile strength: the higher the amount of collagen type III, the lower is the mechanical strength. To our knowledge the role of type V collagen, which is found in small quantities in the vagina, is still unknown.

The turnover of connective tissues throughout the body is maintained by a family of highly conserved, zinc-dependent endopeptidases referred to as matrix metalloproteinases (MMPs). The MMPs are involved in both normal physiological and pathologic proteolytic processes, which are an integral part of tissue remodeling in both women with and without prolapse. An excessive tendency toward connective tissue degradation may underlie the predisposition of some women to prolapse.

Intestinal collagens (types I, II and III) are cleaved by MMP-1, 8 and 13. The cleaved collagen fragments are susceptible to rapid gelatinase (MMP-2 and 9) degradation into amino acids. These gelatinases (MMP-2 and 9) also degrade elastin.

Reports of decreased total collagen in pelvic tissue from women with POP suggest that collagen degradation may contribute to POP. Collagen degradation depends on the activity of MMPs produced by connective tissue cells. MMP proteolytic activity is specifically regulated by their inhibitors, TIMPs, which bind stoichiometrically to MMPs to inhibit their activity. The balance between MMPs and TIMPs defines the collagenolysis.

In women with prolapse, MMP-2 mRNA expression is increased with a concurrent decrease in the inhibitor TIMP-2 [438]. Recent data also indicate increased MMP-1 expression and decreased collagen I in the uterosacral ligaments of women with POP [439]. In contrast, collagen I and III mRNA expression was increased in vaginal tissue from women with POP [440]. Discrepancies in the literature can be due to the different methodological issues (different tissues targeted or a different method of protein quantification) used. Mismatches between mRNA and protein data are often found when examining proteins in the extracellular matrix. Thus, gene expression should always be confirmed with protein expression. These issues contribute to significant variations in the reported data and underscore the importance of careful
research methodology. These discrepancies also suggest the possibility that different pathways in the extracellular matrix may be activated depending on injury type and severity, mechanical load and environmental factors [422].

Despite discrepancies in the precise MMP/TIMP or collagen type, the mentioned data and numerous other publications indicate that women with POP show an abnormal pelvic extracellular matrix metabolism with increased collagen remodelling.

Recent data suggested that oxidative stress (a well-recognised mechanism involved in fibre metabolic disorders) may be involved in the pathophysiology of POP by contributing to collagen metabolic disorders in a severity-dependent manner in human uterosacral ligaments fibroblasts, possibly through the regulation of metalloproteinase (MMPs), tissue inhibitor of metalloproteinase (TIMPs) and transforming growth factor (TGF)-ß1 indirectly [441]

Takano et al. [442] demonstrated that the general amount of collagen in the parametria is reduced in pre- and postmenopausal women with pelvic organ prolapse compared with women without prolapse. Moalli et al. [443] showed that collagen III is increased in vaginal subepithelium and muscularis in patients with prolapse relative to patients without prolapse, independent of age and parity. LEVEL OF EVIDENCE II-2. Increase in collagen III has been reported also in the uterosacral and cardinal ligaments of women with prolapse [444, 445]. The Moalli’s group [446] demonstrated that collagen III is the primary subtype in the arcus tendineus fascia pelvis; a decrease in the ratio of collagen I/(III+V) is associated with hormone therapy and a restoration of this ratio to premenopausal levels with hormone therapy. From these data the authors suggested that sex steroid hormones may improve the biomechanical properties of the supportive tissues of the vagina.

As all studies involving the procurement of human tissue are by necessity cross-sectional, it is impossible to determine whether the increase in collagen III reflects the causes or effects of prolapse. In either case, the increased flexibility and distensibility plus the decreased tensile strength associated with an increase in collagen III very likely contribute to the progression of POP.

Elastin is primarily laid down during fetal development and rarely synthesised in adult tissues. In contrast to the other tissues in which elastin fibres do not experience a turnover in a lifespan, there is cyclical remodelling of elastin fibres in the reproductive tract. A massive degradation of elastin occurs at the time of parturition, followed by postpartum resynthesis, allowing recovery of reproductive tissues to their pre-pregnancy state [447]. Mice deficient in LOX (lysyl oxidase) fail to replenish mature elastin fibres in the reproductive tract following parturition and develop spontaneous prolapse [448]. Yamamoto et al. [442] found a marked decrease in elastin mRNA and tropoelastin protein in the cardinal ligaments of women with pelvic organ prolapse relative to women without prolapse. Chen et al. [449] demonstrated a significant decrease in the endogenous inhibitors of elastases with increase in elastolytic activity in vaginal tissue from women with stress urinary incontinence and pelvic organ prolapse compared with control subjects. Therefore, these data suggest that the proper degradation, synthesis, and regeneration of elastic fibres are essential for maintaining pelvic organ support.

If damaged or destroyed, metabolically repaired elastin frequently results in malformed and dysfunctional repair products. Proteolytic enzymes capable of degrading elastin include the serine proteases, such as neutrophil elastase, the cysteine proteases, and MMP-2, 9 and 12. Marked decreases in elastin gene transcripts and elastin synthesis in pelvic fibroblasts were noted in women with POP [424], suggesting that altered elastin metabolism may contribute to prolapse. In rodent models with genetic disruption to LOXL1 or fibulin-5 gene, prolapse develops due to failure to synthesize and assemble functional elastic fibres [448]. Elastin content was decreased in the uterosacral ligaments of women with POP, as were LOX, and LOXL1 and LOXL2 gene expression [450].

A recent study by Moon et al. [451], evaluated the alteration of elastin metabolism in women with pelvic organ prolapse in a prospective case-control study; their results showed that expression of neutrophil elastase and matrix metalloproteinase-2 mRNA was higher in women with than in those without POP. Compared to before menopause, neutrophil elastase and matrix metalloproteinase-2 showed a significant decrease in postmenopausal women without POP, although they remained increased in postmenopausal women with POP. Alpha-1-antitrypsin was significantly lower in postmenopausal women with pelvic organ prolapse than in postmenopausal women without. The activities of neutrophil elastase, matrix metalloproteinase-2 and matrix metalloproteinase-9 were increased in women with POP, and these trends were similar to neutrophil elastase and matrix metalloproteinase-2 expression even after adjusting for age, parity and menopausal status. This study demonstrates that after menopause increased elastolytic protease has a significant role in the development of POP.

In a recent clinical trial of de Landsheere et al [452], the authors shown that biomechanical testing highlights the hyperelastic behaviour of the vaginal wall at low strains, vaginal tissue appeared stiffer when elastin density was low, with a significant inverse relationship between low strains and the elastin/collagen ratio in the lamina propria. They suggested that elastin density deserve consideration as a relevant factor of vaginal stiffness in women with POP.

The strongly heritable connective tissue diseases, in which pelvic organ prolapse predominates as a result of an elastinopathy, highlight the importance of elastic
fibres for maintaining vaginal support. Marfan’s syndrome, characterized by mutations in the fibrillin-1 gene, and cutis laxa with mutations in the elastin and fibrillin-5 genes, are notable for an increased incidence of POP in affected women [453-456].

Childbirth is an important risk factor for POP, not only for the mechanical trauma that the pelvic floor is submitted to: also inflammatory pathways are activated during the complex process of tissue healing after birth trauma. During healing proteinases, growth factors such as TGF-β, cytokines and chemokines are secreted into the extracellular matrix by surrounding cells. TGF-β is one of a family of 25 kDa polypeptide growth factors that is currently viewed as the most important fibrosis promoting cytokine. It is responsible for extracellular matrix synthesis in fibroblasts, the differentiation of fibroblasts to myofibroblasts and the inhibition of matrix degradation by inhibiting MMP expression and up-regulating TIMP expression. Thus, it is important in extracellular matrix metabolism and affects tissues or organs in various ways. There is sparse but growing evidence of TGF-β modulation in pelvic connective tissue. Large quantities of TGF-β1 are stored in readily available form in the extracellular matrix. Release and activation of stored latent TGF-β1 by proteases can generate rapid, highly localised signals. Therefore, the modulation of TGF-β1 activity by extracellular proteases provides faster signal transduction than alterations in gene expression. This is important for tissue remodelling during pregnancy and repair after birth trauma [422].

1.3. Neurological Factors

Integrity of the pelvic innervation is essential to the normal pelvic functions. The changes in neurophysiological parameters seen after childbirth were interpreted to reflect neuromuscular injury caused by forces exerted on the sacral plexus, pudendal nerves, and pelvic floor muscles.

Abnormal tests have also been found in women with prolapse or stress incontinence. Histologically, there were smaller and fewer nerve bundles in women with posterior vaginal wall prolapse compared with women without prolapse [457]. It has been demonstrated that the density of peptide-containing nerves in the periurethral tissue and in the levator ani muscle in women with prolapse is reduced [458, 459].

Between 1985 and 1987, Allen et al. [232] found that 80% of primigravidae developed evidence of partial denervation of the pelvic floor following delivery. However, evidence of reinnervation and increased fibre density 2 months after vaginal delivery has been detected [232, 460]. Snooks et al. investigated 14 multiparous women from their previous studies [231, 460] 5 years after first vaginal delivery and demonstrated that pelvic floor striated sphincter musculature denervation progressed, indicating that age is a contributory factor [233]. Similarly, progressive denervation with time up to 15 years postpartum was found in another prospective study, corroborating the ageing factor [461].

The pudendal nerve innervates the voluntary urethral and anal sphincters, but it does not innervate the levator ani muscles, which receive their own nerve supply from the sacral plexus. Therefore, there is currently no clear evidence whether the neurological damage is responsible, together with the mechanical damage of stretching, of the visible levator defects.

Information from electrodiagnostic studies has demonstrated that birth causes changes in mean motor unit duration after vaginal birth and changes in pudendal nerve conduction patterns [232, 233, 462-464]. Prolongation of the pudendal nerve terminal motor latency (PNTML) is thought to be a result of pudendal nerve damage during vaginal delivery. Significantly prolonged mean PNTML’s have been found in women two to three days after vaginal delivery, compared to a multiparous [231] and a nulliparous control group [389]. At follow-up five years later, prolongation of PNTML persisted [233]. Two prospective analyses demonstrated a prolongation of PNTML antenataly to six to eight weeks after vaginal delivery, particularly after the first delivery [465, 466]. But, again, many of these changes seem to be temporary, as two-thirds of the women with an abnormally prolonged PNTML after delivery had normal measurement six months later [465].

There has been recent electrophysiological work to add to the literature, probably due to the technically difficult of the nerve function tests in clinical practice.

Although it has not been proved in studies, it is reasonable to assume that periods of pain and discomfort after childbirth (e.g., due to perineal tears and episiotomy) and especially the pain related to attempted PFM contraction, could lead to a temporary nonactivation of the PFM. This could be the origin of disturbances in behavioural patterns, which would need to be readjusted. In combination with a particularly vulnerable pelvic floor neural control, whose complexity only evolved phylogenetically after the attainment of the upright stance, such a temporary disturbance of neural control after childbirth may persist, although the lesion(s) would have fully recovered.

Therefore, the effects of vaginal delivery on pelvic floor nerves are still controversial to date. While it seems logical that vaginal delivery causes some neuromuscular injury and this would be at risk for development of pelvic organ dysfunctions, many details are far from be resolved.

1.4. Pregnancy and Pelvic Floor Muscle Remodeling

Several of the changes occurring prior to delivery are in all likelihood normal physiological changes and may be secondary to hormone-induced collagen alterations. Hormonal alterations are essential to prepare the body and to adjust the musculature and connective tissue for vaginal birth.
The high progesterone levels during pregnancy influence the pelvic floor structures: progesterone has smooth muscle-relaxing and oestrogen-antagonising effects, reducing the tonus in ureters, bladder and urethra [467].

Relaxin, increases markedly during pregnancy and it modifies the connective tissue: its collagenolytic effect, that allows appropriate stretching during vaginal birth, has been demonstrated in guinea pigs [468]. As a likely result of connective tissue remodelling in preparation for birth, Landon and colleagues found that the connective tissue of the rectus sheath fascia and the obturator fascia could be stretched to greater length during pregnancy, but it is also much weaker. In some women, these changes may be irreversible and further stretching beyond physiological limits may result in permanent dysfunction [469].

Recently, several researchers have focused on the effect of pregnancy on the pelvic floor and on the development of prolapse.

Rahn et al. [470] identified pregnancy-induced changes in biomechanical properties of the vaginal wall and compare these with fibulin-5 knockout mice (Fbln5<sup>−/−</sup>) with and without prolapse. Compared with nonpregnant mice, vaginas of pregnant and Fbln5<sup>−/−</sup> (with prolapse) mice exhibited increased maximal stress, increased distensibility and strain, plus decreased stiffness. Tissues from Fbln5<sup>−/−</sup> mice without prolapse were similar to non-pregnant wild-type animals. The authors conclude that pregnancy confers remarkable changes in the vaginal wall that include increased distensibility, decreased stiffness and maximal stress. Elastinopathy alone is insufficient to cause significant changes in these properties, but prolapse confers additional alterations in distensibility and stiffness that are similar to those changes that have been observed in pregnancy. These changes may contribute to the poor durability of many restorative surgical procedures for prolapse.

The effect of pregnancy on the development of pelvic organ prolapse was evaluated by O’Boyle et al. [471]: in a series of 135 nulliparous pregnant women, POPQ stage appears to increase during pregnancy and does not change significantly following delivery. POPQ stage assignments and POPQ component measurements were compared for first-, second- and third-trimester examinations. Overall, POPQ stage was significantly higher in the third trimester than in the first. These findings probably represent normal physiologic changes of the pelvic floor during pregnancy, but suggest that significant changes may be objectively demonstrated prior to delivery. In nulliparous women, pregnancy is associated with increased POPQ stage compared with non-pregnant control subjects [472].

Sze et al. reported that 46% of 94 nulliparous women had pelvic organ prolapse at their 36-week antepartum visit. Of them, 26% had a stage II prolapse [473].

A recent prospective cohort study assessing 300 nulliparous pregnant women [474], showed that vaginal POP-Q points made a cranial shift from mid to late pregnancy, a caudal shift following delivery, and again a cranial shift after 6 weeks postpartum. Postpartum change was present following both vaginal and caesarean deliveries, but was more pronounced following vaginal delivery. The perineal body and genital hiatus became longer from mid to late pregnancy, and shortened after 6 weeks postpartum. At 12 months postpartum all POP-Q points, except cervix, had recovered to baseline in the vaginal delivery group. The authors concluded that short-term ability to recover was good after the first pregnancy and delivery.

In a recent review, Gachon et al [475] conclude that pelvic organ mobility, ligamentous laxity, levator hiatus and urethral mobility change in a similar way during pregnancy (increase of mobility or distension) and postpartum (recovery). LEVEL OF EVIDENCE:3

1.5. Childbirth

Undoubtedly, vaginal delivery constitutes a traumatic event for the pelvic floor: it may affect the pelvic nerves, the pubococcygeus-puborectalis muscle complex, the pelvic fascial structures or the anal sphincter. However, all women sustain the trauma of their pelvic floor during vaginal birth, but only some of them experience injury.

Several attempts have been made to define fascial descriptors of difficult vaginal delivery, are associated with increased occurrence of prolapse: forceps delivery, a prolonged second stage of labour, and large infant birth weight. Unfortunately, because of the overlapping nature of these different factors, it is difficult to determine which of them is causal and which of them is associated (e.g., forceps delivery is used when there has been a prolonged second stage of labour, and both of these factors increase in large-sized infants).

A recent mechanical model study has shown that even an apparently uneventful vaginal delivery inflicts...
injuries to the pelvic floor muscles, particularly during the extension of the fetal head, having been obtained more than 10% of damaged fibres; the pubococcygeus component of the levator ani muscle (LAM) is the most prone to damage [479].

The role of childbirth in causing damage to the LAM, which is associated with both vaginal delivery and with pelvic organ prolapse, is probably the mediating mechanism in these injuries. Recent investigations using techniques such as magnetic resonance imaging (MRI) and three-four dimensional ultrasound have focused on the morphology of the levator ani complex and its integrity after delivery.

The occurrence of levator trauma after vaginal delivery is reported to be between 15-39.5% when investigated with ultrasound [205-211, 480] (Figure 12) and between 17.7%-19.1% when assessed with MRI [213-215]. This difference in occurrence rate is probably due to the different postpartum assessment of levator ani muscle (which varies in these studies between 24-72 hours to 12 months postpartum). In fact, it has been demonstrated by Staer-Jensen et al [481] that the levator ani muscle has the ability to recover after pregnancy and delivery and most of the recovery occurs during the first 6 months postpartum (LEVEL OF EVIDENCE: II). These results are consistent with other research evaluating levator morphology using either MRI or ultrasonography: 26 primiparous women demonstrated major levator ani defects at 6 weeks, but at 12 months postpartum, 10 of these 26 women no longer had a major defect (6 were categorized as partial defects and 4 as normal). Others similarly have found that avulsion injuries of the levator ani after childbirth resolve in 10-20% of women [214, 482, 483]. On the other hand, recent results from Valsky et al [484] showed that a sonographic finding of LAM defect identified in the period immediately postpartum persists months or year after delivery; therefore this test may be performed following the delivery, or may be delayed without impact the result. Also the DeLancey group demonstrated that the magnitude of LAM tear did not substantially change by 8 months postpartum, but LAM oedema and bone injuries showed total or near total resolution [485].

The following risk factors for levator trauma after vaginal delivery have been described in literature: obstetric anal sphincter injuries (OR: 4.4-8.1); prolonged active second stage of labour per hour (OR: 2.2); forceps delivery (OR: 14.7); fetal head circumference (OR: 3.3); episiotomy (OR: 3.1); increased maternal age [205, 207, 215, 216, 244, 480, 483, 486].

Memon et al [487] showed that ten years after delivery, the prevalence of levator avulsion is almost tripled after forceps compared with vacuum-assisted vaginal delivery (LEVEL OF EVIDENCE II).

An observational study done in women 2–4 weeks before and 2–6 months after vaginal childbirth provided a direct proof for the hypothesis that childbirth is responsible for certain morphological abnormalities of LAM observed in parous women and suggests that older age at first delivery is a risk factor for such trauma. LEVEL OF EVIDENCE II-3 [209].

Vaginal sidewall and third-fourth-degree perineal tears were found to be independent clinical indicators of an increased risk of levator trauma. Such clinical markers may become useful in the identification of women at high risk of levator trauma and future pelvic floor disorders [488].

A recent study carried out by Kamisan Atan et al [489] investigated if the antepartum use of a birth trainer (Epi-No®) may prevent such injuries by altering the biomechanical properties of the pelvic floor. 504 women were assessed with 4D translabial ultrasound in the late third trimester, and again 3-6 months postpartum, after randomisation to control or intervention (use the Epi-No® device from 37 weeks of gestation until delivery) groups. The results of this trial showed no significant difference in the incidence of levator avulsion, irreversible hiatal overdistension, clinical anal sphincter trauma and perineal tears. A marginally higher rate of significant defects of the external anal sphincter on ultrasound was observed in the intervention group. The authors concluded that the antenatal use of Epi-No® device is unlikely to be clinically beneficial in the prevention of intrapartum levator ani damage, or anal sphincter and perineal trauma.

Figure 12: Levator ani defect early postpartum in a patient had spontaneous vaginal delivery (acquisition screen GE Voluson-e ® System).

From Albrich et al, BJOG 2011 [210] with permission.
In the multiplanar mode, the axial plane (lower left) and the rendered image (lower right) show an unilateral levator discontinuity (**) on the right side of puboccigeal-puborectalis muscle.

Eight slices obtained with TUI in coronal-C plane in the same patients: the discontinuity (arrow) is demonstrated in at least three consecutive slices at and above the plane of minimal hiatal dimension (frames *,-1,-2,-3).

To estimate the risk of prolapse associated with levator avulsion injury among a urogynaecological clinic population, Dietz et al. [219] retrospectively considered 781 women, with a mean age 53 years (range 15-89 years), and a median parity of 2 (range 0-12). Significant prolapse (stage II or higher) was diagnosed in 415 (53%) women, and 181 (23%) women were found to have levator avulsion defects. Prolapse was seen in 150/181 (83%) women with avulsion and in 265/600 (44%) women without avulsion, giving a RR of 1.9 (95% CI: 1.7-2.1). The association was strongest for cystocele (RR 2.3, 95% CI: 2.0-2.7) and uterine prolapse (RR 4.0, 95% CI: 2.5-6.5). The authors concluded that women with levator avulsion defects were about twice as likely to show pelvic organ prolapse of stage II or higher than those without, with an increased risk of cystocele and uterine prolapse.

A cystocele with an intact retrovesical angle is more likely to be associated with avulsion injury of the LAM and thus more likely to be caused by birth-related trauma [490].

Pubococcygeal avulsion injury and levator hiatal ballooning are independent risk factors for symptoms and sign of prolapse. The role of avulsion in the pathogenesis of prolapse is not fully explained by its effect on hiatal dimensions. It likely that avulsion implies not only muscular trauma but also damage to structures impossible to assess clinically or by imaging, i.e. myofascial and connective tissue [491].

Pelvic organ prolapse seems considerably lower after caesarean section [161, 429] but it has been described in a prospective study in 35% of 26 women after caesarean section during active labour compared to 32% of 41 women who had spontaneous vaginal deliveries [473]. On the other hand, one epidemiological study using validated questionnaires ruled out the influence of labour versus no-labour caesarean delivery on pelvic organ prolapse [492] (LEVEL OF EVIDENCE: II-2). Recent studies [210, 212] reported cases of early levator abnormalities after emergency caesarean section, and hypothesised a possible role of the active labour in the occurrence of lesions of the pelvic muscular floor.

A recent study of Leijonhufvud et al. [162] considered a cohort study of all women having their first and all subsequent caesarean deliveries (n = 33,167), and an age-matched sample of women having only vaginal deliveries (n = 63,229). Women who had only vaginal deliveries had an overall increased risk of prolapse surgery (HR, 9.2; 95% CI: 7.0-12.1) compared with women who had only having caesarean deliveries. They conclude that having only vaginal deliveries was associated with a significantly increased risk of pelvic organ prolapse surgery later in life compared with only having caesarean deliveries.

There seems to be sufficient proof for the hypothesis that pelvic organ support can be impaired by vaginal childbirth. It is unclear whether this effect is due to stretching or avulsion of structures and whether the observed changes are primary (i.e. directly due to childbirth) or the medium-term or long-term consequence of levator impairment. Several mechanisms may well coexist in one individual [493].

Furthermore, it has been shown that any delivery-related changes occur against the background of marked variations in pelvic organ support in young nulliparous women [494]. As the most significant changes are observed in those with the least organ mobility antenatally [495], the effect of childbirth may be a partial equalisation of those inter-individual differences.

### 1.6. Obstetric and Maternal Factors

A clear link between vaginal delivery and symptoms and signs of pelvic organ prolapse in urogynaecological patients was recently demonstrated by Trutnovsky et al. [496]: nulliparae showed the lowest prevalence of most measures of POP, followed by women exclusively delivered by caesarean section. Highest prevalences were consistently found in women delivered at least once by forceps, although the differences between this group and women delivered by normal vaginal delivery and/or vacuum extraction were significant in three out of eight measures only. Compared with women in the caesarean section group, the adjusted odds ratios for reporting symptoms of prolapse were 2.4 (95% CI 1.30-4.59) and 3.2 (95% CI 1.65-6.12) in the normal vaginal delivery/vacuum extraction group and forceps group, respectively.

Increasing vaginal parity was the strongest risk factor for pelvic organ prolapse in women younger than 60 years in the Oxford Family Planning Study [405]. Compared with nulliparous individuals, the relative risk of developing prolapse was 8.4 for a woman who had delivered two children and 10.9 (95% CI: 4.7–33.8) for someone with four or more children [405]. The Women’s Health Initiative reported that single childbirth was associated with raised odds of uterine prolapse (OR 2.1;95% CI: 1.7–2.7), cystocele (OR 2.2; 95% CI: 1.8–2.7), and rectocele (OR 1.9; 95% CI: 1.7–2.2) [406]. Every additional delivery up to five births increased the risk of worsening prolapse by 10–20% [406]. Similarly, the Progetto Menopausa Italia study showed that risk of pelvic organ prolapse increases with the number of vaginal biths [497].

To ascertain the effect of a second delivery on pelvic floor anatomy, Horak et al. [498] showed that a second pregnancy and delivery do not seem to have a major effect on bladder support and/or levator function. However, the authors documented a case of major...
levator trauma after vaginal birth after caesarean section.

Caesarean section seems to protect against prolapse development whereas forceps delivery increases the risk [492, 499]. Findings of a cross-sectional study of 3050 women randomly selected from a large southern California Health Maintenance Organisation showed that women who had undergone one or more vaginal deliveries had a significantly greater risk of developing symptomatic pelvic organ prolapse than did those who had only caesarean sections (OR 3.21; 95% CI: 1.96–5.26), after adjusting for age, parity, and obesity [492]. The attributable risk of vaginal delivery for development of symptomatic prolapse, or the proportion that could have been prevented with a policy of routine elective caesarean section, was 46% in this population. LEVEL OF EVIDENCE: II-2 [492].

Other obstetric factors that have been associated with an increased risk of pelvic organ prolapse, albeit less consistently, are high infant birth weight (>4500 g), delivery of a macrosomic infant, prolonged second stage of labour, and age <25 years at first delivery [499, 500]. Somewhat more controversial is whether pregnancy itself, distinct from mode of delivery, alters the risk of pelvic organ prolapse. In a small case-control study, pregnancy was associated with worsening prolapse compared with non-pregnant controls matched for age and ethnic origin [472]. A substantial proportion of pregnant nulliparous women show progression from stage 0 or I support in the first trimester to stage I or II in the third trimester [471]. This loss of vaginal support does not seem to return to baseline in the postpartum period.

To date, the studies are controversial considering younger age (25 versus 28 years of age) [499] as well as older age (more than 30 years) [501] at first delivery as risk factors for the development of pelvic organ prolapse. Another large study did not reveal any association at all [402].

Despite the strong relation between obstetric factors and pelvic organ prolapse, most symptomatic cases arise a long time after vaginal childbirth, and most women who bear children do not have symptomatic prolapse [502].

1.7. Age

Both incidence and prevalence of pelvic organ prolapse increase with advancing age. In a cross-sectional study of 1004 women (age 18–83 years) who came for their yearly examination, the relative prevalence of this disorder rose by about 40% with every decade of life [399]. In the Women’s Health Initiative, American women aged 60–69 years (OR 1.2; 95% CI: 1.0–1.3) and 70–79 years (OR 1.4; 95% CI: 1.2–1.6) had a higher risk of prolapse than did those aged 50–59 [406]. Similarly, findings of a cross-sectional study of 21449 menopausal Italian women showed an augmented risk of pelvic organ prolapse in women aged 52–55 years (OR 1.3; 95% CI: 1.1–1.5) and those 56 years or older (OR 1.7; 95% CI: 1.5–2.0) compared with those younger than 51 years [497]. Surgery for prolapse is uncommon in people younger than 30 and older than 80 years; for women between these ages, incidence rises steadily [400].

1.8. Hormones

As age has been clearly shown to affect the prevalence and progression of POP, it is intuitive to believe that declining sex hormone levels observed with ageing may contribute to biochemical changes observed within tissue. However, several researchers studying hormonal status and prolapse have failed to find an association between oestrogen status and the disorder [405, 410, 429, 497].

The female lower urinary tract is a target organ for the action of the two sex steroid hormones, oestrogen and progesterone.

Steroidal hormones exert their effect on tissue through an interaction with specific intracellular receptors. Hormone receptor affinity may be at the root of the differences between women with pelvic floor diseases and normal controls. Progesterone receptors have been found to be expressed more frequently in women with POP than in women without POP [503]. Several polymorphisms are present in the progesterone receptor gene that can alter its expression. A specific genotype (PGR rs484389) was significantly associated with the risk of having POP [504]. Similarly, the oestrogen receptor β gene also contains multiple single nucleotide polymorphisms that affect its expression. A case-control study of 69 women with POP and 141 control subjects found that a specific haplotype for the oestrogen receptor β gene was associated with an increased risk of POP [505].

Studies have shown lower serum oestradiol (E2) levels in premenopausal women with SUI, with [506] and without concurrent POP [507], compared with control subjects. The impact of oestrogen on tissue may be related to its systemic or local levels, or altered sensitivity from a decreased amount of receptors noted in genitourinary tissues [506, 508].

Skala et al. [509], evaluated the expression of oestrogen receptor (ER) alpha (α) and beta (β) and progesterone receptor (PR) in vaginal and periurethral tissue in women with genital prolapse. The expression of PR and ER varied with the extent of prolapse. For patients with prolapse >stage 1 (n=32), there was a significantly greater amount of PR in periurethral tissue (p=0.007) and a significantly lower expression of ER β in vaginal tissue (p=0.008) compared to patients with a low stage prolapse (n=15). Patients with stage II and III prolapse did not differ in their receptor expression. The authors concluded that the expression of PR in periurethral and ER in vaginal tissue varied with the extent of the prolapse.
In a cross-sectional study aiming to determine whether there is a change in the number of vessels in the lamina propria of the vagina after menopause in parallel to ER-α expression on the vaginal wall, Lara et al. [510] showed that postmenopausal women with genital prolapse have a smaller number of vessels and a lower ER-α expression on the vaginal wall compared to normo-oestrogenic premenopausal controls.

The current status of the literature is controversial: some results suggest a hormonal impact on pelvic floor disease, recent findings suggest that hormone deficiency following menopause is unlikely to play a major role in pelvic organ prolapse support and levator ani function [511]. The weak level of evidence emphasises the necessity for future research endeavours in this field to elucidate these complex relationships.

1.9. Obesity

Increasing body-mass index also seems to have a role in development of pelvic organ prolapse. An high BMI increases the risk for prolapse [399, 405, 499, 512, 513] and specifically for progressive rectoceles [514]. Increased waist circumference was associated with more pelvic organ prolapse in some studies [429, 514]. Handa et al. [514] demonstrated this for cystoceles. Women who are overweight (body mass index 25–30 kg/m²) and obese (>30 kg/m²) are at high risk for developing pelvic organ prolapse [406, 500]. Similarly, women with a body mass index of more than 26 kg/m² are more likely (OR 3.0; 95%CI: 1.6–5.7) to undergo surgery for prolapse than are those with a lower value [499].

1.10. Constipation

Repetitive straining, such as that seen in patients with chronic constipation or workers whose jobs entail heavy lifting, has also been associated with pelvic organ prolapse. Spence-Jones et al. [515] reported that straining at stool as a young adult was more common in women with prolapse than in those without (61% vs 4%; p<0.001). Individuals with stage II or greater pelvic organ prolapse had an increased risk of constipation (OR 3.9; 95% CI: 1.4–11.9) compared with women with stage 0 or 1 prolapse [516]. However, findings of larger studies have disputed this association, and several groups have shown that neither overall stage of prolapse nor stage of the posterior vaginal wall correlate with bowel function [517-519]. Additionally, women with only urinary incontinence and no prolapse seem to meet Rome II criteria for constipation with the same frequency as those with advanced pelvic organ prolapse [519].

1.11. Chronic Pelvic Floor Stress

Low socioeconomic status [520] and a labour-intensive occupation [410, 520, 521] are two demographic factors identified as risk factors for the development of POP.

Housewives, who perform more physically demanding work, seem more likely to have prolapse (OR: 3.1; 95% CI: 1.6–8.8) than do professional managerial women [410]. Similarly, people with occupations involving heavy lifting might have a higher chance of undergoing surgery for pelvic organ prolapse [521].

1.12. Previous Operations

Although hysterectomy might heighten the risk of subsequent POP, prolapse symptoms typically develop many years after this procedure [400, 405, 499, 522, 523]. In the Oxford Family Planning Study, surgery for prolapse in women who had undergone a previous hysterectomy was 29 per 1000 women-years versus 16 per 1000 women-years for the entire cohort [405]. The cumulative risk of surgery for pelvic organ prolapse rose from 1% at 3 years after hysterectomy to 5% at 15 years. Risk was highest in women who had undergone a previous hysterectomy for prolapse (158 per 1000 women-years). In a retrospective cohort study of 149,554 women aged 20 and older, the mean interval between hysterectomy and surgery for pelvic organ prolapse in those who developed the disorder was 19.3 years [400, 524]. Contrary to findings of many other studies, the prevalence of prolapse in women with a uterus in the Women’s Health Initiative was slightly higher than for those who had undergone hysterectomy, suggesting that previous prolapse of pelvic organs might have been repaired at the time of the procedure in this study population [406]. The surgical technique performed during hysterectomy, including performance of prophylactic culdoplasty, can lessen the development of a subsequent prolapse [525].

1.13. The Bony Pelvis

There is evidence from several case control studies that variations in axial and pelvic skeletal structure can be associated with increased POP risks. These include increasing severity of thoracic kyphosis, a decrease in lumbar lordosis and in vertical orientation of the pelvic inlet, and an increase in the transverse diameter of the pelvic inlet [526-528]. In a case control study, Handa [529] compared 59 women with pelvic floor disorders with controls using standardised pelvimetry techniques during MRI. After controlling for age, race and parity and using a multiple logistic regression analysis, pelvic floor disorders were significantly associated with a wider transverse inlet (OR 3.4) and a shorter obstetrical conjugate (OR 0.23). The association between early age, advanced stage POP and severe disruption of pubic bone and pelvic muscle structure in women with bladder extrophy is well recognised [530].

During a woman’s lifespan, the pelvic floor is responsible for the urinary and the faecal continence as well as for sexual function. If the anatomy of the pelvic floor is altered, each one of these functions may be compromised. Pelvic organ prolapse is a common condition that often leads to lower urinary tract symptoms (LUTS) and may require surgical intervention to alleviate those symptoms. Therefore, the clinical
evaluation of women with POP symptoms also requires the assessment of urinary and faecal incontinence symptoms as well as sexual disorders. Physicians, who examine women seeking care for one condition, should enquire about the symptoms of other disorders.

The relationship between LUTS and pelvic organ descent however, is not completely understood, so far. In a recent study, Costantini et al. [531] evaluated the correlation between LUTS and POP. They retrospectively reviewed 256 patients who presented with POP and LUTS and underwent POP surgery. Almost 50% of patients reported two or more symptoms and only 4.2% were asymptomatic for LUTS. 73.8% patients had voiding symptoms, 15% urodynamic detrusor overactivity, 5% suffered from hydronephrosis. 57.8% had SUI. The authors concluded that urologists and gynaecologists should be aware of the high frequency of the association of POP and LUTS. POP repair may restore normal anatomy but LUTS may persist after the surgery or develop "de novo."

1.14.1 Bladder function

In a large community-based questionnaire survey, 44% (104/239) of women who had prolapse symptoms (239/3799) also complained of SUI and 37% of overactive bladder [532]. SUI can be masked by POP. SUI may develop after POP surgery and clinically continent women are at risk for developing symptomatic postoperative SUI.

The role of urodynamic studies (UDS) before prolapse surgery is contentious and a hotly debated topic in urogynaecology. Previous studies in women with prolapse and women with uncomplicated SUI have focused on women without preoperative incontinence. Currently, it has not been possible to reach a universal consensus on the role of UDS before prolapse surgery in women with concomitant symptomatic or occult SUI. It is clear that UDS can add some information in women undergoing pelvic organ prolapse surgery and could facilitate counselling of patients. However, there is no evidence that the outcome of surgery is altered by prior UDS [533]. In fact, Weber et al. [534] showed that urodynamic testing before surgery in women with prolapse and stress urinary incontinence symptoms is not cost-effective relative to basic office evaluation. It is possible that UDS could help to identify some urinary dysfunctions, such as a preoperative detrusor overactivity or a occult SUI, but this information rarely leads to a change in the management plan or the type of surgical procedure. Moreover, at present, we have no data to show that UDS can improve subjective or objective outcomes of surgery for prolapse. New well-designed randomised studies are necessary to improve our understanding of this topic.

Evidence of reduced peptide-containing innervation of perineal and periurethral muscles in women with SUI and POP has emerged [449], suggesting a neural abnormality in their pathogenesis. Connective tissue alterations such as decreased α-1 antitrypsin expression and altered elastin metabolism [449], decreased collagen concentration [535], and decreased estrogen receptors [508, 536] have been described in women with urinary incontinence and/or POP.

Failure of bladder, bladder neck, and urethral support is often part of a more extensive defective pelvic organ support. Poor pelvic organ support can lead to pathological pelvic relaxation in one or more compartment(s). Marinkovic and Stanton [537] published a review of 97 articles regarding incontinence and voiding difficulties associated with POP: they describe the incidence, pathophysiology, anatomical changes and resultant consequences, evaluation and imaging of cystocele, rectocele, enterocele, and uterine and vaginal vault prolapse in combination with urinary incontinence. The authors concluded that POP appears to have significant clinical effects on urethral and voiding function that should be quantified preoperatively to allow appropriate surgical intervention, with the aim of restoring vaginal function and correcting concurrent incontinence, whether overt or occult. Not uncommonly, POP can lead to bladder outlet obstruction, detrusor overactivity, and latent SUI that is unmasked only with reduction of the POP (potential, latent, or unmasked SUI) [538]. It is recognised that POP surgery can improve voiding dysfunction and unmask occult SUI by alleviating the urethral kinking causing outlet obstruction [539].

Burrows et al. [540] described symptoms of bladder, bowel, and sexual function in 330 women with POP, comparing different degrees of prolapse staged by POP-Q system. Women with SUI symptoms had less advanced prolapse (median 5 cm less prolapse in the apical compartment) than those without SUI. Women who needed to manually assist micturition had more advanced prolapse (median 3.5 cm more prolapse in the most severe compartment) than those who did not. Women with urgency and urgency incontinence had less advanced prolapse (median 3 cm or less) but the differences were smaller than those for SUI. Severity of prolapse was not associated with bowel or sexual symptoms in this study. The most important finding is that there are few strong associations between specific symptoms and severity of prolapse.

LEVEL OF EVIDENCE: II-2.

Women without anterior prolapse on POP-Q exam rarely (<10%) report urinary splitting but ranged between 23 and 36% for stage III and IV. Urinary splitting is 97% specific for anterior prolapse. Seventy-seven percent of women with stage II POP report a symptomatic bulge, and report of a bulge has an 81% positive predictive value and a 76% negative predictive value [541]. It seems therefore that if women present with symptoms of vaginal/perineal bulge, then careful assessment for POP is warranted. If a woman with SUI, however, presents with no symptoms of
POP, then surgical treatment of asymptomatic and incidental anterior POP does not seem to be indicated.

The surgical management of women with POP and with latent SUI remains controversial and challenging. Maher et al. [542] aimed to determine the effects of surgery in the management of POP by searching the Cochrane Incontinence Group Trials register (as on June 2004) for randomized or quasi-randomized controlled trials that included surgical procedures for POP. The meta-analysis on the impact of POP surgery on continence was ‘limited and inconclusive’, but they report that 10% of women developed new incontinence symptoms postoperatively.

Levin et al. [543] prospectively evaluated 313 women who underwent TVT procedure for overt (228 women) or occult (85 women) SUI. About 50% women also underwent POP surgery concurrently. Overall, for 241 women with a follow-up of at least 12 months, 6.6% had persistent mild SUI, an additional 7% had urodynamic evidence of asymptomatic sphincter incontinence, whereas 8% developed de-novo urgency incontinence.

Among 130 women who underwent surgical treatment for an enterocele (75% the vaginal wall protruded through the introitus), 77% presented with SUI or detrusor overactivity. Sixty-seven percent patients underwent Burch colposuspension with enterocele repair. Postoperative SUI requiring further treatment occurred in 10% after a mean period of follow up of 10 months, and cystocele developed in 1.5% [544].

Urologists and urogynecologists are faced with the challenge of determining which women with POP associated with SUI will benefit from concurrent surgical intervention for the POP. A comprehensive and anatomic approach to pelvic floor reconstruction is recommended, but no high-level evidence-based studies exist in the contemporary literature.

The intended goal of surgical correction of SUI and POP is durable restoration of normal anatomy and function, with symptomatic relief and avoidance of morbidity. At present, few evidence-based conclusions can be drawn regarding when to surgically intervene for SUI in women who present with POP. The available contemporary studies are few with a small number of patients; however, it seems prudent to recommend repairing symptomatic POP in women who present with SUI. So far, routine performance of anti-incontinence procedures at the same time as reconstruction of anterior compartment does not seem to be justified by the current evidence. In women with symptomatic SUI and incidental, asymptomatic POP, one must balance any potential treatment associated morbidity with the intended clinical/surgical outcome.

Recently, Ramanah et al [545] compared changes in urinary symptoms before and after POP surgery, using either laparoscopic sacrocolpopexy (LSC) or transvaginal porcine dermis hammock placement with sacrospinous ligament suspension (VS). Out of the 151 patients included, 87 patients underwent LSC, and 64 VS. Overall, after a median follow-up of 32.4 months, POP surgery improved urinary frequency (P=0.006), voiding difficulty (P=0.001), stress urinary incontinence (P=0.001), but not urgency (P=0.29). VS was more effective in treating SUI (P<0.001 vs. 0.52) while LSC more effective on voiding difficulty (P=0.01 vs. 0.08). Postoperative de novo symptoms were observed in 35.8% of patients with no difference between the groups (P=0.06). UDI (P=0.04) and UIQ (P=0.01) scores were significantly lower after surgery. However, LSC significantly improved UDI (P=0.03) with no effect on UIQ (P=0.29) scores while VS significantly improved both scores (P=0.02 and 0.001, respectively). Upon multivariate analysis, only the improvement in the impact of urinary symptoms on daily living was independently associated to VS (OR 5.45, P=0.01). The authors concluded that most preoperative urinary symptoms decreased after POP surgery with equivalent proportion of de novo symptoms after vaginal and laparoscopic approaches.

The prevalence of OAB symptoms in relation to sign and symptoms of POP is reported to be between 22.5-36.8% in community based studies [532, 546-548] and between 16-88% in hospital based studies [538, 549-551]. By and large, the prevalence of OAB with POP is greater in the hospital-based studies than in the community-based studies, which is not surprising, given the selected nature of the hospital samples. Only three studies, one community-based and two hospital-based, were identified that presented data specified by compartment and showed conflicting results: in the study by Miedel et al. [548], there is a clear relationship between anterior and posterior compartment prolapse and OAB symptoms in contrast to central compartment prolapse. In the studies by Bradley and Nygaard [552] and Sobhigol and Charandabee [553] such a relation could not be identified. In a study by Ellerkmann et al. [554] no correlation between worsening of the anterior compartment and urgency incontinence could be found. Data regarding the relationship between the stage of prolapse and OAB are very sparse. Burrows et al. [540] found that urgency and urge incontinence occurred more often in women with a less advanced prolapse. Another study using ultrasound reached the same conclusion; women with a higher grade of bladder descent were less likely to suffer from urgency incontinence [555].

The pathophysiology of OAB in women with POP is unclear. Several theories exist: bladder outlet obstruction; release of various chemical factors (ATP, Ach, and P2X3) by bladder distension stimulating the detrusor receptors; traction on the urethra due to prominent cystocele resulting in an open urethra with urine entering the urethra that causes detrusor contractions. Bladder outlet obstruction is likely to be the most important mechanism by which POP induces OAB symptoms and DO signs. However, several other mechanisms might also play a role but indicators show a causal relationship between OAB and POP [556].
1.14.2 Anorectal function

Prolapse of the posterior vaginal wall, alone or in combination with other compartment defects, can be challenging for the pelvic surgeon. Pelvic pressure, vaginal/peri-anal splinting to defecate, difficult defecation, faecal incontinence (FI) and impaired sexual relations are some of the symptoms associated with posterior POP. Whether the prolapse is the cause of the symptoms or is a result of straining and stretching of supporting structures in women with defecation disorders, remains unclear.

Bowel symptoms like incontinence of flatus and obstructed defecation are common in women with POP. In several surveys, the incidence of anal incontinence (AI) ranges from 15-50% [517, 532, 557-564]. FI was reported in 5-22% of women with prolapse [414, 557, 563] which was significantly more than bowel symptoms in a control group [563]. There were no associations found between prolapse stages and symptoms after adjusting for age and BMI [517, 562].

Meschia et al. [559] reported that among 881 women with symptoms of urinary incontinence and pelvic organ prolapse, the prevalence of AI was 20%. Urinary incontinence and severe rectocele were found to be associated with AI.

Disparities have been shown between the degree of POP, pelvic floor symptoms and defaecography results [414, 565]. Two series of defaecographies in consecutive patients with prolapse and/or evacuation disorders described defaecographic findings that changed the patients diagnosis (though not always the management) in 46 of 62 of cases and noted enterocoeles that were not found on physical exam in approximately 50% of cases [566-568]. Sigmoidoceles are present in 4-11% of reported series, and are nearly always missed on physical examination [568, 569]. Their clinical impact and management remain unclear. Defaecography is not a routine investigation in women with POP and interpretation may be difficult in some cases since normal asymptomatic women may have focal defaecographic abnormalities [565]. The prevalence of abnormal colonic transit time is approximately 20% in patients presenting with evacuation disorders [570]. An abnormal preoperative colonic transit study is the most consistently cited risk factor for failure of rectocele repair to relieve evacuation symptoms, regardless of the surgical technique [571-573]. Goh et al. [574] reviewed the management of rectocele and clearly describe the complexity of clinical conditions resulting from the possible combination of various gynaecological and colorectal symptoms with anatomical abnormalities and the different surgical approaches.

Recently, Ramanah et al. [575] evaluated changes in anorectal symptoms before and after POP surgery, using laparoscopic sacrocolpoperineopexy. Preoperative and postoperative anorectal symptoms, colorectal-anal distress inventory (CRADI) and colorectal-anal impact questionnaire (CRAIQ) scores were prospectively compared from 90 consecutive women undergoing laparoscopic sacrocolpoperineopexy. After a median follow-up of 30.7 months, laparoscopic surgery significantly worsened CRADI (p=0.02) with no effect on CRAIQ (p=0.37) scores. Post-operative and de novo straining (27%) and the need for digital assistance (17%) were the most frequent anorectal symptoms. No correlation was found between laparoscopic surgery and anorectal symptoms after multivariate analyse (OR 2.45, p=0.05). The authors conclude that anorectal symptoms are not improved after POP surgery by laparoscopic sacrocolpoperineopexy.

1.14.3 Sexual function

Patients who present with POP symptoms should be questioned about their sexual function. Surgical treatment in these patients may be curative of their sexual disorders (e.g., by solving incontinence in patient with coital incontinence) but may also have undesired effects on sensation, blood flow, and the anatomy. These effects can affect sexual arousal and orgasm or cause dyspareunia.

Dyspareunia, coital incontinence and vaginal dryness are common complaints in women with pelvic floor disorders [576, 577]. Although sexual dysfunction appears to be more frequently observed in these women, pelvic organ prolapse seems not to negatively impact on sexual satisfaction when controlled for confounders like age [577-579].

Clinical populations are likely to have more severe pelvic floor symptoms and more advanced pelvic organ prolapse, with a greater potential for impact on sexual function, whereas community populations may have mild symptoms and prolapse, with minimal impact. These conflicting results may also be the result of population differences in other related factors, such as age, menopause, or the status of the woman’s intimate relationship. Other challenges in studying the factors associated with sexual function in women with POP include a limited characterisation of female sexual function in some studies and difficulties assessing sexual function among women who do not have intercourse.

Handa et al. [580] reported that, with respect to anatomic prolapse, women with stage III-IV prolapse were more likely to report decreased libido and infrequent orgasm than women with stage 0 support. Adjustment for other characteristics attenuated the strength of these associations, although the association between prolapse and infrequent orgasm remained statistically significant. In the final adjusted model, the odds of infrequent orgasm were increased more than three times for women with stage III-IV prolapse (P=0.02). The authors conclude that women the anatomic prolapse (stage III-IV) were more likely to report infrequent orgasm but they were not at increased risk of other sexual problems. An important observation is that women with stage II support were
not more likely to report any sexual complaint than women with stage 0 support. This suggests that the physical presence of stage II prolapse alone is not associated with sexual dysfunction. In contrast, women with prolapse symptoms (as reflected by a high score on the prolapse scale of the Pelvic Floor Distress Inventory) were much more likely to report sexual complaints. Thus, one can conclude that sexual function is worse in women with symptomatic prolapse. LEVEL OF EVIDENCE II.

In 305 women over 40 years seeking outpatient gynecological care association between sexual complaints and perceived sexual distress has been investigated. Women with sexual distress were also more likely to report sexual difficulty related to pelvic floor symptoms, sexual avoidance due to vaginal prolapse (13.9% vs. 1%, P=0.001) [581]. A better understanding of the anatomy of this area and of sexual function will guide us in a more targeted approach to management of these conditions.

2. CONCLUSIONS AND RECOMMENDATIONS

The aetiology of POP is thought to be multifactorial with contributions from both environmental and genetic risk factors. Vaginal delivery is the most traumatic event for the pelvic floor during the woman lifespan, recent growing evidence underlines the possible genetic influence in aetiology of POP. High concordance in the POP stage between nulliparous and parous sister suggest a familial predisposition toward developing this condition [413]. LEVEL OF EVIDENCE II-2. Recent studies provided strong scientific evidence of genetic contribution to pelvic organ prolapse: 6 single-nucleotide polymorphisms are significantly associated with POP in high-risk familial case group participants [416]. LEVEL OF EVIDENCE II.

Also with respect to abnormal extracellular matrix (difference in collagen type and metabolism, elastin turnover), increasing evidence supports the genetic aetiology of POP. LEVEL OF EVIDENCE II. This has been confirmed by severe heritable connective tissue disease, in which POP predominates [453-456].

Hormonal and mechanical physiological alteration during pregnancy affect the pelvic floor support, but it has still to be demonstrated if it is a reversible factor. Even if it has been demonstrated that vaginal delivery is the major traumatic event for the pelvic floor during the woman lifespan, caesarean section does not seem to be completely protective (LEVEL OF EVIDENCE II). Forceps, vaginal parity, prolonged second stage of labour, infant birthweight >4500 g are obstetrics risk factors for development of POP. The neurological sequelae of the vaginal delivery on the pelvic floor are still controversial.

Declining sex hormone level, ageing, age, obesity, constipation, chronic pelvic floor stress are associated with pelvic organ prolapse. Although it has been documented that most of the patients with POP experience, beside prolapse symptoms, urinary, faecal and sexual symptoms, their anatomical-functional relationship remains unclear. Moreover, last findings demonstrated that there are few strong associations between specific symptoms and severity of prolapse. LEVEL OF EVIDENCE: II-2.

It is becoming imperative to better understand the pathophysiology underlying the SUI concomitant with POP, in order to adapt the surgical management of these patients.

Also the complexity of anorectal function in patient with POP need to be clarified, as well as sexual function, which seems to worse in women with symptomatic prolapse but not with the physical presence of stage II prolapse alone.

New research focuses on the identification of at-risk populations to develop pelvic organ descent. Establishing the familiarity of POP may identify populations that can be targeted for primary and secondary prevention studies, such as elective caesarean delivery. If specific genes can be identified, we may understand why some patients do not respond to certain therapies. Moreover, biomarkers or novel proteins, are expected to be related to various POP phenotypes.

The research priorities in pelvic organ prolapse are:

- to understand the mechanical and functional aspects of the vaginal birth
- to clarify the effects of the labour on the pelvic floor and consequently of emergency caesarean section
- to quantify the importance of genetic heritability for POP
- to increase the number of genetic resources (racial and ethnic background investigated with genetic studies)
- to determine possible explanations for related conditions (e.g. hernia, bowel dysfunction)

VI. PATHOPHYSIOLOGY OF FAECAL INCONTINENCE

Faecal continence is maintained by a complex, poorly elucidated process involving the structural and functional integrity of the anorectal unit, the central and peripheral nervous system and pelvic structures. Continence requires a closed anal canal at rest, sensory function to detect the presence of flatus or stool in the rectum, intact reflex response of the appropriate muscles, cognitive recognition of the sensory signal, adequate storage capacity in the rectum and adequate function of the puborectalis and sphincter
muscles. In addition, other factors such as stool consistency and physical mobility play a role. Disruption in the normal anatomy or physiology in any of these areas may lead to incontinence. Often, multiple factors are contributing in patients with significant faecal incontinence [582-586].

1. STRUCTURE AND FUNCTION OF THE ANORECTUM

The anus is a muscular tube 2 cm to 4 cm long consisting of the internal anal sphincter, conjoined longitudinal muscle, external anal sphincter and puborectalis muscle.

1.1. Muscles

1.1.1 Internal anal sphincter (IAS)

The internal anal sphincter (IAS), an involuntary smooth muscle, is a 0.3 cm to 0.5 cm thick expansion of the circular smooth muscle layer of the rectum. The IAS ends about 10 mm proximal to the distal end of the external sphincter. It is primarily responsible for closure of the anal canal at rest through both myogenic and sympathetic excitatory activity. Studies disagree about the relative contribution of myogenic and nerve induced activity to the resting tone [587, 588]. The IAS generates slow waves occurring 6-20 times per minute; about 10 % of asymptomatic people also have ultra-slow waves with pressures fluctuating between 20 mmHg and 50 mm Hg. [589-591]. The significance of variations in recordings between controls and incontinent patients is not well understood [592]. The internal anal sphincter contains non-adrenergic, non-cholinergic (NANC) fibres which contribute to contraction of the muscle mediated by nitric oxide [593-595]. The possible roles of other neurotransmitters and of the interstitial cells of Cajal are being actively studied in animal models [596-600]. Other animal studies have focused on the cellular regulation of basal tone in the IAS. Up regulation of RhoA/Rho kinase in the smooth muscle cells of the IAS plays a significant role in the maintenance of the basal tone [601]. The RhoA/Rho kinase components are responsible for the inhibition of myosin light-chain phosphatase of resulting in high level of myosin regulatory light chain [602].

1.1.2 External anal sphincter (EAS)

The external anal sphincter, a 0.6 cm to 1.0 cm thick cylinder of striated muscle covers the whole length of the internal sphincter and extends more distally into the subcutaneous tissue. The external sphincter contributes to the resting tone. Its primary function, however, is to contract to preserve continence when stool or flatus is present in the rectum or intra-abdominal pressure increases. The contraction may be voluntary or reflexive with increased abdominal pressure from coughing or distension [603]. The muscle also relaxes to facilitate evacuation. The separation of the external sphincter into sections is controversial [604]. Many authors describe three sections termed superficial, subcutaneous and deep but they have also been described as subcutaneous, main body and deep winged portion based upon MRI imaging [605, 606]. On MRI images, the subcutaneous portion is visibly distinct from the other portions with less clear separation between the middle and deeper portions [605]. Others argue the EAS functions as a single muscle unit. The EAS is a predominantly slow-twitch, fatigue resistant muscle with a majority of Type I fibres although there are also Type II rapidly contracting fibres as well [607, 608].

1.1.3 Conjoined longitudinal muscle

The outer longitudinal muscle layer of the rectal wall joins with fibres of the levator ani muscle to become the conjoined longitudinal muscle. The muscle extends distally between the internal and external anal sphincter and then splits into extensions that traverse the superficial portion of the external sphincter to attach to the perianal skin and medially through the internal anal sphincter to join the submucosa smooth muscle [609]. Suggested roles for this muscle include provision of supporting meshwork for the anal sphincters and assistance in maintaining anal closure. A more functional role is suggested by the differential response of the longitudinal muscle to neurotransmitters when compared to the internal anal sphincter [595]. One suggested role is that contraction of the muscle flattens the anal cushions and shortens the anal canal [610].

1.1.4 Puborectalis muscle (PR)

The puborectalis muscle, the most medial portion of the levator ani muscle, is a U-shaped loop of striated muscle that encircles the anorectal junction and attaches to the posterior aspect of the pubis. The puborectalis muscle is a mixture of Type I and Type II fibres but has fewer Type II fibres than the EAS [611]. It functions to close the upper anal canal [612, 613]. It is situated immediately cephalad to the external sphincter. The configuration of the puborectalis muscle results in the anorectal angle between the distal rectum and anal canal. At rest, the anal canal forms an angle with the axis of the rectum of approximately 90°; during voluntary squeeze the angle becomes more acute, approximately 70°; during defecation, the angle becomes more obtuse, about 110° to 130°. Some data support the concept that the puborectalis muscle is part of the levator ani muscle (embryology, in vitro stimulation studies, innervation) [614-620], while other research suggests that it is part of the external anal sphincter (anatomic dissection, function during cough and straining [621-623]. The puborectalis muscle responds to increased abdominal pressure (coughing or straining) and rectal distension by contraction.
1.1.5 Levator ani

The levator ani muscles are a pair of broad sheets of striated muscle lying below the pelvic organs. There are three major components with different attachments. The ileococcygeus muscle arises from the ischial spine and attaches to the lateral aspect of the lower sacrum and coccyx. The pubococcygeus muscle runs from the posterior aspect of the pubis, mixes with fibres from the contralateral muscle at the anococcygeal raphe and inserts at the distal sacrum and coccyx. The third component is the puborectalis muscle which is described above. The urethra, vagina and rectum pass through an opening between the levator ani muscles called the levator hiatus.

1.2. Nerve Structure and Sensation

The somatic nerve supply arises from the second, third and fourth sacral spinal segments. The lower motor neuronal cell bodies for these nerves are located in Onuf's nucleus of those sacral spinal segments. The primary nerve is the pudendal nerve which has both motor and sensory functions [624]. The pudendal nerve divides into three main branches. One branch, the inferior rectal nerve, supplies the external sphincter. The levator muscles including the pubococcygeus receive innervation directly from those spinal segments [617, 618, 620, 625]. However, the pubococcygeus muscle frequently receives an auxiliary supply from the inferior rectal and perineal branches of the pudendal nerve on its inferior aspect [626]. Both the EAS and levator ani muscles may be controlled voluntarily through corticospinal descending motor pathways [611]. They are also under reflex control through sacral reflex pathways. Pudendal nerve block creates a loss of sensation in the perianal and genital skin and weakness of the anal sphincter muscle, but it does not affect rectal sensation [627]. It also abolishes the rectoanal contractile reflexes, suggesting that pudendal neuropathy may affect the rectoanal contractile reflex response.

The anorectum also has a rich nervous supply thought the enteric, sympathetic, parasympathetic and extrinsic spinal sensory neurons. Enteric motor neurons control most aspects of rectal motility; parasympathetic and sympathetic influence is mediated largely through modulation of the enteric neuronal circuits [628]. Within the myenteric plexuses there are motor, sensory and interneurons. The sympathetic supply of the rectum arises from the first three lumbar spinal segments. The innervation is carried through the preaortic plexus to the upper rectum and through the presacral nerves to the hypogastric plexus and then through the hypogastric nerves to the pelvic plexus. The parasympathetic fibres originate in the sacral parasympathetic nucleus in the sacral spinal cord and emerge through the sacral foramen as the nervi erigentes. They join the sympathetic fibres at the pelvic plexus and pass through rectal nerves to the rectal wall. The parasympathetic pathways have a role in propulsive activity of the colon and defaecation.

Extrinsic sensory innervation of the rectum seems to be responsible for sensory perception of rectal distension. Sacral afferents have cell bodies in the dorsal root ganglia of the sacral segments. Specialised sacral afferents have mechano-sensitive transduction sites within the myenteric ganglia of the rectum [629, 630]. These sites are sensitive to distension and contraction of surrounding muscle layers. Both thinly myelinated A-fibers and unmyelinated C-fibres are present in the rectal mucosa, and the myenteric plexus [7631-634]. The C-fibres are mostly present in the wall of the rectum, while the A-fibres predominate in the rectal mucosa [634]. These nerves most likely mediate the distension or stretch-induced sensory responses as well as the viscerovisceral, the rectoanal inhibitory, and the recto-anal contractile reflexes [633-635]. The sensation of rectal distension is most likely transmitted along the S2, S3, and S4 parasympathetic nerves [633]. Clinical studies confirm that balloon distension is perceived in the rectum and that such perception plays a role in maintaining continence [636, 637]. Furthermore, sensory conditioning can improve hyposensitivity of the rectum [638, 639].

Anal sensation is carried in the inferior rectal branch of the pudendal nerve. The upper anal canal particularly has a rich mixture of free and organised nerve endings such as the Krause end-bulbs, (cold) Golgi-Mazzoni bodies (pressure), genital corpuscles (friction), and the sparse Meissner’s corpuscles (touch) [633, 640, 641]. Specialised afferent nerves may exist that transmit the sensations of touch, temperature, tension, and friction, but are incompletely understood [633]. The role of anorectal temperature sensation is subject to debate [642-646]. The likely role of anal sensation is to facilitate discrimination between flatus and faeces and the fine-tuning of the continence barrier, but its precise role needs to be characterised.

1.3. Cerebral Cortex

Rectal distension produces activations bilaterally in the secondary somatosensory cortex, sensory association cortex, the anterior cingulate cortex and insular cortex, as well as bilateral activation in the prefrontal cortex and extending from the peri-orbital cortex to the anterior temporal lobe [647-650]. Studies have identified activation in multiple areas of the cortex including those involved in spatial discrimination (secondary somatosensory cortex, sensory association cortex) and those that process affective and cognitive aspects of sensation (the anterior cingulate cortex, insula and prefrontal cortex). While rectal and anorectal stimulation activated similar regions of the brain the locations within the regions varied [651]. Anal musculature is represented bilaterally on the superior motor cortex (Brodman area 4); the degree of symmetry varies [652].

1.4. Reflexes

Distension of the rectum results in contraction of the rectum, relaxation of the internal anal sphincter and contraction of the external anal sphincter.
1.4.1 Rectoanal inhibitory reflex (RAIR)
Rectal distension is associated with a fall in anal resting pressure known as the rectoanal inhibitory reflex. The amplitude and duration of this relaxation increases with the volume of rectal distension [653]. It has been suggested that bowel contents are periodically sensed by anorectal “sampling,” the process by which transient relaxation of the IAS allows the rectal contents from the rectum to come into contact with specialised sensory organs [654-656]. This process allows discrimination between flatus and stool.

1.4.2 Cough reflex
A abrupt increases in intra-abdominal pressure, such as those caused by coughing or laughing, are associated with increases in anal sphincter pressure [603, 657-660]. The increased pressure may be achieved through multiple mechanisms, including reflex contraction of the puborectalis [661]. The response is relative to the intensity of the cough [657]. It is unclear whether the response is a polysynaptic spinal reflex [603, 658] since it is preserved after spinal cord transection [662] or also requires central integrative centers [659].

1.4.3 Rectoanal contractile reflex (sensorimotor response)
The rectoanal contractile reflex (or rectal anal excitatory reflex or inflation reflex) is the contraction of the EAS in response to rectal distension [663-665]. The amplitude and duration of the rectoanal contractile reflex increases with rectal distension up to a maximum volume of 30 ml [653].

1.5. Rectum
The rectum is a hollow muscular tube, 12 cm to 15 cm long, composed of a continuous layer of longitudinal muscle that interfaces with the underlying circular muscle. These muscles are a mixture of smooth muscle cells and several types of interstitial cell of Cajal [628]. A network of interstitial cells of Cajal joined by gap junction connections coupled to smooth muscle cells trigger mechanisms that give rise to large, slow repetitive depolarisation of the smooth muscle, the slow waves [666]. The proximal end is defined either as the sacral promontory, the third sacral vertebral bone or the area where the colonic taenia splay out and end. The distal end is the dentate line or anorectal ring. The rectum serves as a reservoir for storage and a “pump” for evacuation of stool facilitated by several characteristics. The rectal walls are compliant maintaining a relatively low pressure with increasing volumes. Its innervation allows the sensation of increasing volume [582, 628].

1.6. Anal Endovascular Cushions
The submucosa of the anal lining contains blood vessels, connective tissue, smooth muscle and elastic tissue. They typically form three separate complexes of smooth muscle fibres and vascular channels called the anal cushions [667, 668]. A recent study of women demonstrated the normal variation in size; the size did vary with posture and parity but not age, history of obstetrical trauma or mild haemorrhoid symptoms [669]. Their contribution to continence is poorly studied and controversial.

1.7. Stool Consistency
Considerable evidence exists that evacuation of formed stool is more easily deferred than loose stool (discussed in detail under diarrhoea).

1.8. Physical Mobility
The ability to defer evacuation until a socially acceptable time and place requires the physical mobility to reach a bathroom in the required time frame. The contribution of physical mobility to continence is largely inferred from studies identifying lack of physical mobility as a risk factor for incontinence [670-672]. There is limited information about the relative role for mobility in continent patients.

2. CONTINENCE MECHANISM
Complete continence is most likely with normal transit of formed stool, anal closure at rest, sufficient reservoir capacity and sensation in the rectum, functional reflexes for sampling and sphincter contraction, adequate cognitive function to recognise the urge to defaecate and physical mobility to reach the bathroom in time.

The anus is normally closed by the tonic activity of the IAS with contribution from the EAS and PR at different levels of the anal canal [613, 673]. Studies of the relative contribution of the IAS to the resting tone yield results varying from 55-85% [588, 627]. Some of that variation is likely related to the measurement technique utilised but it has also been found that resting pressure varies during the day and with posture, increasing with the upright position [674, 675]. The IAS contribution is also influenced by rectal distension [588, 676]. Some postulate that the anal cushions provide a tight seal based upon studies showing that the sphincter muscles in their circular configuration cannot contract sufficiently to provide complete closure [677, 678]. An in vitro study showed that even during maximal involuntary contraction, the internal sphincter ring was unable to close the anal orifice completely and a gap of approximately 7 mm was left open. This gap was filled by the anal cushions [679]. Anal cushions may exert pressures of up to 9 mmHg and thereby may contribute 10% to 20% of resting anal pressure [680]. These barriers are further augmented by the puborectalis muscle, which pulls the anal canal forward forming the anorectal angle. The extent to which the anorectal angle contributes to continence is controversial [673, 681-685]. One study suggests that it is important to the control of semi-solid material more than the control of liquid [686].
With rectal distension or increased intra-abdominal pressure, this barrier is reinforced by reflex or voluntary contraction of the EAS and PR. The contraction requires functional peripheral, spinal and cerebral function to sense and recognize the distension, activate the reflex and voluntary responses. In addition, adequate muscular contraction to increase the anal pressure is required. The rectal wall must distend to allow accommodation to the increased pressure. Finally, the mobility to reach an appropriate setting before the muscle fatigues is required.

3. DEVELOPMENT OF INCONTINENCE

Clearly there are a number of potential areas of injury or dysfunction in the complex mechanisms required for continence that might result in incontinence. Faecal incontinence (FI) occurs when one or more mechanisms that maintain continence is disrupted to an extent that other mechanisms are unable to compensate. Hence, FI is often multi-factorial [582-586]. In a prospective study, 80% of patients with FI had more than one pathogenic abnormality [583]. The interaction of those factors and when they result in clinical incontinence is poorly understood.

3.1. Passive Incontinence

Compromise of anal closure and loss of sensation may result in soiling or incontinence without awareness. Prolapsing tissue (either mucosal or full thickness rectal prolapse, rectal lesions) prevents closure of the anus. Some believe that the anal cushions are a necessary component of anal closure [678]. Injury secondary to trauma, surgery or childbirth and weakness of the IAS are other causes. IAS atrophy occurs in systemic sclerosis and likely contributes to FI [687, 688] although neuropathy appears to be a contributing factor as well [689]. Loss of sensation occurs from peripheral neuropathy, spinal cord and cerebral cortex events or after transection of the nerve supply by surgical or other trauma. Increasing evidence suggests that rectal hyposensitivity significantly contributes to passive incontinence [690-694]. Interestingly faecal seepage in men occurs despite normal anorectal physiology testing [690, 695, 696].

3.2. Urgency Incontinence

Incontinence occurs when the ability to hold stool or flatus is overwhelmed. If the rectum cannot distend to hold stool or the muscles do not contract adequately incontinence results. Changes in the reservoir function of the rectum from disease processes, radiation therapy or surgical resection. Pelvic floor muscle dysfunction may result from direct injury causing a defect or weakness. Iatrogenic or obstetrical trauma to the IAS is the most common cause of injury to that muscle. Direct injury to the EAS occurs most frequently from obstetrical injuries which are comprehensively presented elsewhere but may also occur from surgery or other trauma. The puborectalis and levator ani muscles may also be injured and the presence of defects appears to correlate with poor contractility and symptoms in several studies [697-701]. Major levator ani muscle injuries are more frequent in women with EAS obstetrical injuries and those with combined injuries are more likely to be symptomatic [699]. However, other investigators found no relationship between the presence of levator ani injuries and FI [702, 703].

Rectal hypersensitivity, a lower threshold for the urge to defaecate, also contributes to urgency incontinence [584, 585, 704-708]. Complex, poorly understood mechanisms mediate rectal hypersensitivity. Variables include decreased compliance, increased sensitivity of extrinsic peripheral pathways or central afferent mechanisms [706].

4. RISK FACTORS FOR FAECAL INCONTINENCE

Many events and conditions impact the mechanisms of continence often in multiple ways. The next section covers the conditions that most frequently contribute to incontinence.

4.1. Ageing

Multiple studies document the increasing incidence of FI with aging in both men and women [586, 709-715]. One study of women in a community found that 70% of incontinence developed after the age of 40 [716]. Another study of women in the United States documented an initial 15% prevalence of incontinence in women over 50 years old and onset rate of 7% over the next 10 years [717].

While the rising incidence is well documented, understanding of the physiologic impact of aging is less clear. Conflicting evidence exists about the effect of ageing on anal resting pressure. While a number of studies report decreased anal resting pressures in older continent and incontinent persons [707, 718-721], some found lower pressures in patients with incontinence but not asymptomatic older persons [722, 723]. Increased thickness of the internal anal sphincter is associated with aging [707, 724-727]; the finding is thought to represent increased fibrosis although that hypothesis is not proven. Animal studies of smooth muscle contraction demonstrate decreased contractility with aging [728]. Studies of the internal sphincters of ageing animals found changes in translocation of signalling molecules as well association and phosphorylation of contractile proteins [728].

Most studies of the effect of ageing on anal squeeze pressures found decreasing pressures with advanced age [719-723, 729, 730] but not all [707, 731, 732]. One report found decreasing anal squeeze pressures with age in women but not men [730]. The decrease in anal squeeze pressures does not correlate with easier fatigability of the external sphincter. Indeed, studies show no change with age [733] or that the
external sphincter becomes more resistant to fatigue with age [734]. These findings are consistent with studies of skeletal muscle in general which show that reduction of muscle fibers with increasing age with a greater loss of Type-II fibers which are less fatigue resistant [735]. The result is a weaker but more fatigue resistant muscle. Very little specific data about the external anal sphincter exists, however.

The decreased anal squeeze pressures might also be related to external sphincter atrophy. Thinning, presumed to be secondary to atrophy, of the external sphincter has been documented in both endoanal ultrasound and MRI studies [724-726, 736-738]. One study found excellent correlation of atrophy on imaging with the pathologic changes of atrophy [739]. Some studies found that atrophy is related to aging [726, 737], but not all [707]. FI did correlate with external sphincter atrophy [707]. Data from studies of nerve injury in animals reveals that sphincter atrophy and decreased function develops after nerve injury [740-742]. It is known that muscle atrophy secondary to age related loss of anterior horn cell occurs [743]. Human studies demonstrate increased muscle fiber density suggesting re-innervation in the external sphincter with age [723, 744].

Finally several studies found a decrease in rectal sensitivity with increasing age [718, 729]. One study found that decrease only in women [721]. The relationship of this finding to FI is not clear.

There is early and sometimes inconsistent evidence from primarily animal research of age related changes in spinal neurons, dorsal root ganglion cells and interstitial cells that govern bowel reflexes and continence.

4.2. Gender

Prevalence studies suggest that FI occurs more frequently in young women but as people age, many studies report essentially equal incidence in men and women [711, 713-715, 730, 745, 746]. In a large epidemiologic study, risk factors for men and women with incontinence differed [747]. Advanced age, depression, heart disease, urinary incontinence and polypharmacy were significant risk factors in women while malnutrition was a significant risk factor in men. Increased dependence for basic activities of daily life were significant risk factors for both genders. The mechanisms of FI in men appear to differ from women [586, 690, 695, 696, 748-750]. In general external sphincter defects, low resting and squeeze pressures and POP are more common in women with rectal hypersensitivity and evacuation disorders being more common in men. Normal anorectal physiology testing is notably more common in men.

Oestrogen and progesterone receptors are found in the IAS and EAS. Because of this finding, some proposed that menopause is a risk factor for incontinence in women. However, since ageing and menopause are closely related, an independent relationship is difficult to prove. Symptomatic improvement from oral oestrogen replacement supports the proposed relationship; however study of topical oestrogen compared to placebo showed no difference. In addition one study found a 30% increased risk of incontinence in patients currently taking oral oestrogens [751]. At the present, the role of the hormone receptors and relationship of menopause to the onset of incontinence is uncertain.

4.3. Diabetes

Diabetes is reported as a risk factor for FI in several prevalence studies [714, 715, 751, 752]. One study reported a 40% increase in the risk of FI [751]. Another population based study found that both occasional and frequent episodes of incontinence were more common in diabetic patients (OR 2.7) [753]. In a study of elderly Korean patients, diabetes was associated with FI in women but not men [754]. A review of incontinence in community dwelling men did identify diabetes as a risk factor, however [749]. A case control investigation found that diabetic patients had more frequent and severe episodes of FI [755]. Several reports found that incontinence was more frequent in patients with other diabetic complications particularly neuropathy and retinopathy [755-757]. It is uncertain whether longer duration of disease increases the likelihood of incontinence as one study found an association [756] but two did not [755, 757]. FI was associated with poor glycaemic control in one report [755], however not confirmed by another study [757]. As in other conditions, multiple risk factors appears to increase the chance of incontinence. In a study of the subset of diabetic women from the National Health and Nutrition Examination Survey (NHANES) increasing age, depression, poorer health status, urinary incontinence and greater bowel frequency were associated with fecal incontinence in a multivariate regression model adjusted for race, BMI, medical co-morbidities and stool consistency [758]. The underlying mechanism for FI in diabetic patients is not clear. One likely contributor is oral medication taken for diabetic control. Metformin has been found to be independently related to faecal incontinence in diabetic patients [759]. In addition, withdrawal of metformin was reported to eliminate the incontinence [760]. One confounding factor is that diarrhoea, a known risk factor for FI, occurs in 5-35% of patients with diabetes [753, 756, 761, 762].

There is evidence that acute hyperglycaemia in patients with either Type 1 or 2 diabetes results in decreased squeeze pressures and rectal compliance. When studied when blood glucose was normal, the results in the diabetic patients were the same as the normal controls [763]. An animal study showed that those changes could be reversed by administration of a nitric oxide synthase antagonist suggesting that change in anal pressure is related to oxidative stress [764].
One hypothesis on the underlying mechanism is that microvascular changes associated with diabetes result in damage to pelvic floor innervations and muscles [763]. A comparative study of anorectal physiology of controls, incontinent patients with diabetes and continent and incontinent patients with multiple sclerosis found that the incontinent, diabetic patients had higher sensory thresholds and lower resting and squeeze pressures [765]. An anal physiology study compared findings of patients with the diagnosis of diabetes for less than 10 years to those with the diagnosis for longer than 10 years [766]. Both groups of patients had lower resting and squeeze anal pressures (P < 0.01), impaired rectoanl inhibitory and anocutaneous reflexes, and reduced sensitivity in rectal distention. Although both groups had statistically significant differences from the control group, the patients with the longer duration of disease had lower sphincter pressures and more blunted sensation in addition to more frequent episodes of incontinence. The latter group also had more evidence of microvascular disease and neuropathy. Blunted rectal sensation and internal sphincter dysfunction were identified in diabetic patients in two separate studies [639, 767]. Another group performed anorectal physiology tests on diabetic patients with FI and normal sphincters on ultrasounds. The findings were compared to controls [768]. While the patients had decreased resting and squeeze pressures, multivariate analysis found that the rectoanal inhibitory reflex recovery time was the only test result that correlated with severity of symptoms. They postulate that those changes are related to decreased sympathetic innervation. These findings would be consistent with underlying neurologic and/or microvascular changes. It is unclear how to reconcile that hypothesis, however, with the lack of association of incontinence with neuropathy in some epidemiology studies [761, 769].

4.4. Gastrointestinal Disorders

4.4.1 Diarrhoea

Diarrhoea is consistently reported as a risk factor for FI. For many patients symptoms of diarrhoea include loose consistency of the stool and rectal urgency. Loose stool is an independent risk factor for incontinence with OR 745, 749, 751, 770, 771. Diarrhoea has a significant impact on the development of incontinence in patients with otherwise normal anorectal function. Overflow incontinence occurs in some patients with faecal impactions. The use of laxatives may exacerbate the problem [778]. One study of elderly patients with impaction compared to controls found that they had blunted rectal sensation and less frequent external sphincter contractions in response to rectal distension [779]. In addition the internal sphincter relaxed at lower levels of rectal distension. Studies of impacted patients without incontinence have not been reported.

4.4.4 Irritable bowel syndrome

A number of studies found irritable bowel syndrome to be a risk factor for FI [709-711, 751, 780-782]. Proposed mechanisms include loose stool consistency, rapid colonic motility and rectal hypersensitivity [775, 783]. Incontinence may be more likely in patients with multiple risk factors. In a study of 164 women, the combination of an obstetric sphincter injury, urgency and diarrhoea significantly increased the risk of incontinence [784].

4.5. Neurologic/Psychiatric Conditions

4.5.1 Dementia

The prevalence of FI is higher in patients with dementia compared to others of similar age. One study reported a prevalence of 32% in older patients with dementia [785]. Another study reported a rate of 34% in patients with dementia compared to 6.7% in those without dementia [786]. Although diarrhoea was the greatest risk factor for incontinence in a study of nursing home residents, dementia also contributed to the development of incontinence [787]. In the study of community-living older adults in the United States, the prevalence odds ratio of FI decreased by 51% with each unit improvement in cognitive score [788]. A Japanese study of community dwelling older adults found dementia to be a risk factor for double incontinence [789]. There is limited information available about the relationship of intellectual disability and FI
Proposed mechanisms for the specific contribution of dementia include lack of recognition or understanding of the urge to defecate and lack of ability to articulate the need for the bathroom.

4.5.2 Depression

Several studies identified depression as a risk factor for FI [712, 714, 745, 747, 749, 758, 791]. Many assume that the association occurs because of the psychological burden of the symptoms while it is also possible that side effects of anti-depressant medication contribute to the symptoms. An editorial challenged investigators to “clarify the link between the cerebral impact of neurotransmitters and anorectal physiology” given the role of serotonin in depression and gastrointestinal function [792]. Depression and FI are both associated with poor nutritional status in the elderly [793]; that association confounds understanding of any true causal relationship between any two of the conditions.

4.5.3 Spinal cord injury

Patients with spinal cord injuries frequently report difficulty with both constipation and incontinence [794, 795]. The level of the injury determines the effect on continence. Supraconal lesions lead to delayed colonic transit and exaggerated rectal contractions and anal relaxation in response to rectal distension. Cauda equina lesions interrupt the efferent limb of the reflex arc which results in loss of rectal sensation and tone as well as impaired sphincter function [796]. Paraplegics or persons with sacral neuronal lesions may retain some degree of sensory function, but virtually no sensation is felt if lesions reach the higher spine [637, 662].

4.5.4 Stroke

In several large surveys, stroke is identified as a risk factor for incontinence [714, 745, 749, 789]. Studies of stroke patients demonstrate fairly consistent rates of FI from 30-40% on admission [785, 797-800]. The rates decreased to 20% by the time of discharge [797, 799] and 7-11% at 6-12 months [785, 798, 800]. The Copenhagen Stroke Study found that the events in patients with incontinence were more likely to haemorrhagic, larger in size and involve the cerebral cortex than stroke patients without incontinence [800]. Research identified that FI may develop early after a stroke or months later [801]. Early onset seems to be related to age, stroke severity, diabetes and other medical co-morbidities while late onset is associated with anticholinergic drugs and requirement for assistance with toileting [798, 801].

4.6. Nutrition

4.6.1 Obesity

Population based studies of FI identify obesity as a significant risk factor [709, 710, 751]. In addition studies of pelvic floor symptoms in obese patients find a higher incidence of FI than generally found in the non-obese population with rates ranging from 16-68% [802-809]. A non-significant trend towards worsening incontinence was found in another study [810]. Four studies investigated the relationship between the rate of incontinence to the BMI; three found increasing rates of incontinence with increasing BMI [751, 807, 811]. One did not [809]. The relationship is further supported by data that weight loss after bariatric surgery decreases the incidence of FI [803, 807, 812-814]. But again, not all studies showed that result [815, 816]. While the findings of these studies are generally consistent a recent systemic review of obesity and pelvic floor disorders found the number of studies to be limited, primarily focused upon women, and usually lacking control groups and physiology testing [817]. Two confounding factors were noted in studies of this relationship. One is that diarrhoea, an independent risk factor for incontinence, is also frequently associated with obesity [817]. The second is the association of FI with low fibre intake in obese women raising the question of dietary contribution to the increased incidence of FI with obesity [805]. Chronically elevated intra-abdominal pressure, known to be associated with obesity [818, 819], is typically proposed as the reason for pelvic floor dysfunction in obesity. Other factors including diabetes, neurological changes and intervertebral disc herniation which are common in the obese population may very well contribute.

4.6.2 Vitamin D

Vitamin D is a key micronutrient of muscle function. Vitamin D deficiency is associated with urinary incontinence in men and women [820, 821]. One small study of ten patients with FI found that all had either vitamin D deficiency or relative vitamin D insufficiency [822]. These rates are much higher than the 36-57% rate of deficiency or relative insufficiency from historical data of the general population. In a large study of 1881 women in the US, there was a non-significant trend towards an association between lower vitamin D levels and FI [820]. A case control study compared vitamin D levels in women with FI symptoms to controls [823]. The incontinent women had significantly lower vitamin D levels and higher odds of vitamin D deficiency. It is known that vitamin D absorption and synthesis in the skin declines with age [824, 825]. Any association between lower levels of vitamin D and FI may represent only that both are common in the elderly. Another potential mechanism is that the antioxidant effect of Vitamin D reduces the apoptosis of sphincter muscles associated with aging. That mechanism is postulated based upon the protective effect of Vitamin D on castration induced generation of reactive oxidative species and apoptosis in rats [826].

4.7. Obstetrical Injury

The impact of pregnancy and vaginal delivery on continence is described in the section on obstetrical injury. While those injuries occur with reasonable frequency, quite often the patient does not develop clinical incontinence until later in life. The reasons for the
onset of symptoms and the required combination of factors are poorly understood. However, the contribution of EAS defects to incontinence is supported by data demonstrating that clinical improvement after sphincteroplasty is more likely in patients with successful anatomic repair seen on ultrasound [736, 827-829]. The frequency of puborectal or levator ani muscle injury as well as the degree to which it contributes to FI is unclear but is being more actively investigated [698, 700, 702, 830].

4.8. Physical Mobility

Intuitively, adequate physical mobility to reach the toilet in a timely manner in response to the urge to defecate is necessary for continence. Limited mobility was found to be a risk factor for incontinence in two population based studies [745, 747] and an investigation of nursing home residents [671]. In a study of urban dwelling older persons, the odds of prevalent incontinence increased by 20% for each unit decrease in the physical performance measure [788]. In a study of long-term care patients, immobility was one of the strongest predictors of incontinence [831]. In another study, the use of physical restraints (maximal limitation of mobility) was found to be the most significant cause of incontinence when the data was adjusted for other risk factors [832].

4.9. Radiation

FI occurs after pelvic radiation for prostate, gynecological, anal and rectal cancer [833-837] with an incidence as high as 43%. Radiation therapy adds to the risk of incontinence associated with rectal resection [838-842]. It appears that short course radiotherapy carries a higher risk than long term radiation [843]. Direct comparison trials powered to answer the question are currently in progress [844, 845]. Recently a 14 year follow up study of patients without stomas from the Dutch rectal cancer trial revealed significantly more incontinence in the group treated with short course radiation and surgery versus those treated with surgery alone [846]. In a study of the relationship of radiation dosage to symptoms after prostate radiotherapy, FI was associated primarily to radiation to the EAS and PR [847]. Another study of gynecological cancer survivors treated with pelvic radiation found that mean doses greater than 50 GY to the anal sphincter, sigmoid and small intestines were associated with FI [848]. The exact mechanism(s) that radiation therapy causes incontinence is uncertain. A systematic review published in 2014 review 21 studies rated low to moderate quality. Most studies found that decreased anal resting pressures, impaired rectal distensibility with less consistent changes in squeeze pressures [849].

The rectum may be stiffer and less compliant [850] and the anal pressures reduced either from muscle or nerve injury by the radiation [839, 851, 852]. A study of incontinent men compared those with a history of radiation for prostate cancer to those no history of radiation; the authors reported a markedly increased incidence of pudendal nerve injury in the radiated patients but similar anal pressures and sensitivity measures [853]. Genetics may also play a role. A study of rectal cancer patients treated with pelvic radiation identified specific genotypes with an increased risk of acute post-treatment incontinence [854].

4.10. Rectal Prolapse

Mucosal, external and full thickness rectal prolapse – a significant portion (48-63%) of patients with prolapsing haemorrhoids or mucosal prolapse report soiling [855, 856]. Symptoms resolve with successful treatment [855-858].

External rectal prolapse is associated with FI in up to 66% of patients [859-862]. Diminished anal resting tone commonly accompanies rectal prolapse [662, 860, 863]; that finding suggests that internal sphincter dysfunction perhaps from repeated stretching is one mechanism for incontinence. Other considerations include the presence of neuropathy; it is unclear if the prolapse results in prolonged pudendal nerve latencies [864, 865] or if both share a common aetiology. The exact mechanism or combination of causes is uncertain. Other investigators, however, found that patients with rectal prolapse and persistent incontinence had evidence of sphincter defects either from surgical or obstetrical injury [866, 867].

Internal rectal prolapse is also associated with FI [868, 869] and decreased anal pressures [863]. In one study, an increase in the grade of intussusception is associated with an increase in severity of FI; the relationship remained significant in a multivariate analysis controlling for age [870] but not in another [871]. Surgical intervention was controversial in the past but there is increasing evidence that incontinence improves after ventral rectopexy [872-876]. Finally there is evidence that the presence of an internal intussusception reduces the benefit of sacral nerve stimulation and biofeedback [877-879]. One group raised the question of how often internal rectal prolapse is the explanation for idiopathic incontinence. In a group of patients without sphincter defects or constipation who underwent pelvic floor testing, high grade intussusception was found in 49% of the 174 patients [871]. It was largely associated with urgency incontinence.

4.11. Surgery

4.11.1 Anorectal surgery

Lateral internal sphincterotomy, is the recommended surgical procedure for refractory anal fissures. The surgery involves the division of the internal sphincter and may result in incontinence of flatus and stool [880-885]. Quite variable rates of post-operative incontinence from none to 36% are reported. The definition of incontinence, type of follow-up and length of sphincterotomy contribute to the variability. A number of studies sought to identify risk factors for incontinence after LIS. Age [880, 882], female gender [886],
increase the risk. Some authors suggest that pre-existing sphincter injury might predispose to incontinence [889, 890]. Another author found evidence for increased sphincter asymmetry in the patients with incontinence after sphincterotomy compared to continent post-operative patients but no differences in pre-existing sphincter defects [891]. Patients with anterior fissures developed incontinence after partial lateral internal sphincterotomy at a much higher rate than ones with posterior fissures (39% versus 6% p < 0.003) [892]). A recent report suggests that the development of symptoms of incontinence may be delayed similar to women with obstetrical sphincter injuries [893].

Incontinence is reported in 0-14% of patients after haemorrhoidectomy [894-897]. In the limited studies available, increased risk of incontinence has been related to previous vaginal deliveries [895], number of haemorrhoids excised [898] and post-operative internal sphincter defects [895, 898]. Within a cohort of 418 patients following Milligan-Morgan hemorrhoidectomy, 40 patients reported new onset FI [899]. Nineteen of those patients underwent evaluation and were compared to 15 asymptomatic hemorrhoidectomy patients and 19 people from a matched population based control group. The study group had higher incontinence scores, more complaints of incomplete evacuation, lower resting pressures and lower threshold volumes during saline infusion test. Four of the nine patients had sphincter defects on anal ultrasound; all defects were in the external sphincter. This study suggests a multifactorial explanation for the new symptoms.

Some have argued that excision of the anal cushions is the reason for incontinence [678]. Li and colleagues investigated whether removal of the anal cushions alone caused incontinence [900]. Seventy six patients underwent saline infusion testing prior to Milligan-Morgan hemorrhoidectomy. They were categorised into three groups based upon their pre-operative saline threshold volume. Only the group with lowest threshold volume experienced a significant difference in pre and post-operative threshold volumes and Cleveland Clinic incontinence scores; none of the patients reported clinical incontinence. The authors contend that since the anal cushions were excised in all of the patients another mechanism is the explanation for the changes.

Surgery for anal fistulas may result in FI. The frequency depends upon the anatomy of the fistula, baseline sphincter function and the surgical procedure performed. The reported rates of post-operative incontinence range from 0-50% [901-913]. The definition and measurement of incontinence varies among the studies. Treatment of high fistulas involving more sphincter muscle is more likely to be followed by incontinence [881, 901, 908, 913]. Injections of fibrin glue and endorectal advancement flaps have lower post-operative incontinence rates than other fistula procedures in a Cochrane review [904]. However, most studies did not include pre and post-operative evaluation or standardized instruments. Roig and colleagues prospectively analysed 143 patients with pre and post-operative surveys, manometry, pudendal nerve testing and anal ultrasounds after fistula surgery [914]. Pre-operative incontinence was noted in 14.2% of patients and in 49.2% of patients post-operatively. Incontinence scores worsened in patients after fistulotomy and endorectal advancement flap but improved slightly in patients after fistulotomy and immediate sphincter reconstruction. All surgical approaches produced new defects in the internal sphincter on ultrasound; new defects in external sphincter developed only after fistulotomy. The presence of defects correlated significantly with post-operative incontinence and lower manometry results. Age over 45 years old [901] and gender [903, 912] were found to increase the risk in some studies. The mechanism appears to be iatrogenic (and at times intentional) sphincter injury.

4.11.2 Rectal resection

In a recent meta-analysis of functional outcomes after resection for rectal cancer inclusive of studies reported between 1978 and 2004, FI of any kind occurred in 3-79% of patients [836]. Rates of incontinence of solid stool ranged from 0-40%, liquids 0-60% and flatus 9-76%. The pooled proportion of incontinence of solid stool was 14 % and liquid stool 29%. The risk of incontinence appears to depend upon the tumour location and level of the anastomosis [915, 916]. Theoretically loss of the rectal reservoir contributes to incontinence. The goal of replacing the reservoir function led to the development various types of reconstruction following resection (coloplasty, colonic J pouch, ileoanal reservoir). While long-term data are sparse, in the first 18 months post-operatively colonic J pouches result in lower rates of incontinence than straight anastomoses or coloplasty according to a recent Cochrane review [917]. Damage to the internal sphincter occurs during this type of resection presumably from transanal introduction of stapling devices and may contribute to incontinence as well [918, 919]. However a recent study comparing patients undergoing handsewn anastomoses to double stapled ones found no difference in FI post-operatively or anorectal manometry results [920]. Diminished rectal sensation and changes in motility seen post-operatively indicate that nerve damage may also contribute [920-922]. Rectal sensation and the ability to defecate can be abolished completely by resection of the nervi erigentes [923]. If parasympathetic innervation is absent, rectal filling is only perceived as a vague sensation of discomfort. Cadaver studies after total mesorectal excision reveal the close proximity of the levator ani nerve and pelvic splanchnic nerves to the plane of dissection particularly for low rectal resections [924]. Damage to those nerves would impact function of the puborectalis muscle. It is likely that
multiple factors contribute to incontinence after rectal resection and difficult to assign relative importance.

### 4.11.3 Hysterectomy

Several reports identified hysterectomy as a risk factor for FI [709, 745]. However, another study found a decreased risk of incontinence [751] and two found no association [710, 925]. In addition to conflicting results, the mechanism is not understood. Nerve injury during surgery is thought to be one factor. A series of 56 women who underwent either a standard or nerve-sparing radical hysterectomy were evaluated prospectively [926]. Although more women reported FI after a standard procedure in the first year, there was no statistical difference in the last two years of follow up. The study may have been underpowered to resolve the issue.

#### 4.11.4 Cholecystectomy

Cholecystectomy results in diarrhoea in some patients. It is often assumed at incontinence occurring after cholecystectomy is related to the onset of diarrhoea. However, two studies identified cholecystectomy as a significant independent risk factor for incontinence [709, 927]. The underlying mechanism, if not associated loose stool, is uncertain but perhaps could be related to rectal urgency secondary to bile salt irritation.

### 4.12. Smoking

A study from the Mayo Clinic reported an association of incontinence in older adults with current smoking with an odds ratio of 4.7 [709]. An earlier study reported the same finding in post-partum patients with FI. This finding has been confirmed by others [712, 928]. The reason is unclear [929]. Chronic obstructive pulmonary disease has been associated with FI [751] but in Mayo Clinic study pulmonary disease was not found to be a factor. Other proposed mechanisms include the anti-oestrogen effect of nicotine [930] or accelerate colonic transit secondary to nicotine induced high amplitude contractions in the colon [931]. In addition, heavy smoking (20+ pack years) is associated with external sphincter atrophy on MRI [932].

### 4.13. Urinary Incontinence

Many studies report an association of urinary and FI. It is likely that it is not a causative relationship but rather that the two conditions result from common aetiology [709, 712, 715, 745, 751, 771, 933-935].

## 5. SUMMARY AND RESEARCH RECOMMENDATIONS

Since the last report, it is even clearer that FI is most often multifactorial. The role of obstetrical injury is somewhat better understood. The importance of rectal urgency and internal rectal prolapse has been identified but both require further research to understand their role in FI and the underlying mechanisms. Basic science research continues about the impact of aging on the anal sphincter, other pelvic floor muscles and neurologic structures. Recent work has also focused on remediable risk factors such as nutritional factors and lifestyle choices.

However, the complex interaction of the pelvic floor structures, gastrointestinal function including stool consistency and perhaps the microbiome is not fully understood and requires more investigation. More information about the aging process including the potential for reversible changes is of interest. The ability to identify specific phenotypes and perhaps genotypes should facilitate targeted therapy and perhaps prevention for patients with FI. Testing of alternative methods of evaluation of neurologic function that are more tolerable for patients would be very beneficial. Understanding the mechanism for sphincter weakness in patients without sphincter injury should be part of that effort. The reservoir function of the rectum and underlying causes of rectal urgency warrant more investigation. Increased focus is required on the pathophysiology of incontinence in men. In addition, little data exists to demonstrate whether changes in theoretically remediable risk factors will decrease incontinence.

### VII. CHILDBIRTH AND FAECAL INCONTINENCE

Pregnancy and childbirth have a significant impact on the emotional and physical wellbeing of a woman. It is reported that as many as 91% of women report at least one new symptom eight weeks post-partum [936]. A fall in maternal mortality accompanied by an increase in female life expectancy (86 years in the Japan) has now shifted the focus of attention towards identification of factors that may minimise morbidity. Although pre-existing bowel symptoms may be aggravated during pregnancy and childbirth, the development of symptoms de novo is a more frequent occurrence. Obstetric trauma is the most common cause of FI. However, the onset of symptoms may occur many years after delivery with a peak incidence in the perimenopausal years. This may reflect the effect of contributory factors such as the process of aging, the effect of the menopause or progression of neuropathy. This section focuses on the association between obstetric trauma and FI. The term ‘anal incontinence’ is used to include incontinence to flatus, liquid and solids.

Anal incontinence (AI) has been reported to occur between 5 [937, 938] to 26 [939] percent of women during the first year following vaginal delivery. In a Canadian study [940] involving 949 consecutive women who delivered vaginally, 26% reported AI while 3% reported FI. They identified forceps delivery and third/fourth degree tears as independent risk factors. In a population based study of 8774 women in Oregon, USA, more than 25% reported FI within 6 months of childbirth [941].
1. NEUROGENIC TRAUMA

The mechanism that maintains continence is complex and affected by various factors such as mental function, lack of a compliant rectal reservoir, rectal hypersensitivity, enhanced colonic transit and changes in stool consistency and volume. However, the ultimate barrier is the anal sphincter. AI may ensue if there is mechanical disruption to the anal sphincter muscles, disturbance in neurological function or a combination of both factors. In about 80% of women with presumed “idiopathic” anorectal incontinence there is histological evidence of denervation of the striated pelvic floor muscles, particularly the puborectalis and external anal sphincter (EAS) [942]. This feature has also been demonstrated electro-physiologically by means of an increased fibre density in patients with idiopathic FI indicating re-innervation following denervation [943]. Another finding in these patients is a conduction delay in pudendal nerves as measured by pudendal nerve terminal motor latency (PNTML) [944].

Although Hertz in 1909 suggested that pelvic floor damage may result from a normal vaginal delivery, objective scientific evidence for this was only produced in 1984 [945] and a follow-up of 14 patients 5 years later [946]. These authors studied 122 women, 71 after delivery with manometry, perineometry, PNTML and EMG, and 51 before and after delivery with EMG. This study demonstrated an increase in anal sphincter striated muscle fibre density in the vaginal delivery group at 2 months post-partum indicating evidence of re-innervation following denervation. The fibre density was not altered following elective caesarean section. Thirty three percent of primiparae and 50% of multiparae had prolonged PNTML within 48 hours of delivery. However, by 2 months, the PNTML had returned to normal in 60% of these women, indicating that damage to pudendal nerve conduction is reversible. Multiparity, forceps delivery, increased duration of the second stage of labour, third degree perineal tears and high birth weight were important factors leading to pudendal nerve damage. In the five year follow-up study of 14 women, only multiparae who did not have a forceps delivery were selected; the denervating process was found to be progressive in the majority of women and 5 women suffered from stress incontinence of urine, 3 of whom were also incontinent to flatus.

In another prospective neurophysiological study, Allen et al [947] studied 96 nulliparous women with EMG, PNTML and vaginal pressure measurements during pelvic floor contraction. They found evidence of re-innervation in the pelvic floor muscles of 80% of primiparae 2 months after vaginal delivery. The only obstetric factors associated with re-innervation were a high birth weight and a longer active stage of labour. Forty five of the original 96 women were studied again 6 years later and they concluded that changes in pelvic floor neurophysiology occur with time and do not appear to be related to further childbearing [948].

A third prospective study [949] measured anal pressures, anal sensation and the perineal plane in 72 antenatal women and repeated 72 hours post-partum and in 41 women 2 months postpartum. Anal sensation was unchanged. Cornes et al. [950] measured anal sensation in 96 primiparae within 10 days after delivery and measurements were repeated in 74 women 6 months after delivery. They found that at 6 months anal sensation had returned to normal. Anal sensation remained unchanged after caesarean section. In women who had a torn EAS, only impairment of sensation in the upper anal canal persisted at 6 months. More than half the women who admitted to persistent anal incontinence had normal anal sensation. Chaliha et al. [951] measured anal electro-sensitivity before and after childbirth and found it unchanged. Anal sensation in isolation therefore probably plays a minor role in the development of obstetric related faecal incontinence.

2. MECHANICAL TRAUMA

Until the advent of anal endosonography, mechanical trauma to the anal sphincters was only suspected when there was a history of third or fourth degree tears collectively known as obstetric anal sphincter injuries (OASIs). Consequently, when anal endosonography was performed in patients believed to be suffering from “neurogenic” FI unsuspected internal anal sphincter (IAS) and EAS defects were identified [952]. The sonographic appearance of EAS defects has been verified histologically to represent fibrosis [953] while the appearance of IAS defects have been validated prospectively in patients undergoing lateral internal anal sphincterotomy [954]. Trauma as identified by ultrasound may represent unrecognised OASIs (previously referred to as occult) or the consequence of recognised and repaired OASIs.

2.1. Unrecognised (“Occult”) Anal Sphincter Trauma

Sultan et al [937] performed the first prospective study (before and after childbirth) to demonstrate both “occult” anal sphincter trauma (Figure 13) and pudendal nerve damage during childbirth in both primiparous and multiparous women (n=150). In 35% of primiparous and 44% of multiparous women anal sphincter defects were identified at 6 weeks postpartum by anal endosonography that were not present before vaginal delivery. Thirteen percent and 23% respectively developed defecatory symptoms (fecal urgency and/or AI) after delivery. Only two of the 150 women (both primiparous) had recognised tears of the anal sphincter at the time of delivery. A strong association was demonstrated between the presence of any defect and the development of symptoms. Only 4% of multiparous women sustained new sphincter...
damage following a subsequent delivery. The single independent factor associated with anal sphincter damage was forceps delivery. The 23 women delivered by cesarean section remained asymptomatic and none developed sphincter defects. No relationship was demonstrated between PNTML measurements and defecatory or urinary symptoms.

Donnelly et al. [955] interviewed 219 nulliparae in the third trimester regarding bowel habits and performed anal vector manometry. At 6 weeks postpartum 184 women returned and the same bowel symptom questionnaire was completed and anal vector manometry plus PNTML measurements were performed. Anal endosonography was performed in 81 women with altered faecal continence or abnormal physiology. Instrumental vaginal delivery and a passive second stage of labour prolonged by epidural analgesia were significantly associated with the greatest risk of anal sphincter trauma and impaired faecal continence. As instrumental delivery is a known risk factor (8 fold increased risk of sphincter trauma), early use of oxytocin was recommended to shorten the second stage. A continuation of the same study [956] reported that PNTML was prolonged and the squeeze pressure increment was reduced in women who had a caesarean section (>8cm cervical dilatation) or second stage.

Chaliha et al. [951] measured anal sensation and manometry in 286 nulliparae during the third trimester and repeated in 161 women postpartum when anal endosonography was also performed. Anal endosonography revealed sphincter defects in 38% of women and this was associated with the presence a lowering of anal squeeze and resting pressures. Threshold anal electrosensitivity remained unchanged and bore no relationship to symptoms. Postpartum sphincter defects were associated with perineal laceration and vaginal delivery.

Abramowitz et al. [957] performed a prospective study of 233 women who had anal endosonography performed before and 6 to 8 weeks after childbirth. Of the 233 women (118 primiparae), 202 had a vaginal delivery. Postpartum AI in the 233 women was reported by 13% of primiparae and 8.5% of multiparae and anal sphincter defects in 21% and 12% respectively. However, the prevalence of anal sphincter defects amongst those who had a vaginal delivery (n=202) was 26% and 13% respectively. Previous studies [958, 959] including others mentioned in Table 4 and 5 have shown that the first delivery is at greatest risk for anal sphincter trauma but this study is at variance as it claimed that secundiparous females have the same risk as primiparous women. However, this finding remains unsubstantiated and is further disputed by a subsequent prospective study [959].

Fynes et al. [960] undertook a prospective study of 59 previously nulliparous women through 2 successive pregnancies and found that 34% had anal sphincter injury after their first delivery but only 2 new injuries occurred after the second delivery confirming the findings in Sultan's study [937]. An important finding in this study was that 42% of women (5 of 12) who had a severe ‘occult’ sphincter injury during their first delivery (squeezing pressure increment < 20mmHg or anal sphincter defect > one quadrant) developed AI after the second delivery.

Willis et al. [961] performed anal vector manometry, endosonography, PNTML and rectal sensibility at the 32 weeks and 6 weeks postpartum. Using the Kelly-Holschneider score they reported AI in 5% and identified occult injuries in 19%. PNTML and rectal sensibility was unaffected by vaginal delivery.

Nazir et al. [962] performed vector manometry and endoanal ultrasound in 73 nulliparous women at 25 weeks and 5 months postpartum (Table 4). There was no correlation between vector manometry and anal endosonography or clinical variables.

Belmonte-Montes [963] performed anal endosonography in 98 nulliparous women 6 weeks before and 6 weeks after delivery and after excluding 20 third degree tears found occult sphincter injuries in 13%. Seventy five percent of women with defects were symptomatic and there was a good correlation between defects and symptoms. However, it is not clear as to how many with ‘occult’ defects were symptomatic (Table 4).

In 3 further studies [964, 967, 968] anal ultrasound was performed only after delivery and defects were identified in 11.5 to 34% (Table 5). Varma et al. [964] studied 159 postnatal women (105 primiparous and 54 secundiparous) and found occult anal sphincter defects in 11.5% of primiparous and 19% of secundiparous vaginal deliveries but 80% of forceps deliveries. None of their patients suffered FI but only 72% of questionnaires were returned. However, their cohort was recruited before 1998 and had a high caesarean section rate (25%) and a low forceps rate (4%).
Williams et al [969] performed a prospective study in 45 nulliparous women before and after vaginal delivery using 3 dimensional endosonography. There was evidence of perineal trauma in 29% (external sphincter 11%, puboanalis 20%, transverse perineal muscle 7%). Sudoł-Szopinńska et al [970] performed 3 dimensional endoanal ultrasound in 112 primiparous women and found only 2.6% sonographic injuries. However, their obstetric practice was different in that they had a 77% episiotomy rate and a 59% epidural rate.

Oberwalder et al [971] performed a meta-analysis of 717 vaginal deliveries and found a 26.9% incidence of anal sphincter defects in primiparous women and an 8.5% incidence of new sphincter defects in multiparous women. Although two thirds of these women with “occult” defects were asymptomatic in the postpartum period, the probability of FI associated with a sphincter defect was 76.8 to 82.8%.

Some 15 years after having first coined the term “occult” OASIs based on anal endosonography, Sultan [937] began questioning whether the 28% sonographic anal sphincter defects (Table 6) identified some weeks after delivery were really genuine occult defects that were not identifiable clinically at delivery. They therefore conducted a prospective study [976] in which 241 women having their first vaginal delivery had their perineum re-examined by an experienced research fellow and endoanal ultrasound was performed immediately after delivery and repeated 7 weeks postpartum. When OASIs were identified by the research fellow, the injuries were confirmed and repaired by the duty registrar or consultant. The prevalence of clinically diagnosed OASIs increased from 11% to 25% (n=59). Every clinically diagnosed injury was identified by postpartum endoanal ultrasound. However, there were three women with sonographic defects in whom the injury was not identified clinically. Two of these had only small IAS defects that were not considered clinically significant. The other was a combined defect of both the IAS and EAS and while this could be classified as an occult tear, it is most probably a tear that was not recognised by the research fellow. At 7 weeks postpartum, no de novo defects were identified by ultrasound. This study concluded that virtually all sphincter defects that have previously been designated as “occult” injuries (Table 6) were in fact OASIs that could have been identified by a trained clinician [977] and that less than one percent are genuine occult OASIs (if indeed they exist). Interestingly, 87% of midwives and 27% of junior doctors failed to recognise OASIs clinically. Although it is likely that some of these injuries would have been detected at the time of suturing the tear, it is concerning that clinical recognition of OASIs is suboptimal [977]. However, this finding is not unique as Groom and Patterson [978] also found that the rate of third degree tears rose to 15% when all “2nd degree tears” were re-examined by a second experienced person.

Table 4: Prospective studies before and after vaginal delivery of “occult” anal sphincter injury (using 2d ultrasound) and anal incontinence but excluding fecal urgency.

*Includes 2 with secondary sphincter repair \(\dagger\) includes only 4\textsuperscript{th} degree tears

These studies [976, 978] confirm the lack of adequate training as previously highlighted by Sultan et al [979] who reported that 91% of doctors who had done at least 6 months of training in obstetrics and 60% of midwives indicated inadequate training in perineal anatomy and 84% and 61% respectively reported inadequate training in identifying 3\textsuperscript{rd} degree tears. Another possible reason for under-diagnosis is that...
tears of the anal sphincter have been wrongly classified and therefore anal sphincter tears have been under-reported. Any involvement of the anal sphincter should be classified as a third degree tear. However 41% of doctors and 16% of midwives classified a torn anal sphincter as a 2nd degree tear [979]. Sultan and Thakar [980] reviewed every relevant text book (n=65) in the library of the Royal College of Obstetricians and Gynaecologists (RCOG) and found that there was a lack of consistency in classification and in about 40% the classification was omitted or wrong. Furthermore, previous classifications were incomplete because they did not incorporate depth of EAS rupture or involvement of the IAS. This therefore has epidemiological, clinical and medicolegal implications. If a third degree tear is incorrectly classified as second degree, then inappropriate repair could result in sub-optimal outcome (see below). Sultan [981] therefore proposed the following classification (Figure 14) that has been incorporated into the 29th RCOG green top guidelines [982], adopted by The American College of Obstetricians and Gynecologists (ACOG) [983] and included in this ICI textbook since it first edition in 2002:.

**First degree**: laceration of the vaginal epithelium or perineal skin only.

**Second degree**: involvement of the perineal muscles but not the anal sphincter.

**Third degree**: disruption of the anal sphincter muscles and this should be further subdivided into:

3a: <50% thickness of external sphincter torn.
3b: >50% thickness of external sphincter torn.
3c: internal sphincter torn also.

**Fourth degree**: a third degree tear with disruption of the anal epithelium.

An isolated rectal tear without involvement of the anal sphincter is rare and should not be included in the above classification.

### 2.2. Recognised Obstetric Anal Sphincter Injuries

The rate of OASIs is increasing and in England alone there has been a 3 fold increase between 2000 and 2012 from 1.8 to 5.9% in primiparous vaginal deliveries. This has been attributed to improvements in understanding anal sphincter anatomy and clinical diagnosis [977]. Primary repair of OASIs are usually performed by obstetricians using the end-to-end repair technique [985]. However, as shown in Table 6, AI occurs in 37% (range 10 to 67%) and in addition, urgency can affect a further6 [985] to 28% [986, 988]. Frank FI affected 12% (range 2 to 42%). The reasons for persistent symptoms are unclear but there are at least six studies [985, 986, 988, 991-993] demonstrating anal sphincter defects following repair in 40 to 91% of women. Although the extent of the sphincter injury appears to be related to outcome of repair, in some studies (Table 6) the data was not interpretable [994], incomplete [993] or inclusive of symptoms other than anal incontinence [996]. Nulliparity, instrumental delivery especially forceps without episiotomy, large baby >4 kg, shoulder dystocia and a persistent occipito-posterior position and prolonged second stage of labour have been identified as the main risk factors for the development of OASIs [957, 958, 982, 985, 992].

Traditionally, the technique described to repair the torn anal mucosa (4th degree tear) was to insert interrupted sutures with the knot tied within the anal canal [985, 989]. However, this was recommended when catgut was in use to minimise tissue reaction and infection. With the availability of polyglactin suture material this is no longer necessary as it dissolves by hydrolysis. Figure of eight sutures should be avoided during repair of the anal mucosa as they can cause ischaemia and therefore a continuous non-locking suture is adequate [982, 989, 1025].

The most popular method of EAS repair is the end-to-end technique but colorectal surgeons prefer the overlap technique for secondary repair because of better outcome [1025]. It is now known that similar to other operations for incontinence, the outcome can deteriorate with time and one study has reported continence in 50% of women at 5-year follow-up [1026]. However, at least one third of women in this study had more than one attempt at sphincter repair and therefore these findings cannot be extrapolated to that following primary repair of acute injury [1026]. In 1999, Sultan et al [1025] were the first to explore the feasibility of the overlap technique of repair for acute EAS rupture but more importantly advocated the identification and separate repair of the torn IAS [982]. Until then, very little importance was given to the torn IAS during primary repair. However, subsequently in a study involving 500 consecutive women with OASIs it has been shown that sonographic evidence of IAS injury was predictive of FI [1027]. Roos et al [1028] studied 531 consecutive women with OASIs and found that women who sustained an IAS tear were significantly more likely to suffer incontinence, have lower anal pressures, persistent IAS defects and a reduced quality of life. Increasing IAS defect size has also been shown to be related to symptoms of AI [1022]. Reid et al [1029] performed a prospective study using validated outcome measures at 9 weeks and 3.2 years after primary repair involving 539 women with OASIs. All those who had an internal sphincter injury were classified as major tears (including 4th degree tears). There was no significant difference in outcome between minor and major tears in relation to urgency (10%), flatus (7%) or FI (0.9%). In fact there was a significant improvement in symptoms over time confirming that good outcomes can be achieved when the internal sphincter is repaired as a primary procedure. Oude Lohuis et al [986] have shown that only 10% (26 of the 29) of women who sustained internal anal sphincter injuries (3c and 4th degree tears) had no persistent internal sphincter de-
fects at 3 months follow up indicating adequate repair. Dickinson et al [1030] followed up 136 women who sustained OASIs (25 women sustained 3c/4th degree tears) and found internal sphincter defects in 32% of women but this could have included undiagnosed internal sphincter injuries.

When a patient presents with FI months or years after delivery, it is almost impossible to perform a successful IAS repair highlighting the importance of identification and repair immediately after delivery [989, 1025]. Compared to matched historical controls [985] who had an end-to-end repair, Sultan et al [1025] found that the rate of AI was reduced from 41% to 8% when the overlap technique was used for EAS repair with separate repair of the torn IAS [1025] and therefore recommended the performance of a randomized controlled trial.

The first published randomised trial by Fitzpatrick et al [988] reported no significant difference between end-to-end and overlap repair although there appeared to be trend towards more symptoms in the end-to-end group. However, there were methodological differences in that the torn IAS was not identified and repaired separately and they used a constipating agent for 3 days after the repair. Unfortunately, they included partial EAS tears in their randomised study. A true overlap [989, 1025] is not possible if the sphincter ends are not completely divided and it would be expected that if an overlap is attempted, the residual intact sphincter muscle would have to curl up and hence there would be undue tension on the remaining torn ends of muscle that would be overlapped. This technique would therefore go against the general principles of surgery of deliberately placing tissue under avoidable tension [982, 989].

Garcia et al [1014] also performed a randomized trial of the two techniques and took great care to include only complete ruptures of the EAS (full thickness 3b,3c and 4th degree tears). There were 23 women in the end-to-end group and 18 in the overlap group. Unfortunately, only 15 and 11 women respectively returned for follow-up which was only at 3 months. No significant difference was found between the groups in terms of symptoms of FI or transperineal ultrasound findings. However, the authors have acknowledged that the major limitations of their study were that the randomization process was flawed and that their study was underpowered.

Williams et al [1031] performed a factorial randomized controlled trial (n=112) in which women were randomized into 4 groups: overlap with polyglactin (Vicryl; Ethicon, Edinburgh, UK); end-to-end repair with Vicryl; overlap repair with polydioxanone (PDS; Ethicon, Edinburgh, UK); end-to-end repair with PDS. This trial was specifically designed to test the hypothesis regarding suture related morbidity (need for suture removal due to pain, suture migration or dyspareunia) using the two techniques. At six weeks, there were no differences in suture related morbidity. The authors claimed that there were no differences in outcome based on repair technique. Unfortunately, the majority of patients included in this trial were partial tears of the EAS (70% were 3a tears) and as mentioned above, a true overlap [989, 1025] cannot be performed if the EAS is only partially torn. Furthermore, their follow up rate at 12 months was only 54%. This data therefore needs to be interpreted by caution.

Fernando et al [1032] performed a randomised controlled trial of end-to-end vs overlap technique. The study had adequate power (n=64) and the primary outcome was FI at one year. All repairs were performed by two trained operators and Grade 3a EAS were excluded. At 12 months (81% follow-up rate), 24% in the end-to-end and none in the overlap group reported FI (p=0.009). Faecal urgency at 12 months was reported by 32% in the end-to-end and 3.7% in the overlap group (p=0.02). There were no significant differences in dyspareunia and quality of life between the groups. At 12 months 20% reported perineal pain in the end-to-end and none in the overlap group (p=0.04). During the 12 months period 16% in end-to-end and none in the overlap group reported deterioration of defecatory symptoms (p=0.01). Further calculation revealed that four women need to be treated with the overlap technique to prevent one woman with OASIs developing FI. On the basis of this randomized trial it would appear that the overlap technique of EAS repair accompanied by separate repair of the torn internal sphincter, performed by trained clinicians is associated with a good outcome. In 2006, the Cochrane review [98] concluded that as the surgeon's experience increased flatal incontinence in this group [1035]. At 3 year follow up there was no significant difference in AI between the groups [1036]. This supports the findings of Fernando et al [1032, 1033] who demonstrated a significantly higher risk of deterioration in AI over time in the end-to-end group and highlights the importance of longer term follow-up.

Farrell et al [1034] performed a randomised controlled trial with a 6 month follow-up of end-to-end (n=62) vs overlap (n=63) EAS repair in primiparous women. They reported significantly higher rates of flatal but not FI in the overlap group. However, there were more 4th degree tears in the overlap group and therefore more IAS injury that could explain the increased flatal incontinence in this group [1035]. At 3 year follow up there was no significant difference in AI between the groups [1036]. This supports the findings of Fernando et al [1032, 1033] who demonstrated a significantly higher risk of deterioration in AI over time in the end-to-end group and highlights the importance of longer term follow-up.

Rygh and Korner [1037] performed another randomized controlled trial (n=101) with the primary outcome measure ‘of at least weekly solid stool incontinence’.
They concluded that the overlap technique was not superior to the end-to-end repair. However, there were more women with symptoms of AI with the end-to-end repair (34% vs 20%).

The Cochrane Review concluded, “The data available show that at one-year follow-up, immediate primary overlap repair of the external anal sphincter compared with immediate primary end-to-end repair appears to be associated with lower risks of developing faecal urgency and anal incontinence symptoms. At the end of 36 months there appears to be no difference in flatus or faecal incontinence between the two techniques. However, since this evidence is based on only two small trials, more research evidence is needed in order to confirm or refute these findings” [1033]. Although there are indications from two studies [1022, 1036] that compared to the end-to-end technique, the overlap technique appears to be more robust over time, longer term follow up of a larger cohort is required.

More recently, 3 and 4 dimensional transperineal ultrasound techniques have been used to image the

Table: 4.2

Figure 15: Flow chart demonstrating the Croydon pathway of the management of a subsequent pregnancy following OASIs (EAS = External Anal Pressure; MSP= maximum squeeze pressure)
anal sphincter and 40% residual defects were identified following OASIs repair and levator avulsion in 17% [973].

In terms of long term outcome following primary repair when the Sultan classification [981] was adopted and follow up was greater than 6 months the rates of AI (including flatus) are as follows (modified from Table 4.2 [989]):

2.3. Management of subsequent pregnancy after OASIs

All women who sustained OASIs should be assessed in hospital by a senior obstetrician 6 to 12 weeks after delivery. Some centres have established dedicated multidisciplinary perineal clinics. In a survey conducted in 2010 [1039], 30% of hospitals in the UK had such a dedicated clinic. It is important that a comprehensive history is taken regarding bowel, bladder and sexual function. As these symptoms are embarrassing, a structured questionnaire may be useful. A proper vaginal and rectal examination should be performed to check for complete healing, scar tenderness and sphincter tone [976, 989, 1040]. Mild incontinence (faecal urgency, flatus incontinence, infrequent soiling) may be controlled with dietary advice, constipating agents (Loperamide or Codeine Phosphate), physiotherapy or biofeedback. However, women who have severe incontinence should, in addition, be offered secondary sphincter repair by a colorectal surgeon. Asymptomatic women must be advised to return if symptoms develop [989].

Women with OASIs are at a five-fold increased risk of recurrence in subsequent pregnancy function [1041]. There are no randomized studies to determine the most appropriate mode of delivery. Women who have had a successful secondary sphincter repair for FI should be delivered by caesarean section [1042]. Some women with FI may choose to complete their family prior to embarking on anal sphincter surgery. It would appear that these women could be allowed a vaginal delivery as the damage to the sphincter has already occurred and risk of further damage is minimal and probably insignificant in terms of outcome of surgery. The risk of worsening or de novo neuropathy has not been quantified and in practice, does not appear to be clinically significant.

The management of a subsequent pregnancy after OASIs has not been largely based on obstetrician opinion. It has been suggested that a caesarean section should be performed even after transient anal incontinence: but this has been questioned [1043].

In order to counsel women with previous OASIs appropriately, Sultan et al [989] find it useful to have a symptom questionnaire, anal ultrasound (Figure 13) and manometry results (Figure 15). It has been shown that clinical assessment alone has a poor sensitivity for detecting anal sphincter defects [1044]. If vaginal delivery is contemplated then these tests should be performed during the current pregnancy unless performed previously and found to be normal. In a prospective study over a 5 year period, Scheer et al [1045] followed the protocol shown in Figure 15 and found that when women who had no evidence of significant anal sphincter compromise based on anal endosonography and manometry were allowed a vaginal delivery (the others were offered caesarean section) there was no deterioration in symptoms, anorectal function or quality of life. Other units have also reported favourable outcomes when vaginal delivery and caesarean section were offered on selected criteria [1046, 1047]. Although 11% of textbooks recommend a prophylactic episiotomy [980] there is limited evidence that an elective episiotomy prevents subsequent anal sphincter disruption [1007] while other studies have indicated that episiotomy may increase the prevalence of anal sphincter disruption. However, there is no study that has been done evaluating outcome in subsequent pregnancies in which the angle of episiotomy has been controlled for [1048].

3. INSTRUMENTAL VAGINAL DELIVERY

Although only 4% of women delivered by forceps sustain a 3rd/4th degree tear, up to 50% of those that do tear have an instrumental delivery [985]. Vacuum extraction is associated with fewer OASIs than forceps and this view is supported by two large randomized studies [1049, 1050]. A UK study [1049] where midlateral episiotomy is practised reported severe vaginal lacerations in 17% of forceps compared to 11% of vacuum deliveries and a Canadian study [1050] where midline episiotomy is practised reported OASIs in 29% of forceps compared to 12% of vacuum deliveries. In a Cochrane review [1051], forceps were less likely than the vacuum extractor to fail to achieve a vaginal birth (risk ratio 0.65, 95% confidence interval (CI) 0.45 to 0.94). However, with forceps there was a trend to more caesarean sections, and significantly more third- or fourth-degree tears (with or without episiotomy), vaginal trauma, use of general anaesthesia, and flatus incontinence or altered continence. Facial injury was more likely with forceps (RR 5.10, 95% CI 1.12 to 23.25). Serious neonatal injury was uncommon with either instrument.

A 5 year follow-up of infants who participated in a randomized trial of forceps and vacuum delivery has confirmed that there is no difference in terms of neurological development and visual acuity with use of either instrument [1052]. Compared to vacuum delivery, ‘occult’ trauma to the anal sphincter has been identified more frequently in forceps delivery occurring in up to 80 percent of women [937, 964, 1053]. A small randomized study (n=44) confirmed this by identifying occult anal sphincter defects in 79% of forceps compared to 40% of vacuum deliveries [1053]. Trauma occurs more frequently when a second instrument is used to attempt vaginal delivery [1053] and therefore
if no descent of the head occurs following appropriate cup selection and application technique of vacuum extraction, one should resort to a caesarean section. Metal cups appear to be more suitable for ‘occipito-posterior’, transverse and difficult ‘occipito-anterior’ position deliveries [1054]. The soft cups seem to be appropriate for straight forward deliveries as they are significantly more likely to fail to achieve vaginal delivery. Although, they were associated with less scalp injury, there was no difference between the two groups in terms of maternal injury. Farrell et al [1055] performed a prospective study of 690 primigravid women and found that forceps delivery was associated with a higher incidence of flatal incontinence (RR 2.6) compared to spontaneous vaginal delivery and a higher incidence of both flatal (RR 2.6) and faecal (RR 3.6) incontinence compared to caesarean delivery. Vacuum delivery did not increase the risk of flatus incontinence. MacArthur et al [938] performed the largest questionnaire based multicentre study to establish the prevalence of FI at 3 months post-partum. They reported a prevalence of 9.2%, with 4.2% reporting it more often than rarely. Compared to vacuum extraction, forceps delivery was associated with almost twice the risk of developing FI. Thakar and Eason [1056] performed a meta-analysis and demonstrated that one anal sphincter injury is avoided for every 18 women delivered by vacuum extraction in- strained that one anal sphincter injury is avoided for son [1056] performed a meta-analysis and demonstrated that one anal sphincter injury is avoided for every 18 women delivered by vacuum extraction in contrast to spontaneous vaginal delivery and a higher incidence of both flatal (RR 2.6) and faecal (RR 3.6) incontinence compared to caesarean delivery. Vacuum delivery did not increase the risk of flatus incontinence. MacArthur et al [938] performed the largest questionnaire based multicentre study to establish the prevalence of FI at 3 months post-partum. They reported a prevalence of 9.2%, with 4.2% reporting it more often than rarely. Compared to vacuum extraction, forceps delivery was associated with almost twice the risk of developing FI. Thakar and Eason [1056] performed a meta-analysis and demonstrated that one anal sphincter injury is avoided for every 18 women delivered by vacuum extraction instead of forceps. De Leeuw et al [1057] have shown that when a mediolateral episiotomy is performed during a forceps delivery, the risk of anal sphincter injury is reduced by almost 80%.

The occipito-posterior position at delivery is a known risk factor for the development of a third degree tear and the risk of anal sphincter injury doubles with a vacuum delivery but trebles with the forceps [1058]. It is strongly recommended that a liberal episiotomy should be performed in the presence of an occipito posterior position. When the baby’s head is in the occipito-posterior position the diameter presenting at the outlet is larger than that of an occipito-anterior position. Therefore it is more likely to cause a delay in progress and also more likely to result in a more extensive perineal tear particularly with an instrumental delivery.

4. EPISIOTOMY

There are observational data to indicate that a reduction in episiotomy rate is not associated with an increase in OASIs. The Cochrane database [1059] shows that restricting the use of episiotomy is associated with less posterior trauma. Although there was an increase in anterior perineal trauma it had no effect on the development of urinary incontinence. Henriksson et al [1060, 1061] performed an observational study in which they noted that when midwives who previously had a high episiotomy rate reduced their rate, the prevalence of OASIs also reduced. However, this beneficial effect was abolished when midwives with a low rate of episiotomy attempted to reduce it even further. Based on this evidence, it was suggested that the ideal episiotomy rate should lie between 20 to 30% and no more. Midline episiotomies are more popular in North America as it is believed that they are more comfortable and recovery is less complicated. However Coats et al [1062] performed a quasi-randomised study of 407 primiparae and found 24% of midline episiotomies extended into the anal sphincter (partial or complete tears) compared to 9% of mediolateral episiotomies. Although the perineum was significantly less bruised in the midline group and sexual intercourse commenced earlier, pain and wound breakdown was similar in both groups. Kushid et al (2008) performed an observational study in the USA of 46 239 singleton vertex vaginal deliveries and identified two modifiable risk factors for severe perineal trauma, namely, midline episiotomies and forceps delivery. They recommended the use of vacuum extraction and mediod lateral episiotomy [1063]. However, care needs to be taken to ensure that mediolateral episiotomies are performed correctly as Andrews et al [1064] has shown that only 22% of doctors and no midwife made the incision commencing from the posterior fourchette with a 40 to 60 degree angle from the midline. Another study demonstrated that for every six degrees away from the midline there was a 50% reduction in OASIs [1065]. It has also been shown that the angle of incision when the head is crowning is underestimated such that a 60 degree angle measures 45 degrees after delivery [1066]. However, Naidu et al have shown that doctors and midwives were poor at cutting at the prompted episiotomy angle of 60° [1067]. This highlights the need to develop structured training programmes to improve the visual accuracy of estimating angles or the use of fixed angle devices to help improve the ability to estimate the desired angle. There is evidence that Episcissors 60 does cut at a 60 degree angle and its introduction in obstetric units is associated with a reduction in OASIs in nulliparous women undergoing spontaneous vaginal deliveries [1048].

5. DELIVERY TECHNIQUES

Pirhonen et al [1068] compared the frequency of OASIs in low risk deliveries between two Scandinavian countries (26 541 vaginal deliveries) and found the risk to be 13 times higher in Sweden (Malmo) vs Finland (Turku). They speculated that the only explanation for this was a difference in manual support given to the baby’s head during crowning and pushing the perineum under the chin. Jonsson et al [1069] performed a randomised trial between the Ritgen’s maneuver and standard delivery but found no significant difference in OASIS rates. However, only 50% of the eligible women were assigned and almost 20% of the women randomized to the Ritgen’s maneuver did not have this method of delivery. Hals et al [1070] provided the best available evidence to show how an interventional program in four Norwegian hospitals can reduce the frequency of OASIs. The program involved a 2-3 day course at the delivery suite of each

CHILDBIRTH AND FAECAL INCONTINENCE | 429
hospital that included training on delivery with perineal support and delivery of the neonates chin. In addition, restrictive mediolateral/ lateral episiotomy was recommended. OASIs rates reduced from 4.16-5.25% before intervention to 1.73% during the last year of intervention.

The following interventions with randomized controlled trials evidence regarding effectiveness demonstrated no effect on OASIs: antenatal perineal massage, pelvic floor exercises in pregnancy, water births, positions during labour and birth, epidural analgesia, early vs delayed pushing with epidural and second stage pushing advice [1056]. Although one small randomized trial showed otherwise [940] other large observational studies, have shown that duration of the second stage of labour is an independent risk factor for the occurrence of OASIS [955, 958, 982, 1070, 1071].

6. TRAINING

McLennan et al [1072] who surveyed 1177 fourth year residents and found that the majority of residents had received no formal training in pelvic floor anatomy, episiotomy or perineal repair and supervision during perineal repair was limited. Stepp et al [1073] found that textbooks used in American practice offered little in terms of prevention and repair of perineal trauma. There is evidence from one study [975] that perineal anatomy is poorly understood by midwives and trainee doctors, who perform the bulk of deliveries in the UK. In this study 41% of trainees and 16% of midwives incorrectly classified a partial or complete tear of the EAS as ‘second degree’. Inconsistency in classification of tears would allow many injuries to pass, unrecognised. In another study conducted in the USA, the majority of residents demonstrated substandard skill in repairing OASIs [1074]. It has been shown that hands-on workshops on perineal repair (www.perineum.net) can change practice [1075-1078] and intensive and focused training in perineal anatomy and repair should therefore become an essential module in the programme for trainees and midwives.

7. IRRITABLE BOWEL SYNDROME (IBS)

IBS affects 3-17% in selected populations and the cause remains unknown. Donnelly et al [1079] recruited 312 primiparous women and reported that 11% of young primiparous women (n= 34 of 208) suffered from pre-existing IBS prior to their first pregnancy. Twenty four percent reported symptoms of impaired faecal continence in the puerperium but symptoms were found significantly more frequently in those with IBS compared to those with normal bowel habit (71% vs 18%). However, women suffering from IBS are no more likely to incur mechanical or neurologic injury to the anal sphincter. Women with IBS delivered by caesarean section did not have altered continence postpartum. However, 6 months postpartum there were no symptomatic differences between those with IBS and those without but only 90 of the 107 women who had either impaired faecal continence or abnormal anal manometry were studied. Treatment is directed towards the predominant symptom and although antispasmodics such as hyoscine, mebeverine and dicyclomine are used widely to relax intestinal smooth muscle, they should be avoided during pregnancy. Robinson et al used validated questionnaires and bowel symptom diaries and found that the symptoms of urgency and diarrhoea in women with irritable bowel syndrome amplify the risk of anal FI in women who have sustained OASIs [1080].

8. CONCLUSIONS AND RECOMMENDATIONS

i) Compared to forceps, the vacuum extractor is associated with less perineal and anal sphincter trauma. (Level 1)

j) Compared to midline episiotomy, mediolateral episiotomy is associated with a significantly lower risk of 3rd/4th degree tears (Level 1)

k) Liberal use of episiotomy is not beneficial (Level 1) and restricting the rate of episiotomy to about 30% may reduce the risk of trauma to the anal sphincter (Level 4)

l) A prolonged active second stage of labour is associated with denervation of the pelvic floor and one study has suggested that this also occurs with a prolonged passive second stage of labour with epidural analgesia. In these circumstances, early use of oxytocics in the second stage of labour may be useful. (Level 4)

m) Selective use of caesarean section may be beneficial particularly in those who have evidence of compromised anal sphincter function and those who have had previous successful continence or prolapse surgery. (Level 4)

n) Modification in techniques of delivery of the baby particularly appropriate perineal support may reduce anal sphincter injury and future compared to midline episiotomy her research is needed (Level 3)

o) A more focused training program for doctors and midwives needs to implemented. There is a poor understanding of perineal and anal sphincter anatomy and hence identification of anal sphincter trauma, incorrect classification and poor outcome of repair (Level 4)

p) There is increasing evidence supporting the identification and repair of the internal anal sphincter.
Urinary incontinence (UI) in men as in women, which is subdivided into three major groups as there are urgency, stress and mixed UI, may be caused by either an abnormality of the bladder (UUI), an abnormality of the bladder outlet (SUI) (bladder outlet which includes the internal (IUS) and distal of the prostate the external urethral sphincter (EUS)), or a combination of both (MUI) [1081-1083]. Changes in bladder ultrastructure and function that can occur as a result of neurological disease or ageing (that can cause detrusor overactivity or underactivity) are in men [1084].

Many of these foci are around benign and/or malignant diseases of the prostate and their treatment. For example in men the prevalence of detrusor overactivity and impaired compliance causing incontinence are not associated with the bladder outlet obstruction caused by benign prostatic obstruction [1084, 1085].

Key outlet functions are; maintained closure for urine storage, increased closure (guarding) during exercise, sustained opening for voiding, transient opening for territorial marking in animals and orthograde male ejaculation. These are coordinated by several spinal and higher CNS centers, with overlap of the somatic, sympathetic and parasympathetic nervous systems [1086]. Also sphincter insufficiency resulting in stress urinary incontinence (SUI) does not generally occur as the result of ageing, but rather as the attribute of surgery (for benign or malignant conditions) or radiation of the prostate followed by transurethral resection or neurological injury [1087]. The ectopic ureter in the male does not cause incontinence as its insertion into the lower urinary tract is always proximal to the external urethral sphincter. Extra-urethral incontinence in men is only known as a result of a fistula, where as it can occur in the female because of embryological considerations. Fistulae in men are most often iatrogenic (surgery, radiotherapy, cryotherapy, HIFU (High-intensity focused ultrasound)) or inflammatory (diverticulitis).

This section will focus on the Pathophysiology of incontinence as it relates to prostatic obstruction and its treatment and the treatment of prostate cancer.

1. CONTINENCE MECHANISM IN THE MALE

The internal urethral sphincter (IUS) has its source at the urinary bladder’s inferior neck (smooth muscle) continues through the prostatic urethra above the verumontanum and remains under autonomic control. The external urethral sphincter (EUS) located distal to the prostate at the level of the membranous urethra as the secondary sphincter to control the flow of urine. It contains mainly striated muscle and is therefore under voluntary control by the somatic nervous system. Opposite to the female sphincter, the male closing mechanism of the bladder is separated by the prostate.

At the boundary between the IUS and EUS, the striated and smooth muscle fibres intertwine to some extent. The externa urethral sphincter (EUS) extends from the prostatic urethra below the verumontanum through the membranous urethra. EUS includes the rhabdosphincter (intrinsic skeletal and smooth muscle) and extrinsic paraurethral skeletal muscle. At the prostate level, the superior part of the striated EUS is largely confined to the anterior side of the urethra and prostate. Inferior to the prostate, the EUS is horseshoe-shaped (although named as the rhabdosphincter, omega shaped) with the opening on the dorsal side. The dorsal muscle fibers of the left and right sides approach the midline and sometimes cross the prostate [1088-1090]. For simplicity, the normal male urinary sphincter mechanism may be divided into two functionally separate units, the internal urethral sphincter (IUS) and the external urethral sphincter (EUS) [1091]. The IUS consists of the bladder neck, prostate and prostatic urethra to the level of the verumontanum. The IUS is innervated by autonomic parasympathetic and sympathetic fibres from the inferior hypogastric plexus. The EUS extends from the verumontanum to the proximal bulb and is comprised of a number of structures that help to maintain continence. The male EUS urethral sphincter complex is composed of the prostatic membranous urethra, cylindrical rhabdosphincter (external sphincter muscle) surrounding the prostatic membranous urethra, and extrinsic paraurethral musculature and connective tissue structures of the pelvis. The rhabdosphincter is a muscular structure consisting of longitudinal smooth muscle and slow-twitch (type I) skeletal muscle fibers, which can maintain resting tone and preserve continence [1088, 1092, 1093]. The striated muscle of the rhabdosphincter is considerably thicker ventrally and thins dorsally. Striated muscle fibers of the rhabdosphincter have been shown to intermingle with smooth muscle fibres of the proximal urethra, suggesting a dynamic and coordinated interaction. The rhabdosphincter is invested in a fascial framework, and supported below by a musculo-fascial plate that fuses with the midline raphe, which is also a point of origin for the rectourethralis muscle [1094]. Superiorly, the fascial investments of the rhabdosphincter fuse with the puboprostatic ligaments [1095]. This dorsal and ventral support probably contributes to the competence of the sphincter. The striated fibers of the extrinsic paraurethral muscle (levator ani complex), on the other hand, are of the fast-twitch (type II) variety [1092]. During sudden increases in abdominal
pressure, these fibers can contract rapidly and forcefully to provide continence. Continence is maintained even after inducing paralysis of the striated sphincter indicating that this structure is not solely responsible for continence [1096]. In addition, unlike in the female where urethral support can be compromised as a result of childbirth and aging [1097], in the majority of the cases the male rhabdosphincter is functioning improperly related to prostate surgery [1098]. The striated muscle fibres of the rhabdosphincter intermingle with smooth muscle fibres of the proximal urethra and in fact have been shown to be inseparable from each other [1089]. In the past related to the approach of radical prostatectomy the smooth muscle fibres concordant into the bladderneck (IUS) were resected, which interrupted innervation. It is worth noting that impaired detrusor contractility seems to be frequently associated with intrinsic sphincter deficiency. With the increasing knowledge of the periprostatic nerves and the improvement of the preservation of the bladder neck (IUS) the functional outcome improved even further [1099].

The EUS is innervated by the autonomic (via the pelvic nerve) and somatic (by the pudendal nerve) nervous systems. Nerve fibres are seen proximally in a dorsolateral position (5 to 7 o’clock), while more distally, they are located primarily laterally [1094, 1100]. The intrinsic smooth muscle of the proximal urethra receives parasympathetic innervation from pelvic nerve branches of the inferior hypogastric plexus [1100, 1101]. The rhabdosphincter may also receive somatic innervation. Hollabaugh et al. described the so-called “putative continence nerves” as branches of the pelvic nerve travelling under the endopelvic fascia picking up intrapelvic branches of the pudendal nerve, given off before it enters the pudendal canal, which was further verified by Castello et al. [1100, 1102]. It has also been proposed that somatic innervation from the pudendal nerve after it exits the pudendal canal is primarily sensory in origin, facilitating reflex contraction of the sphincter complex to maintain continence [1103, 1104].

An elegant histological and immuno-histochemical study with 3-D reconstruction in the male fetus has confirmed mixed autonomic and somatic innervation (Figure 16) [1088]. Unmyelinated (autonomic) nerve fibres destined for smooth muscle fibres run alongside of the myelinated (somatic) fibers. The majority of the unmyelinated fibers approach the smooth muscle layers at 5 and 7 o’clock while the majority of myelinated fibres penetrate the striated sphincter at 3 and 9 o’clock.

Structure and innervation are important components of sphincter function. In addition, Tuygun et al have found a much higher incidence of periurethral (or periurethral sphincter) fibrosis in incontinent vs. continent men after prostatectomy [1105]. Using MRI at least 6 months after prostatectomy they discovered that all 22 continent men had periurethral fibrosis while only 4/14 (29%) continent men did [1106, 1107]. This might lead to the importance of the corpus spongiosum, which surrounds the bulb urethra and supports with its blood filling in addition to the sphincteric function.

In summary, sphincter continence in male is dependent on the integrity of the IUS and/or EUS, its support structures and neural innervation and probably the prostate, as long it is not enlarged to cause obstruction. Following the removal of the IUS during radical prostatectomy, continence seems to be mainly maintained by the EUS mechanism, consisting of soft tissue supportive structures, smooth muscle, and striated muscle. This outcome even improved even further related to the surgical techniques by the additional preservation of the IUS. The smooth muscle and slow twitch striated muscle of the rhabdosphincter (EUS) are probably majorly responsible for the sphincter continence; however, striated muscle contractions of the periurethral and paraurethral muscles

Figure 16: The external urethral sphincter (EUS) and internal urethral sphincter (IUS) in a male fetus (12 wk of gestation). Three-dimensional reconstruction in (A) anterior view, (B) posterior view, (C) right-lateral view, (D) superior view, and (E) inferior view. The EUS is shown in blue, and the IUS is shown in pink. The urethra and prostate are shown in light grey. Anterior and posterior directions are represented by the letters “a” and “p.” Immunohistochemically stained sections: Sections from inferior (F) to superior (H) stained immunohistochemically for striated muscle, showing the EUS (black arrowheads). Panels (I) through (K) are from same level as sections (F) through (H), stained immunohistochemically for smooth muscle, showing the IUS (red arrowheads). Note the smooth muscle tissue at the dorsal side of the urethra, where the striated muscle of the external sphincter is lacking; see red arrow in (J). Red lines in (C) illustrate the level of the sections as seen in (F) through (H). L = levator ani muscle; PB = pubic bone; R = rectum; U = urethra; bar = 0.5 mm. **2. INCONTINENCE ASSOCIATED WITH BPH AND ITS TREATMENT**

Benign prostatic hyperplasia (BPH) and benign prostatic obstruction (BPO) and their treatments have long been associated with incontinence in men. De-

Figure 17: From Colliselli et al., World J Urol, 2000, 18:324-9

supersensitivity of the bladder muscle [1117, 1118], alterations in collagen composition of the obstructed bladder [1119], emergence of altered and increased sensory reflexes mediating the micturition reflex [1120, 1121] and physical changes in detrusor myocytes affecting electrical transmission [1122] or even the the remaining influence of CRP as investigated by Kupelian et al [1123]. In addition, the bladder itself and particularly the trigone may be inadvertently resected during surgery, causing bladder dysfunction or even without prior surgical treatment. Causes of sphincter damage related to transurethral or open prostatectomy include direct damage because of surgical performance and electrocautery or thermal injury to the sphincter [1124].

Recently, Han et al conducted a retrospective data analysis using a managed care data set (Integrated Healthcare Information Services National Benchmark Database) from 1997 through 2003 [1125]. They identified a cohort of men with BPH using International Classification of Diseases, Ninth Revision (ICD-9) codes. From a total of over 12 million men, 411,658 men with BPH (3.3%) were identified. The group then determined the nature of incontinence in these men with BPH focusing on its incidence, prevalence, and management. Furthermore they stratified patients by therapeutic subgroups of watchful waiting, alpha blockers, 5-alpha-reductase inhibitors and surgery. Of the total cohort, 2.7% had a diagnosis of incontinence. Most of these men (87.5%) did not have prior BPH surgery, but those who did have surgery 12.5% were diagnosed with incontinence. The rates were almost identical whether the procedure was transurethral resection or incision, laser, transurethral needle ablation, transurethral microwave therapy [1126]. Newer data suggests that the open prostatectomy might be more effective and safer than the transurethral approaches, which probably depends to the size of the prostate and the experience of the surgeon [1127, 1128]. The rate of incontinence after the surgical treatment was 1.4% for both stress and mixed incontinence, 4.5% for urge incontinence and 6.5% for unspecified incontinence whereas the incontinence rates for men on watchful-waiting, alpha-blockers, 5-alpha-reductase inhibitors and combination therapy were 6.4%, 5.7%, 5.1%, and 6, 5% respectively [1125]. This study provides some interesting data but must be interpreted with caution. The diagnosis of incontinence was limited by what the patient and provider considered incontinence and was not often confirmed by objective testing.

Nevertheless, the relationship of BPH and incontinence can clearly be inferred. Until the last decade, transurethral resection of the prostate and open prostatectomy accounted for the majority of surgical procedures to treat BPO. In 1989, the American Urological Association published two major series on TURP and its complications. The AUA cooperative study included 3,885 patients from 13 teaching centres and private practices [1129], while the second consisted of a survey of all practicing urologists in the United States of whom 2,716 urologists responded [1129].
Rates of post-TURP incontinence requiring a pad or collection device were 0.4% in the first and 3.3% in the second study. The AUA Cooperative study also reported mild stress incontinence in 1.2% [1130]. In 1994, the Agency for Health Care Policy and Research published clinical guidelines for the diagnosis and treatment of benign prostatic hyperplasia. The guidelines panel reviewed 27 articles about transurethral prostatectomy and 30 articles reporting open prostatectomy to analyse treatment outcomes. The panel reported that the risk of total incontinence, defined as complete loss of voluntary control over micturition was of great concern to patients facing a treatment decision for BPH. In an overall ranking of 15 different outcomes, the panel’s proxy judges ranked total incontinence of urine as the fourth most important outcome influencing a treatment decision. After TURP, 2.1% of patients experienced stress incontinence, 1.9% had urge incontinence, and 1.0% reported total incontinence. The panel attempted to abstract data on urge incontinence, but found very few studies reporting this particular outcome, therefore a statistical analysis was not performed. For open prostatectomy stress incontinence occurred in 1.9%, urgency incontinence in 0.5% and total incontinence in 0.5% of patients.

Most studies evaluating post TURP and open prostatectomy incontinence have found a significant incidence of sphincter and bladder dysfunction. The incidence of sphincter dysfunction ranges from 20-92% and bladder dysfunction from 56-97% [1131-1136]. The guidelines panel reviewed 27 articles about transurethral prostatectomy and 30 articles reporting open prostatectomy to analyse treatment outcomes. The panel reported that the risk of total incontinence, defined as complete loss of voluntary control over micturition was of great concern to patients facing a treatment decision for BPH. In an overall ranking of 15 different outcomes, the panel’s proxy judges ranked total incontinence of urine as the fourth most important outcome influencing a treatment decision. After TURP, 2.1% of patients experienced stress incontinence, 1.9% had urge incontinence, and 1.0% reported total incontinence. The panel attempted to abstract data on urge incontinence, but found very few studies reporting this particular outcome, therefore a statistical analysis was not performed. For open prostatectomy stress incontinence occurred in 1.9%, urgency incontinence in 0.5% and total incontinence in 0.5% of patients.

In addition to the surgical treatment, it needs to be kept in mind that males with urinary tract infections (UTIs) had higher adjusted rates of UI with a pooled odds ratio of 3.5 (95% CI: 2.3; 5.2) [1149-1153]. Acute genitourinary toxicity, enuresis, incomplete urination (residual), and other urological conditions were associated with higher adjusted odds of UI in all studies that examined the relationship [1149, 1154-1156].

Recently new minimally invasive treatment options entered the market. Beside one prostatic urethral lift (Urolift®) none has been compared to the standard of surgical benign treatment the TURP. Although the rate if postoperative incontinence did not differ significant after one year (UroLift 85% vs. TURP 75%, p=0.4 patients recovered significantly faster from the minimally invasive procedure [1157]. In a similar way the results in a cross-over study was reported (LiFT®) and during the American Urology Association meeting in San Diego 2016 with a two year follow-up [1158]. Roehrborn reported that the adverse event of UI after UroLift were moderate to mild in the initial published data [1159].

Other treatment options have not yet been adequately evaluated but will influence the patients choice [1160].

### 3. INCONTINENCE ASSOCIATED WITH RADICAL PROSTATECTOMY

#### 3.1. Incidence

The incidence of incontinence after radical prostatectomy has been a source of controversy over the past
several decades as reported rates have varied greatly depending on the definition and methodology of data collection. The incidence has probably declined over the past two decades, owing to advances in surgical technique and to earlier recognition of lower stage disease in younger patients, however the prevalence of post-prostatectomy incontinence has risen; paralleling the increase in surgical procedures performed annually [1161]. In 1991, Foote et al tabulated data from series published between 1977 and 1990, and reported a range of incontinence rates from 2.5 to 87% after radical prostatectomy [1162]. In general, older single-institution studies utilizing physician assessments to determine incontinence rates report relatively low rates (5-8%) [1163-1167]. Another study with a follow-up of up to 5 years reported a frequent leakage in 14% or no urinary control men 60 months after diagnosis [1168]. A variety of definitions of incontinence were used, making comparison of data difficult. Since then, validated patient questionnaires have been developed, which help to standardize definitions of incontinence, allow easier comparison between institutions, and assess the impact of incontinence on quality of life. This eliminates physician bias perhaps improving accuracy [1169-1171], although it introduces the caveat at that questionnaire-based data may reflect subjective urine leakage but does not correlate with bother or actual urine, especially for mild degrees of incontinence [1172-1173]. As expected these studies show the incidence of incontinence to be significantly higher, 13-65%, depending upon the definition.

In recent years robotic radical prostatectomy has gained popularity and nowadays, probably the majority of radical prostatectomies are performed with the support of robot surgical assistance. This surgical approach (trans- vs. extraperitoneal) has been further developed so that the outcome related to the approach needs to be evaluated periodically following further developments [1174]. Similar to what has been observed with open radical prostatectomy, the continence rates tend to increase with longer follow-up and may continue to improve even beyond 12 months [1175]. The continence rates from several large recently published series ranged from 68 to 97% at 12 months post-surgery [1175-1180], reaching to the laparoscopic date with the longer time of experience this doesn’t make sense (continence range 12 months post op: 84.9 – 94 (mean 72%) [1181]. In their prospective study Jacobson et al reported that there were no differences in urinary functional outcomes one year after open radical retropubic prostatectomy or laparoscopic radical prostatectomy [1182] with 20 - 27% reported to have achieved immediate continence following catheter removal [1176, 1178, 1179]. Anterior vesicourethral reconstruction [1183], posterior vesicourethral reconstruction [1184] and total reconstruction [1185] have been described to increase the continence rate and hasten time to recovery of continence. As in earlier open prostatectomy series, robotic series tend to be single institution studies with physician reported outcomes and continence status based on no or 0-1 pads. In the meantime the data, which compared open vs. robotic radical prostatectomy became more robust demonstrating that continence post-operatively is in favour for the robot assistant radical prostatectomy [1186, 1187]. Others report this for the early post-operative phase and equal after one year.[1188]

In 1993, The American College of Surgeons Commission on Cancer reviewed the reported results of 2,122 patients treated by radical prostatectomy performed at 484 institutions in 1990 [1189]. Only 58% reported complete continence, 23% reported occasional incontinence not requiring pads, 11.2% wore 2 or fewer pads per day, 4% wore more than 2 pads per day, and 3.6% were completely incontinent. Fowler et al [1190] published the results of an outcomes study on a series of Medicare patients with less encouraging results. In this series patients age >65 surveyed by mail, telephone, and personal interview, over 30% reported currently wearing pads or clamps to deal with wetness; over 40% said they dripped urine during cough or when the bladder was full; 23% reported daily wetting of more than a few drops. Six percent had surgery after the radical prostatectomy to treat incontinence.

There appear to be differences in physician vs. patient reported outcomes and centres of excellence versus community surgeons’ outcomes [1191]. When trying to interpret all of the data, it is clear that the varying definitions of incontinence make comparisons impossible. Even using the definition of pad free totally continent has its limitations. Rodríguez et al [1180] found that 70% of men who attained “pad-free continence” after radical prostatectomy have occasional incontinence. Conversely, Lepor et al [1192] asked the single question “Do you consider yourself continent?” at 3-24 months after surgery where 97.1% of men answered yes. They found that the best correlation of objective measures with a positive were 0 or 1 pad, total control or occasional dribbling, and no or slight problem from incontinence on the UCLA/RAND questionnaire [1192]. There is a wealth of good quality prospective studies evaluating incontinence after prostatectomy in an objective manner. One such study compared continence in patients undergoing open versus laparoscopic radical prostatectomy at one year, using a 24-hour pad test, symptom scores and quality of life measures [1193]. Incontinence was defined as a pad weight of > 8 grams/24 hours. There were no differences in objective and subjective measures between the two groups. Urinary incontinence was present in 13% of open and 17% of laparoscopic cases. In practical terms incidence of incontinence that produces bother, no matter what its degree, is the true parameter of interest. However, because of the individual variability of bother and the way data have been collected, we must be aware of the limitations of the historical data in the literature. Tables 7 and 8 highlight the reported rates of post-prostatectomy incontinence in large
contemporary series using physician-gathered and self-reported data respectively. Most large series are
on radical retropubic prostatectomy as opposed to radical perineal prostatectomy.

Table 7: Incidence rates of incontinence following radical retropubic prostatectomy based on physician assessment in single institution studies.

### 3.2. Recovery of Continence after Radical Prostatectomy

While the majority of patients experience incontinence immediately following RRP, in most this is transient with a gradual improvement over time. It needs to be kept in mind that there is even a group of about 4% who might be incontinent prior to surgery (≥ 8g) although they might not consider themselves as incontinent [1194]. Most studies report progressive return of continence up to one year after surgery and in general intervention for incontinence is usually delayed until one year after surgery unless absolutely no progressive improvement is seen. Thus, most prostatectomy series report continence rates at 1 year. Lepor and Kaci [1192] showed that continence may continue to improve up to 24 months based on objective and subjective measures. They showed modest improvements in bother (UCLA RAND questionnaire) pad usage and total control rates between 12 and 24 months. Pad weights were not determined so it is possible that some “improvements” could have been related to patient tolerance and expectations over time. Smither et al objectively assessed the natural history of post radical prostatectomy incontinence using a standardised 1 hour pad test [1195]. They showed a rapid improvement in urinary control during the first 18 weeks post-RRP with a flattening of the recovery curve beyond that point. Minimal incontinence defined as < 1 g on a 1 hour pad test was as demonstrated in 3,37,66, 85, 87 and 91% of patients at 2, 6, 18, 30, 42, and 54 weeks. They concluded that the 18-week marker appears to be the time point after which the majority of patients have achieved urinary control, although a small percentage will have continued objective improvement. This estimation is chaired by Socco et al reporting the progressive improvement of continence until two years after RRP but some patients may become? continent incontinent even later [116] whereas others reported that the maximum continence was already reached after three months [1194].

### 3.3. Risk Factors

An increased risk of post-prostatectomy incontinence in older men is supported in theory by anatomical observations. With advancing age, there is evidence of atrophy of the rhabdosphincter [1094] and neural degeneration [1197]. Several studies have shown advancing age to be a risk factor for postoperative incontinence [–1163, 1164, 1167, 1198-1200]. Steiner et al [1166] found no correlation between age and continence status, but only 21 of the 593 patients were 70 years or older. Catalona et al [1163] reported that “Recovery of urinary continence occurred in 92% (1,223 of 1,325 men) and was associated with younger age (p<0.0001) which might be related to surgical approach (nerve sparing), which might be performed more often in the younger than in the older patient, although they ultimately reach a similar outcome [1201]. It was recently stated by Khoder et al that nervesparing makes sense for the elderly (>70y of age). It needs to be kept in mind that this patient group increased significantly over the recent years [1202]. Most large series have found no correlation between the stage of disease and incontinence rates, whereas Loeb reported the benefit to the younger patient in the high risk group to aim to maintain continence [1203]. However, in certain cases, the stage of disease may affect the surgical technique (i.e. nerve sparing), but this appears to be a reflection on surgical technique and not disease stage [1164].

Authors of several single-institution studies have argued that surgeon experience and surgical technique

PATHOPHYSIOLOGY OF INCONTINENCE IN MEN | 437
are important determinants of post-operative incontinence rates [1100, 1183, 1204, 1205] and many have found that changes in their own technique have led to reduced rates of incontinence or a reduced time to recover continence [1100, 1183, 1206-1208].

This includes procedural modifications such as, nerve sparing (probably secondary to a more careful dissection) [1209, 1210] bladder neck preservation [1211], preservation of anterior urethral ligamentous attachments and urethrovvesical junction reconstruction (Figure 18) [1212]. Patients who have undergone prior radiation for prostate cancer are at high risk of developing incontinence (Figure 18) [1212].

![Surgical anatomy of the urethral sphincter complex. (A) Fixation of the urethral sphincter (modified from Luschka [16]). (B) Lateral aspect of the urethral sphincter after nerve sparing. PPL = puboprostatic ligament; PVL = pubovesical ligament; PP = puboperinealis muscle; DA = detrusor apron; B = bladder; FSS = fascia of the striated sphincter; ML = Mueller’s ligaments (ischioprostatic ligaments); NVB = neurovascular bundle; R = rectum; MDR =medial dorsal raphe; RU = rectourethralis muscle; OI = Os ischiadicum; SS = striated sphincter (rhabdosphincter); PB = pubis bone.

From Schlomm et al, Eur Urol 2011](image)

It is well established that both bladder and sphincter dysfunction may be present after radical prostatectomy, most studies agree that sphincter dysfunction (stress incontinence) is the main cause. Ficazzola and Nitti found that although 46% of patients had bladder dysfunction, incontinence on urodynamic study was demonstrated in only 27%. Even in those patients, sphincter dysfunction was the main cause of incontinence in the overwhelming majority [1207]. Groutz and colleagues found a 33% incidence of bladder dysfunction, but found that it was the main cause of incontinence in only 7.25% [1218]. Two earlier series reported a higher incidence of bladder dysfunction [1132, 1133]. Some authors feel that in some patients with severe intrinsic sphincter deficiency, bladder dysfunction may occur as a result of filling the bladder to volumes that it is not accustomed to holding [1217]. The study or Giannantoni et al. reported that after RRP a high proportion of patients (70.3%) were affected by DO and about half of these patients complained of overactive bladder symptoms of which DO was also observed in 61.2% of patients before surgery, which indicates that the abnormality can be attributed to the surgical damage in a small percentage of patients [1219]. At the 36-month follow-up, the dysfunction persisted in 56.3% of 32 men, and about 40% of these presented with overactive bladder symptoms. At the three year follow-up, the dysfunction persisted in 25% of cases [1219]. Filling to capacity may produce detrusor overactivity or decreased compliance. Thus, bladder dysfunction is in a sense an artefact, but one possibility is partial decentralisation of the bladder as a result of its mobilisation during prostatectomy [1218], combined with somatic denervation, because the branches of the pudendal nerves innervating the pelvic floor muscles and the striated urethral sphincter split before reaching the urogenital diaphragm [86]. This may explain why the outcomes for artificial urinary sphincters for the treatment of stress incontinence are not adversely affected by the presence of detrusor overactivity [1220, 1221]. In addition, bladder dysfunction may be chronic and stem from obstructive uropathology present before prostatectomy. It is also important to note that most of these studies are performed in men seeking treatment for their incontinence. However, it appears that sphincter dysfunction is the primary cause of post-radical prostatectomy incontinence, but bladder dysfunction may be present in a significant number of men (though rarely alone) and must not be completely excluded when planning treatment [1222].

The majority of evidence in the literature supports the conclusion that sphincter damage is the primary cause of incontinence after total prostatectomy. Direct exposure and manipulation of the sphincter during radical prostatectomy would suggest that sphincter damage is the most likely cause of incontinence. Successful treatment with the artificial urinary sphincter and male sling procedures also indirectly suggests that primary sphincter injury is the major cause of incontinence, since outcome is not usually complicated.
by bladder dysfunction. It might be helpful to include urodynamics and especially urethral pressure profilometry as suggested by Bentzon et al [1223]. They suggested that postoperative urodynamics after 6 months may be predictive for persistent incontinence due to the bladder, sphincter, and both, that immediate intervention is more appropriate than watchful waiting. They found that sphincter insufficiency was diagnosed by stress incontinence with maximal urethral closure pressure below 30 cmH2O, decreased functional length and a distinctive profile. For the placement of the artificial sphincter the 2015 consensus conference suggested waiting at least 6 months prior to a AUS-placement [1224]. Bladder dysfunction after prostatectomy may have been present pre-operatively, for example due to pre-existing outflow obstruction, may be caused by the operation itself, or may be due to age related changes in bladder function.

Many patients who have prostate surgery have pre-existing bladder dysfunction, which may or may not be symptomatic. While it is more obvious how an overzealous TURP (with resection into the trigone) can cause detrusor overactivity, it is less apparent how radical prostatectomy affects detrusor function. Some have suggested that denervation of the urethra or the bladder may occur during radical prostatectomy. John et al [1225] studied trigonal innervation by biochemical markers and found that “urinary incontinence was associated with decreased trigonal innervation, a high sensory threshold and low maximal urethral closure pressure” which was evaluated differently by the same author in different reports [1085, 1226].

4. INCONTINENCE RELATED TO RADIATION THERAPY FOR PROSTATE CANCER

Radiation therapy, whether external beam or brachytherapy, can be a cause of voiding dysfunction and incontinence [1222, 1227]. Sometimes this is a direct effect of the radiation or it can be related to the treatment of other sequelae such as urinary retention. The initial response to it is primarily oedema and then gradually degeneration, fibrosis and disorganisation ofthe bladder musculature. While radiation is primarily delivered to the prostate, portions of the bladder may also be affected. Perivascular fibrosis of blood vessels may then cause vascular occlusion followed by ischemia of the bladder wall, which can then progress to fibrosis within 6 to 12 months [1228]. Choo et al [1229], found that urodynamic bladder capacity decreased by an average of 54 ml, 18 months after radiation therapy. Blaivas et al [1230] evaluated 47 men with symptomatic LUTS after brachytherapy and found that 71% were incontinent and 85% had detrusor overactivity. Similarly, radiation can cause damage to the distal urinary sphincter, which can result in incontinence. In addition there is a dose-effect relationship for individual pelvic floor muscles and anorectal complaints after prostate radiotherapy, which is related to incontinence-related complaints showing specific dose-effects to individual pelvic floor muscles [1231].

Urinary retention and increased obstructive LUTS are other common problems that radiation therapy and particularly brachytherapy is urinary retention this doesn’t make sense. The incidence of retention has been reported to range from 2% to 30% after brachytherapy [1232-1235]. Most patients with retention will have resolution of their obstruction within weeks while others may require surgical procedures. A retrospective review of over 2,100 Medicare patients who underwent brachytherapy for prostate cancer found that 8.3% required a surgical procedure to relieve bladder outlet obstruction post-brachytherapy [1236]. Flam et al reported that 19 of 600 (3.1%) patients receiving brachytherapy required TURP [1237]. Kollmeier and colleagues reported a similar rate of 2% in 2050 men [1238]. Most authors have found significant rates of post TURP incontinence after radiation. Incontinence following TURP after brachytherapy has been reported in 0-70% and is often severe [1237-1239]. External beam radiation is also a risk factor as Green et al reported a 33% incidence of incontinence following TURP in patients post-irradiation for prostate cancer [1240]. Some authors have emphasised that incontinence can be minimised by performing a limited resection [1241] or by performing TURP within 2 years of brachytherapy [1238]. In the latter study, two of 24 patients (8%) that underwent TURP within 2 years of treatment were incontinent and 5 of 14 patients (36%) that underwent TURP 2 years or more after brachytherapy were incontinent (p=0.04), which is supported by the findings of Pinkawa et al [1242]. However, others suggest that delaying TURP until 5 years after radiation can actually reduce the risk of incontinence [1243-1245].

5. CONCLUSIONS

Incontinence in the male as in the female can be broadly divided into causes related to bladder and/or sphincter dysfunction. The pathophysiology of incontinence as it relates specifically to the male is fairly well described; however advances in science and anatomy will undoubtedly provide better understanding in the future. For example, the causes of sphincter insufficiency are known (i.e. damage to muscle, nerve and/or supporting structures) but clinicians are not able to accurately assess the exact cause of sphincter insufficiency in any given patient. Therefore much of our under-standing of post treatment incontinence “pathophysiology” is derived from reports of incontinence (incidence/prevalence) after surgery or radiation. In addition investigators have not done an adequate job in defining the incidence of incontinence related to interventions for prostatic disease, whether benign or malignant. Some work has been provided to understand and discriminate the issue of pre-
post-operative incontinence, but as an issue of the shortened hospitalisation those prospective investigations, which are mandatory for the understanding of the physiological functioning and the pathophysiology, which might become clinically significant after the intervention this doesn’t make sense. Problems have been two-fold: first in defining incontinence and what is bothersome/significant and second in accurately reporting data. New technologies for the treatment of BPH have provided us with Level 1 evidence regarding the incidence of incontinence in trials comparing new technology to TURP and Level 2 evidence through meta-analysis and prospective series. Data regarding the incidence of post-radical prostatectomy and postradiation incontinence has been less robust and of a lower quality - level 2-4. Even the level 2 evidence lacks consistency.

IX. CAUSES OF REVERSIBLE INCONTINENCE IN OLDER ADULTS

1. URINARY INCONTINENCE

Transient causes of incontinence probably accounts for one-third of cases among community-dwelling older people (>65 years old), up to one-half of cases among acutely-hospitalised older people, and a significant proportion of cases among nursing home residents [1246-1250]. Transient urinary incontinence arises suddenly, lasts less than six months, and results from reversible causes [1251]. Most causes of transient incontinence in the older population lie outside the lower urinary tract but two points are worth emphasising. First, the risk of transient incontinence is increased if, in addition to physiological changes of the lower urinary tract, the older person also suffers from pathological changes [1252, 1253]. Overflow incontinence is more likely to result from an anticholinergic agent in a person with a weak or obstructed bladder, just as urge incontinence is more likely to result from a loop diuretic in someone with detrusor integrity of multiple domains - mental state, mobility, manual dexterity, medical factors, and motivation, as well as lower urinary tract function. Although in younger individuals incontinence usually results from lower urinary tract dysfunction alone, incontinence in older patients often results from deficits in multiple domains that together result in incontinence [1250, 1256]. Attention to any one or more of these risk factors can restore continence or at least improve it. Second, although termed “transient,” these causes of incontinence may persist if left untreated, and so they cannot be dismissed merely because the incontinence is of short duration.

1.1. Quality of Data

In older people, continence status may not be absolute, especially in those who are frail. Infrequent leakage of small amounts may appear and disappear, and reporting accuracy varies as well [1257]. Sometimes the changing status of incontinence is the initial symptom of LUTS, neurological disorder (Parkinson’s disease, MS etc.), cardiogenic changes or diabetes. Furthermore, ethical constraints and methodological issues preclude robust investigations of the conditions commonly impugned as causes of transient incontinence. Thus, it is not surprising that evidence supporting the association between these conditions and transient incontinence consists predominantly of case reports and case series.

1.2. Results of Literature Review

Transient causes of incontinence in older people are shown in Table 9 and can be recalled using the mnemonic DIAPPERS (Delirium, Infection, Atrophic vaginitis, Pharmaceuticals, Psychological condition, Excess urine output, Reduced mobility, Stool impaction) [1251, 1258-1260].

Table 9. Transient Incontinence in Older Adult

- Delirium

- Excess urine output
- Reduced mobility
- Stool impaction

1.2.1 Delirium

“D” is for delirium, a confusional state characterised by fluctuating attitudiniveness and disorientation. Its onset occurs over hours to days, as contrasted with dementia, which develops over years. Delirium can result from almost any medication and from virtually any acute illness, including congestive heart failure, deep vein thrombosis, or infection. Many of these conditions may present atypically in older patients, and if the patient becomes confused because of them, incontinence may be the first abnormality detected [1261]. Delirium leads the list because, if unrecognised, it is associated with significant mortality [1262]. Thus, in this case, meticulous medical evaluation - not cystometry - is crucial [1263].

1.2.2 Urinary tract infection

Symptomatic urinary tract infection is another cause of incontinence, although it is supposing uncommon
one [1249]. However, asymptomatic urinary infection, is much more common in older people [1264–1266]. Women with recurrent urinary tract infection had the highest increase in UI by 230% for weekly UI [1267] and for monthly UI [1268], 220% for UI in the past year [1269], and by 470% for ever having UI [1270]. In addition Arya at al reported that women with recurrent UTIs have greater urinary frequency and increased perceived bladder sensation in the absence of an active infection than control women [1271].

1.2.3 Atrophic vaginitis
Atrophic vaginitis in older women is frequently associated with lower urinary tract symptoms, which occasionally include incontinence [1272]. As many as 80% of such women attending an incontinence clinic are reported to have physical evidence of atrophic vaginitis, characterised by vaginal mucosal atrophy, friability, erosions, and punctuate haemorrhages. While the evidence supporting the use of oestrogens in lower urinary tract dysfunction remains controversial there are considerable data to support their use in urogenital atrophy and the vaginal route of administration correlates with better symptom relief by improving vaginal dryness, pruritis and dyspareunia, greater improvement in cytological findings, and lower serum oestradiol levels [1273]. Atrophic vaginitis has been associated with urgency and occasionally a sense of “scalding” dysuria, but both symptoms may be relatively unimpressive. More recent epidemiologic and clinical studies have called these beliefs into question since they have demonstrated an association with oestrogen treatment and the onset of incontinence [1274]. Unfortunately, limitations in their design allow for the possibility of both bias and confounding factors. Further research is warranted.

1.2.4 Medications
Pharmaceuticals are one of the most common causes of incontinence in older people, with several categories of drugs commonly implicated [1275, 1276] (Table 10). Of note, many of these agents also are used in the treatment of incontinence, underscoring the fact that most medications used by older people are “double-edged swords.” The first category of relevant drugs is the long-acting sedative/hypnotics, such as diazepam and flurazepam, which can cloud an older patient’s brain “Loop” diuretics, such as furosemide or bumetanide, by inducing a brisk diuresis, can also provoke leakage. Drugs with anticholinergic side effects are a particular problem and include major tranquillizers, antidepressants, anti-Parkinsonian agents (e.g., benztropine mesylate or trihexyphenidyl), first generation (sedating) antihistamines, anti-arrhythmics (disopyramide), antispasmodics, and opiates. By decreasing detrusor contractility, they can cause urinary retention and overflow incontinence. They can also cause confusion. Anticholinergic agents are particularly important to enquire about for two reasons. First, older patients may often take more than one of them at a time. Second, they are contained in many non-prescription preparations that older people frequently take without consulting a physician.

Adrenergically-active agents have also been associated with incontinence. Many alpha-adrenoreceptor antagonists (used mainly for treatment of hypertension) block receptors at the bladder neck and may induce stress incontinence in women [1277]. Older women are particularly at risk because their urethral length and closure pressure normally decline with age. Thus, prior to considering other interventions for stress incontinence in a woman taking such a drug, substitution of an alternative agent should be tried and the incontinence re-evaluated. Calcium channel blockers can cause incontinence. As smooth muscle relaxants, they can increase residual volume, especially in older adults with impaired detrusor contractility. Increased residual urine may occasionally lead to stress incontinence in women with a weak urethral sphincter, or to overflow incontinence in men with concurrent urethral obstruction. Finally, angiotensin converting enzyme inhibitors, by inducing cough (the risk of which is age-related), may precipitate stress incontinence in older women whose urethra has shortened and sphincter weakened with age [1278].
1.2.5 Diuresis

Excess urinary output can also cause incontinence, especially in individuals with impaired mobility, mental state, or motivation, particularly if they also have detrusor overactivity. Causes of excess output include excess intake, diuretics (including theophylline-containing fluids and alcohol), and metabolic abnormalities (e.g., hyperglycemia and hypocalcaemia). Nocturnal incontinence can be caused or exacerbated by disorders associated with excess nocturnal excretion, such as congestive heart failure, peripheral venous insufficiency, hypoalbuminemia (especially in malnourished older people), and drug induced peripheral oedema associated with NSAIDs, thiazolidinediones, and some calcium channel blockers (e.g., dihydropyridines such as nifedipine, isradipine, and nicardipine). In addition, certain foods are natural diuretic like asparagus, parsley, beets, grapes, green beans, leafy greens, pineapple, pumpkin, onion, leeks, and garlic, as well as juices such as orange juice. The role of caffeine and timing of drinking fluids (e.g., in the evening or before bedtime) is still not clear, but should nonetheless be considered a possible contributing cause for nocturia and nocturnal incontinence, whereas it is known to increase the bowel motility [1279-1281].

1.2.6 Restricted mobility

Restricted mobility is an easily understood but frequently overlooked cause of incontinence [1282]. In addition to obvious causes, restricted mobility may be associated with orthostatic or postprandial hypotension, poorly-fitting shoes, poor physical state, or fear

of falling, all of which are common geriatric conditions. All of the prior mentioned reasons and because of the restricted mobility might be the cause of incontinence because of nocturia.

### 1.2.7 Nocturia

For frail/older people with bothersome nocturia, assessment should focus on identifying the potential underlying cause(s), including (GR: C):

- Nocturnal polyuria;
- Primary sleep problem (including sleep apnea);
- Conditions resulting in a low voided volumes (e.g. elevated post-voiding residual) co-morbidity.

### 1.2.8 Post-void residual (PVR) volume

A post-void residual volume (PVR) is impractical to obtain in many care settings. However, there is compelling clinical experience for measuring PVR in selected frail/older persons with:

- Diabetes mellitus (especially if longstanding);
- Prior episodes of urinary retention or history of high PVR;
- Recurrent UTIs;
- Medications that impair bladder emptying (e.g. anticholinergics);
- Chronic constipation;
- Persistent or worsening UI despite treatment with antimuscarinics;
- Prior urodynamic study demonstrating detrusor underactivity and/or bladder outlet obstruction (GR: C).

## 2. FAECAL INCONTINENCE

### 2.1 Background

The prevalence of FI in older adults ranges from 3.7-27% in community dwelling elderly persons to over 50% in nursing home residents. In addition FI is a common reason for referral of elderly persons to a nursing home [1284, 1285]. Underreporting is an issue with both urinary and faecal incontinence [1286-1289]; memory-loss and dementia exacerbate this problem in the elderly. While the prevalence is fairly well documented, the percentage of those people who have transient as opposed to long-term incontinence is not well known. There is significant financial and social cost associated with management of FI in the community and nursing homes [1286, 1290-1295]. Identifying transient and remediable causes would benefit patients, caregivers and the health care system. One confounding aspect in the discussion of transient incontinence is the largely unknown natural history of FI. It is clear that the symptom is intermittent in some patients and spontaneously resolves in others. As noted earlier in this chapter, continence for stool is a complex mechanism involving the consistency and transit time of stool, rectal capacity and pelvic floor function. Rectal capacity and pelvic floor function are less likely to undergo transient changes but stool consistency, transit time and medical conditions would be more likely to result in incontinence in the elderly although there is minimal confirmatory data.

The literature on transient FI is limited with a dominance of case series and retrospective reports. Some information is inferred from data from large studies of prevalence and risk factors. Treatment recommendations are frequently based upon an empirical rather than evidence-based approach.

### 2.2 Causes

FI occurs when the propulsive forces in the colon and rectum overwhelm the resistant forces of the pelvic floor. Continence for stool requires the receipt and recognition of the urge to defecate, mobility to reach the toilet in time, and the ability to postpone defaecation until reaching the bathroom. Delaying defaecation requires sufficient rectal capacity and compliance and adequate neurologic and anal sphincter function.

#### 2.2.1 Altered mental status

Acute medical illness, hospitalisation, surgery and medications such as opiates and sedatives may result in delirium or disorientation in the elderly. The reported rates of mental status changes to as high as 74% after surgery and from 11 to 42% during medical hospitalisation [1302, 1303]. In a systematic review of delirium associated with medication, opioids, benzodiazepines, and dihydropyridines were found to clearly increase the risk of delirium. There was uncertainty regarding antihistamines, tricyclic antidepressants, anti-Parkinson medications, steroids and non-steroidal anti-inflammatory medication [1304]. Delirium, confusion and other transient changes in cognitive function may impair a patient’s ability to recognise the urge to defaecate and/or their motivation to remain continent. The limited investigations of the relationship of delirium and incontinence studied patients with chronically altered mental status; any relationship of acute delirium and/or confusion with faecal incontinence is inferred from those data. Studies of the impact of delirium on continence show that delirium plays an important role in the development of incontinence [1305, 1306]. The impact of altered mental status on continence has also been inferred from studies showing improvement in continence with scheduled toileting programs [1307, 1308]. Ignoring the urge to defaecate combined with the effect of medications
may result in faecal impaction followed by incontinence. Delirium may require the use of restraints. Need for a restraint has been reported as an independent factor in incontinence [1309].

2.2.2 Impaired mobility

Lack of adequate mobility may prevent a patient from reaching the bathroom in time to avoid incontinence. In addition to the causes described in the urinary incontinence section, musculoskeletal ailments, such as arthritis and bone fractures, occur more commonly in the elderly and limit mobility. During the recovery phase from joint replacements ambulation may be slow and unsteady. Acute neurological conditions such as stroke may affect a patient’s gait as well as debilitated states from other illness. FI is fairly common (up to 30% in first week) immediately after a stroke; with rehabilitation, the rate decreases [1310, 1311]. The use of anticholinergic medication and requiring assistance to reach the toilet were significant independent factors [1310]. For patients temporarily requiring assistance to reach the bathroom, the timeliness of the assistant may impact on their continence.

2.2.3 Stool consistency

Change in stool consistency affects continence; both constipation and diarrhoea may result in FI.

2.2.4 Diarrhoea

Loose stool is clearly a risk factor for incontinence [1299, 1311-1315]; one study identified loose stool as the most important independent risk factor [1290]. Any condition or medication resulting in loose stools may also lead to incontinence including acute infection, intestinal inflammatory processes, medication and supplements (Table 11). Medications with the side effects of diarrhoea and/or steatorrhoea may result in faecal incontinence. Table 12 lists the medications, which cause diarrhoea or steatorrhoea with reasonable frequency [1316, 1317]. Laxatives and the medications used for bowel preparation for colonoscopy and surgery frequently result in temporary incontinence in older patients.

Although rarely described in the literature, intuitively cessation of the causative medication should decrease the incontinence. In a case report, withdrawal of the offending medication, metformin, resolved the incontinence [1318].

2.2.5 Constipation

Paradoxical FI may occur in patients with faecal impaction [1319-1323]. Immobility, inadequate dietary and fluid intake, depression, metabolic disorders neurological conditions, connective tissue disorders and medications contribute to constipation [1319, 1320]. Impaction may result in overflow incontinence with

444
loose stool leaking around the faecal bolus [1324]. Evaluation of impacted patients compared to elderly controls revealed similar resting and squeeze pressures although both groups had lower pressures than younger healthy controls. However, perianal and rectal sensation was impaired in 74% of the impacted patients [1325]. The theory is the patients with impaired sensation do not experience the urge to defecate with the typical volume of stool. The stool bolus causes the usual reflex relaxation of the internal anal sphincter but the lack of perception prevents the normal contraction of the external sphincter muscle. Incontinence is often aggravated by the use of laxatives to relieve constipation.

3. SUMMARY

Apart from re-challenged data for alpha-adrenergic agents (Level of Evidence = 2), the level of evidence for most of these causes is Level 3-4. Nonetheless, because many are easily addressed and contribute to morbidity beyond the lower urinary tract and perianal area, they are worth identifying even if the evidence is not strong.

4. RECOMMENDATIONS

Despite the lack of robust data regarding the incidence and causes, transient urinary and faecal incontinence is a clinically common problem. Since in most cases treatment is relatively straightforward, it is important to consider the causes discussed in this section when elderly patients present with new onset incontinence. Moreover, addressing them may further improve the incontinence even if it does not eliminate it completely, and it may make the incontinence more amenable to subsequent therapy. (Grade of recommendation C).

5. RESEARCH PRIORITIES

Further research should be performed on the mechanisms, prevalence, incidence, and remission rates of each of the known causes of transient incontinence, and possible additional causes should be identified as well. Since the clinical circumstances of older people are heterogeneous, studies should be conducted among several subgroups, including independent and homebound and community-dwelling older people, bedbound and mobile institutionalised older people and acutely hospitalised older people.

844. Protocol, S. The Stockholm III Trial on Different Preoperative Radiotherapy Regimens in Rectal Cancer. [cited 2012 February 4]; Preoperative radiotherapy (RT) is recommended to many patients with localised rectal cancer, not previously treated with pelvic RT. However, the optimum fractionation, the timing of surgery and the best use of concomitant chemotherapy remains controversial. Short-course, preoperative RT may induce both acute and late morbidity and has been claimed to cause more morbidity than long-course preoperative RT. There are theoretical reasons to believe that RT given in larger fractions during a shorter period of time might result in more late side effects than giving a conventional, more protracted RT. In addition, the optimum timing of surgery after RT, with respect to postoperative morbidity, mortality and potential downsizing of the tumour is not known. INTRODUCTION

The aim of this report is to provide an update of the evidence-based recommendations from the 6th ICI regarding the initial assessment of urinary incontinence (Committee 5A) and outcome measurements (Committee 5B) of incontinence for adult men and women.

II. GENERAL INFORMATION

1. TERMINOLOGY

A critical step in the evaluation of urinary incontinence (UI) is the use of up-to-date terminology to describe different types of UI and their associated lower urinary tract symptoms (LUTS). LUTS includes both storage and emptying symptoms in contrast to overactive bladder syndrome (OAB) which describes a subset of storage symptoms (e.g., urgency, frequency, nocturia), with or without the symptom of UI. The use of standardised terminology during the taking of the history of UI ensures an accurate characterisation of the type of UI experienced by each patient.

The ICS 2002 report (1) and the ICS /IUGA Joint Report (2) are recommended for reference, as well as an update of the terminology for nocturia (3). It should be noted however that a bibliometric and questionnaire analysis of the use of standardised terminology documents the low rate of acceptance of new terminology in both the literature and practice, and the slow abandonment of previously accepted common terms. (4)

The Standardisation Steering Committee (SSC) of the International Continence Society (ICS) “establishes terminology and methodology in the ICS’s areas of activity, to underpin professional standards of clinical management and research”. The value of the SSC is in promoting best standards when clinicians and allied professionals communicate with patients and colleagues, undertake diagnostic tests, proceed to therapeutic interventions and undertake research. Precise use of agreed terminology ensures clear understanding for collaborating centres and readers of publications. Adherence to the diagnostic testing standards gives patients and clinical colleagues confidence that conclusions on which important therapeutic decisions are based are reliable. Development of future insights into mechanisms and treatments of the disease areas relevant to the ICS is enhanced where research studies employ internationally standardised approaches.

The term “urinary incontinence” refers to the complaint of any involuntary loss of urine. The symptom of urinary incontinence can be volunteered by, or elicited from, the individual or may be described by the individual’s caregiver. Urinary incontinence can be categorised into several distinct sub-types based on associated characteristics and circumstances surrounding episodes of urine leakage. Although defining the type of incontinence will not establish a definitive underlying diagnosis, it will ultimately guide investigation and treatment. The following are the accepted ICS definitions of these conditions unless referenced (1).

1.1. Types of urinary incontinence

a) Stress (urinary) incontinence: Complaint of involuntary loss of urine on effort or physical exertion e.g., sporting activities), or on sneezing or coughing. (Sporting activities)

b) Urgency (urinary) incontinence: Complaint of involuntary loss of urine associated with urgency.

c) Postural (urinary) incontinence: Complaint of involuntary loss of urine associated with change of body position, for example, rising from a seated or lying position.
d) Mixed (urinary) incontinence: Complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing.

e) Incontinence associated with chronic retention of urine: Complaint of involuntary loss of urine which occurs in conditions where the bladder does not empty completely as indicated by a significantly high residual urine volume and/or a non-painful bladder which remains palpable after the individual has passed urine. (Note: The ICS no longer recommends the term overflow incontinence. A significant residual urine volume denotes a minimum volume of 300 ml, although this figure has not been well established.)

f) Nocturnal enuresis: Complaint of involuntary loss of urine which occurs during sleep.

g) Continuous (urinary) incontinence: Complaint of continuous involuntary loss of urine.

h) Insensible (urinary) incontinence: Complaint of urinary incontinence where the individual is unaware of how it occurred.

i) Coital incontinence (for women only): Complaint of involuntary loss of urine with coitus. This symptom can be further divided into that occurring with penetration and that occurring at orgasm.

j) Functional incontinence: Complaint of involuntary loss of urine that results from an inability to reach the toilet due to cognitive, functional or mobility impairments in the presence of an intact lower urinary tract system.

k) Multifactorial incontinence: Complaint of involuntary loss of urine related to multiple interacting risk factors, including factors both within and outside the lower urinary tract such as comorbidity, medication, age-related physiological changes and environmental factors.

Urinary incontinence can exist in isolation or may be associated with other lower urinary tract symptoms. The ICS classifies lower urinary tract symptoms (LUTS) into bladder storage, voiding and post-micturition, and pelvic organ prolapse symptoms. The following section summarises the definitions of LUTS described by the ICS-SSC.

1.2. Bladder storage symptoms

Bladder storage symptoms are experienced during the bladder filling phase:

a) Increased daytime urinary frequency: Complaint that micturition occurs more frequently during waking hours than previously deemed normal. Traditionally seven episodes of micturition during waking hours was considered as the upper limit of normal, although it may be higher in some populations.

b) Nocturia: Complaint of interruption of sleep one or more times because of the need to void. Each void is preceded and followed by sleep. The number of nocturia episodes and the degree of bother based on number has been questioned and the threshold of 2-3 per night has been suggested (5) (6-10).

c) Urgency: Complaint of a sudden, compelling desire to pass urine which is difficult to defer. (Note: The ‘all or none’ nature of ‘urgency’ has been questioned) (8).

d) Overactive bladder syndrome (OAB): Urinary urgency, usually accompanied by increased urinary frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology.

1.3. Bladder sensation

Asking patients about bladder sensory symptoms during bladder filling may be helpful in characterising certain types of incontinence.

a) Increased bladder sensation: Complaint that the desire to void during bladder filling occurs earlier or is more persistent to that previously experienced. This differs from urgency by the fact that micturition can be postponed despite the desire to void.

b) Reduced bladder sensation: Complaint that the definite desire to void occurs later than that previously experienced despite an awareness that the bladder is filling.

c) Absent bladder sensation: Complaint of both the absence of the sensation of bladder filling and a definite desire to void.

1.4. Voiding and postmicturition symptoms

Voiding symptoms are experienced during the voiding phase and post-micturition symptoms are experienced immediately after micturition.

a) Hesitancy: Complaint of a delay in initiating micturition.

b) Slow stream: The individual’s perception of reduced urine flow, usually compared to previous performance or in comparison to others.

c) Intermittent stream (intermittency): Complaint of urine flow which stops and starts, on one or more occasions, during micturition.

d) Straining to void: Describes the muscular effort used to initiate, maintain or improve the urinary stream.

e) Spraying (splitting) of urinary stream: Complaint that the urine sprays or splits rather than coming out as a single, discrete stream.
f) Terminal dribble: is the term used when an individual describes a prolonged final part of micturition, when the flow has slowed to a trickle/dribble.

g) Feeling of incomplete bladder emptying: Complaint that the bladder does not feel empty after passing urine.

h) Need to immediately re-void: Complaint that further micturition is necessary soon after passing urine.

i) Postmicturition leakage: Complaint of a further involuntary passage of urine following the completion of micturition.

j) Position-dependent micturition: Complaint of having to take specific positions to be able to micturate spontaneously or to improve bladder emptying, for example, leaning forwards or backwards on the toilet seat or voiding in the semi-standing position.

k) Dysuria: Complaint of burning or other discomfort during micturition. Discomfort may be intrinsic to the lower urinary tract or external (vulvar dysuria in women).

l) (Urinary) retention: Complaint of the inability to pass urine despite persistent effort.

2. ASSESSMENT OF SUB-POPULATIONS REVIEWED BY OTHER COMMITTEES

The targeted assessments and specific outcome measures for conditions of UI in Children (Cmte 9), Neurogenic Patients (Cmte.10), Frail Elderly (Cmte.11), Painful Bladder Syndrome (Cmte.19) and Faecal Incontinence (Cmte.16) are presented separately in the respective reports. The requirements of specific sub-populations negate the ability to recommend a ‘universal’ initial evaluation. Within the initial assessment of UI, these sub-populations / subgroups are recognised because of the differences within patient groups or the interrelationship between the conditions. Congenital and developmental issues are critical considerations in children. Specific risks for combined storage and emptying abnormalities and upper urinary tract deterioration in the neurogenic population demand a more involved initial and complex evaluation. The effects of ageing on the lower urinary tract, altered toileting functions, and medical co-morbidities in the frail elderly group present unique challenges. These subgroups also include patients with LUTS with and without incontinence and with the presence of pelvic pain or faecal incontinence.

The sub-sections in this report should be utilised in conjunction with other population or condition specific Committee Reports of the Consultation and with the final recommendations of the Consultation which are presented in simplified form in Appendix (1. Definitions). Recommendations for initial evaluation have been developed by the International Scientific Committee and are also published in Appendix (2. Evaluation). In addition, History and Symptom Assessment recommendations are further detailed as the initial steps in the evaluation of the index adult male (3. Initial Management, II. Male), and adult female (3. Initial Management, III. Female). The reader is encouraged to refer to these recommendations and algorithms in combination with this report.

3. EVIDENCE BASED RECOMMENDATIONS

The recommendations presented in this report are evidence-based and utilise the ICUD-EBM grades. A search of the available literature in English obtained from Medline and Pubmed up to June 2016 by the individual committee members employed multiple search terms related to the initial assessment of the patient with urinary incontinence and patient reported outcome assessment.

III. INITIAL ASSESSMENT

1. PURPOSE OF INITIAL ASSESSMENT (EXPERT OPINION OF THE COMMITTEE)

As will be noted, especially in this committee report (5A), the amount and sophistication of the literature that is applicable for the development of evidence-based guidelines is limited. For this reason, the grade of recommendation in the area of “initial assessment” will often rely on ‘expert opinion of the panel’. For the purpose of subsection 5A, the ‘initial assessment’ represents the components of the history, physical examination, laboratory tests, and basic office testing to:

1. Establish a presumptive or condition specific diagnosis, and exclude underlying organ-specific related or unrelated conditions that would require intervention.

2. Assess the level of bother and desire for intervention from information obtained from the patient or caregivers, utilising objective measures or patient reported outcomes.

3. Prepare for the institution of empirical or disease specific primary therapy based on the risk and benefit of the untreated condition, the nature of the intervention and the alternative therapies – including Conservative (Cmte. 12) or Pharmacological (Cmte. 8) therapies.
4. Prompt the recommendation of additional more complex testing or specialist referral (when indicated).

5. Assess the level of improvement after intervention from information obtained from the patient or caregivers, utilising objective measures or patient reported outcomes (Cmte. 5B).

Once the type of Urinary Incontinence (UI) with associated lower urinary tract symptoms (LUTS) has been established, elaboration of a differential diagnosis can occur, and further investigations may be elected and an eventual treatment plan can be formulated to address or modify the effects of the underlying cause(s). The success of the treatment plan can be measured by patient-reported outcomes (from a simple "yes" or "no" to more complex questionnaires), and/or other objective measures of urinary leakage events (including bladder diaries, pad tests, or urodynamics studies).

The initial assessment must consider the degree of bother, and the costs of further evaluation, balanced against the consequences of a failure to diagnose an underlying condition, the risks and benefits of empirical conservative management or pharmacological therapy, and the need for an accurate diagnosis before more complex intervention or empirical therapy. The burden of these conditions and the availability of resources for individual patients, caregivers, physicians, and health care systems requires that primary intervention strategies be formulated, when available, from evidence based findings and decisions emanating from the initial evaluation.

Of note, LUTS cannot be utilised with confidence to make a definitive diagnosis of a specific lower urinary tract condition or lower urinary tract disease (LUTD), as these symptoms may suggest and indicate pathologies such as urinary tract infection (UTI) or more serious underlying conditions. Basic laboratory tests, such as testing for urinary tract infection (UTI) or blood (haematuria), and appropriate screening for malignancy should be considered before the decision is made to choose therapy for incontinence. Urinary retention with overflow may present as urinary urgency, frequency, and nocturia with urinary loss mimicking OAB.

Concomitant pathology may affect urine production as a co-morbid contributory factor, by affecting fluid balance or renal function (fluid intake and output regulation) and may need to be addressed prior to or in combination with bladder or bladder outlet therapy. A thorough review of medications which alter fluid production or lower balance and urinary tract function should be addressed. The physician should also seek a history of pelvic pathology or surgery and neurological symptoms and signs that may indicate alterations in the control of the lower urinary tract function or be responsible for the cognitive, motivational, or physical factors that determine the ability to perform toileting functions effectively. The physical examination and the appropriate laboratory tests are necessary to refine the differential diagnosis and therapeutic course.

**2. INITIAL ASSESSMENT – GENERAL RECOMMENDATIONS**

1. Lower Urinary Tract Symptoms (LUTS) cannot be used to make a definitive diagnosis; they may also indicate pathologies other than Lower Urinary Tract Disease (LUTD). Specific to this report, LUTS includes Overactive Bladder (OAB) a syndrome which may be associated with urgency incontinence (OAB-wet) or without incontinence (OAB-dry). (Level 4 - Grade D)

2. Urinary incontinence should be described by specifying relevant factors such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and quality of life, the measures used to contain the leakage and whether or not the individual seeks or desires help. (Level 4 - Grade D)

3. Urinary incontinence should be categorized by symptoms into urgency incontinence, stress incontinence or mixed incontinence and conservative (non-invasive) therapies may then be started based on this classification to treat the most troublesome component, or either component of the incontinence (Level - Grade D). More sophisticated testing (e.g., urodynamic studies) is not required prior to the institution of conservative therapy (see indications for urodynamics in the Committee Report on Dynamic Testing Committee 6). (Level 3 - Grade C)

4. Both objective (bladder diary) and subjective (patient reported outcomes – PROs) are recommended for assessment and measurement of the degree of symptoms and bother of UI at baseline, and for the assessment of the impact of therapy. (Level 3 – Grade D).

5. Normal lower urinary tract function requires the ability of the bladder to adequately store urine at low pressure while the bladder outlet remains competent, and the bladder to contract until completely empty while the bladder outlet remains open. In addition to an evaluation of LUT function, a thorough evaluation for co-morbid conditions which affect fluid intake and output should be undertaken. Diseases of the nervous system and pelvic disorders, as well as medications which may affect the LUT should be addressed. (Level 4 - Grade D).

6. Referral to a specialist is recommended for hematuria (visible or microscopic), urinary tract infection (persistent or recurrent), prolapse (symptomatic or below the introitus), obstruction or re-
tention (symptoms or findings of palpable bladder, hydronephrosis or obstructive renal insufficiency), suspected neurological disease, mass (urethral, bladder or pelvic - benign or malignant), fistula (urinary or bowel), faecal incontinence, a history of prior pelvic surgery or radiation (incontinence, oncologic) (Level 4 - Grade D).

3. INTIAL ASSESSMENT – GENERAL RESEARCH RECOMMENDATIONS

1. Standardisation of the ‘definition of symptoms’ and the ‘measurements of symptom frequency, severity and bother’ are essential for patient care and research. Continued research into the appropriate scales and metrics should be accompanied by a significant attempt to establish best practice guidelines for their use and a consensus on the adoption of universal standards.

2. Recognition and resolution of the differences in common language usage and scientific utilisation of terms should continue. Resolution of the differences in definitions and metrics between recognised societies and agencies is essential for communicating data with respect to patient care, research, and treatment outcomes.

3. Research into the development of accurate measures to objectify subjective symptoms such as “urgency” and other bladder sensory symptoms.

4. Development, standardisation, and universal adoption of symptom assessment tools (questionnaires) to improve the diagnostic accuracy of lower urinary tract symptoms. (Refer to section 5B of this committee’s report)

5. Validation of the accuracy of specific components of the history and physical findings to establish an accurate diagnosis and to initiate non-invasive conservative or pharmacological therapy. In addition, to further identify components that would indicate the need for more invasive testing, complex therapeutic interventions, and indications prior to or as a result of referral.

6. Creation and institution of evidence based guidelines for the referral of patients to a specialist are needed to improve the efficiency of the healthcare system in treating the large burden of disease. (See Epidemiology, Committee 1). The institution of conservative measures and pharmacology are in the domain of the primary caregiver. Further improvement in the ability to define the index patient, but more importantly the subgroups of patients who will require more complex specialist therapy, will aid in counselling and referral at the primary level. In addition, refining the true risks for significant underlying disease noted while obtaining the history, or during the examination or laboratory findings will improve resource utilization.

IV. GENERAL POPULATIONS

1. INITIAL ASSESSMENT OF URINARY INCONTINENCE

Individuals with UI can be identified through routine screening, or the patient may initiate discussion about incontinence problems. The initial assessment of UI should help the health care provider to understand the type of incontinence, while identifying potentially modifiable contributing factors. Most primary treatment options, such as lifestyle modifications and behavioral treatments, do not vary by type of UI. However, it is important to determine the type of UI since some treatment options do vary according to incontinence. Equally important, establishing the type of UI will lead the health care provider to a list of possible underlying causes, or differential diagnosis of the urinary symptoms. Most causes of UI are non-life threatening, however symptoms of incontinence may also herald life-threatening or more severe disease such as bladder cancer when associated with haematuria; when more specialized testing will be required immediately. Finally, assessing the level or bother and desire for intervention from information obtained from the patient or caregiver is essential for guiding the nature of the treatment plan.

1.1. History

Taking a careful clinical history is fundamental to the clinical process. Some studies have indicated that patient history alone is not completely accurate as the sole determinant of incontinence type \cite{11,12}. However, Martin et al. \cite{13} in a systematic review and meta-analyses on the methods for diagnostic assessment of urinary incontinence, suggested that women with urodynamic stress incontinence (USI) can be correctly identified in primary care from clinical history alone with a sensitivity of 0.92 (95% C.I.: 0.91- 0.93) and specificity of 0.56 (0.53- 0.60); symptoms of urge incontinence were found to be 0.61 (0.57- 0.65) sensitive and 0.87 (0.85-0.89) specific for the diagnosis of detrusor overactivity.

Despite the lack of formal evidence, there is universal agreement that taking a history should be the first step in the assessment of anyone with UI\cite{1,14}.

The general history should include questions relevant to establish the type of UI and to precipitating and aggravating factors of urinary loss, time of onset and duration of symptoms, severity, degree of bother and finally the association with voiding, storage and other urinary symptoms.
The incontinence first should be characterized subjectively. Does the leakage occur: With physical activity? With a sense of urgency? Without sensory awareness? If the nature of the incontinence is mixed, does one component cause more bother or occur more frequently than the other? Secondly, the leakage should be quantified if possible. Appraisal of the degree of leakage before therapy can be helpful during postoperative assessment of treatment impact. For the purposes of routine outpatient assessment, this quantification can be achieved based on the number of pads used per day or the frequency of clothing changes because of urinary leakage.

Acute symptoms can be defined by documenting patterns of fluid intake and output, acute infection, recent surgery or trauma. Chronic symptoms should prompt queries about a history of congenital abnormalities, neurological disease, relevant surgery or general health issues. History should also identify patients who need rapid referral to an appropriate specialist. These include patients with associated pain, haematuria, a history of recurrent urinary tract infection (UTI), pelvic surgery (particularly prostate surgery) or radiotherapy, constant leakage suggesting a fistula, voiding difficulty or suspected neurological disease (Red Flag Symptoms).

The voiding pattern should also be defined. What is the frequency of urination during the day and during the night? Are there any voiding symptoms and/or storage symptoms? Previous surgery such as pelvic or back surgery and, in males, prostate or urethral surgery for benign or malignant disease should be investigated.

Information should be obtained concerning medications with known or possible effects on the lower urinary tract. The general history in women should also include assessment of menstrual, obstetric, sexual, gynaecological and bowel function. It is also helpful to determine the impact that the leakage has on the patient’s daily life and activities if incontinence limits the individual’s activity and if the patient made life-style changes because of the threat of leakage. Finally, it is important to emphasize the importance of establishing patient expectation of treatment and an understanding of the balance between the benefits and risks/burden of available treatment options (see Committee Report (5B)).

The reader is referred to the report on Epidemiology (Cmte. 1) for specific risk factors to be considered during the medical history, and to the report on Frail Elderly (Cmte. 11) for a list of co-morbidities and medications that can cause or contribute to UI.

A later section of this Committee Report (5B) presents a complete review and evaluation of questionnaires that are applicable for clinical and research use in evaluating patient symptoms. Structured condition specific questionnaires may be utilised, and may be either clinician or self-administered. Use of questionnaires may facilitate disclosure of embarrassing symptoms, ensure that symptoms are not omitted, and standardise information for audit and research.

In the absence of questionnaire use, Table 1 summarises key questions for the initial assessment of urinary incontinence based on the expert opinion of this committee. Note that the committee strongly encourages the use of standardised questions.

### 1.2. Bladder Diaries

The micturition time chart records the timing of voids in 24 hours. The term frequency-volume chart is used to describe a chart that records the time of each micturition and the volume voided for at least 24 hours. The bladder diary may include fluid intake, incontinence episodes, pad usage, the degree of incontinence as well as a record of episodes of urgency and sensation and activities performed during or immediately preceding the involuntary loss of urine. Therefore, bladder diaries are most suited for the purpose of comprehensive evaluation of urinary incontinence. However, documentation of the frequency of an individual’s lower urinary tract symptoms and the voided volume for at least 24 hours can already be extremely helpful in the initial assessment of urinary incontinence, although 2-3 days of recording generally provide more useful clinical data. Moreover, a diary may be therapeutic as it provides insight into bladder behavior and it can be utilised to monitor the effectiveness of treatment during follow-up.

A frequency-volume chart (FVC) or bladder diary (BD), if properly completed, can confirm all of the following information.

- a) Daytime urinary frequency: Number of voids by day (wakeful hours including last void before sleep and first void after waking and rising).
- b) Nocturnal frequency/nocturia: Number of times sleep is interrupted by the need to micturate. Each void is preceded and followed by sleep.
- c) Twenty-four-hour frequency: Total number of daytime voids and episodes of nocturia during a specified 24-hr period.
- d) Twenty-four-hour urine production: Summation of all urine volumes voided in 24 hr.
- e) Maximum voided volume: Highest voided volume recorded.
- f) Average voided volume: Summation of volumes voided divided by the number of voids.
- g) Median functional bladder capacity: Median maximum voided volume in everyday activities.
- h) Polyuria: Excessive excretion of urine resulting in profuse and frequent micturitions, defined as
greater than 2.8 L of urine during 24 hours for an individual weighing 70 kg.

i) Nocturnal urine volume: Cumulative urine volume from voids after going to bed with the intention of sleeping to include the first void at the time of waking with the intention of rising (excludes last void before sleep).

j) Nocturnal polyuria: Excess (over 20–30% age dependent) proportion of urine excretion (nocturnal voided volume/total 24 hr voided volume x 100%) occurring at night (or when the patient is sleeping)(15)

However, it should be noted that there are some limitations to the use of a frequency-volume chart or bladder diary. There is no evidence that the results of these charts provide a valid prediction of the type of urinary incontinence experienced by each patient (16, 17). Some patients may have difficulty completing the diary in a reliable, meaningful or timely fashion, especially when increasing the complexity or the amount of time (days) required to complete the diary (18). The bladder diary may not yield information about the evolution of incontinence episodes that occurs less frequently than once per day(18, 19).

Several studies have compared patients’ preference for, and the accuracy of, electronic and paper voiding diaries in voiding dysfunction(20-24) , but the utility of electronic diaries has not been fully clarified yet. Due to intraindividual variation, FVC recordings differ on different days. The more days recorded, the more likely it will be that the recordings will capture the whole spectrum of variation. Few data have been reported on the intraindividual variation of FVC parameters(25) (26, 27) . However, these variations have been used in statistical analysis leading to statements on the optimal duration of FVCs. Recommendations for diary duration vary considerably including 24 hours, 3 days or 7 days; this inconsistency is partially explained by differences among study populations, based on diagnosis, age, sex, and geography, and by differences in methods of analysis and in interpretation of the results. In a mini-review on the reliability of FVCs, Yap et al argued that using FVCs of 3 days or
longer might be the most defensible policy, but they found no evidence that compliance rates had been accounted for in the studies reviewed (28). They concluded that in some reports reliability was overestimated. Another review by Bright et al focusing on the validation of FVCs summarised that excessive duration reduces patient compliance, but too short a duration may produce unreliable measurements [(17)

The choice of diary duration may not only be based upon better validity or reliability but also on the possible behavioural therapeutic effect of keeping a diary (29-31). Recently, Bright et al have described the development of the first validated bladder diary for the assessment of LUTS in both male and female adults, using a psychometric validation methodology. The resulting bladder diary is recommended for use over a 3-d period and has been accepted as the ICIQ bladder diary. Urinary incontinence is assessed by the recording of pad use. The ICIQ bladder diary has been validated using a British English-speaking population and as with all such tools, will require cultural adaptation and linguistic validation for other languages using the formal ICIQ protocol (30, 31). The sample validated ICIQ bladder diary is illustrated with the instructions for use in Chapter 24.

In conclusion, voiding diaries generally give reliable data on lower urinary tract function. However, there remains a lack of consensus on diary duration and how well diary data correlate with some symptoms.

1.2.1 Bladder Diary Recommendations

1. Ask patients with urinary incontinence to complete a bladder diary to evaluate co-existing storage and voiding dysfunction. A bladder diary is recommended in order to document and communicate both objective information and to objectify observations by the patient during the diary period. Although never completely diagnostic, diary patterns may characterise normal and abnormal states. (Grade A)

2. A 1-day frequency volume chart (FVC) which includes the first morning void the following day is a reasonable tool to gain insight into voiding habits during normal daily routine. A 3-day FVC or diary is recommended for accurate assessment of LUTS and for confirming a consistent clinical pattern in day-to-day practice. For atypical clinical patterns or clinical research, a 7-day diary may be recommended (most pharmacological studies now employ a 3-day diary as a standard to improve patient compliance). (Grade C)

3. The validated ICIQ bladder diary is recommended for use over a 3-d period. The inclusion of the diary in research studies is recommended and will provide ongoing evidence of validation, as well as the external validity of the diary. (Grade A)

1.2.2 Future Research

a) The ideal duration of a bladder diary based on accuracy, compliance, and the utility of the diary for diagnosis, the selection of therapy, and improving the outcomes of therapy requires further investigation.

b) The utility of paper versus electronic methods of recording voiding patterns requires further research.

c) The ICIQ bladder diary should be culturally and linguistically validated for other languages than British English and be included in research studies for further validation as well as determining external validity.

1.3. Urgency Scale

According to the IUGA/ICS definition urgency is: "Complaint of a sudden, compelling desire to pass urine which is difficult to defer" (2). However, in clinical practice, urgency is often accompanied by other symptoms. Urgency, with or without urgency incontinence, usually with frequency and nocturia, is the cornerstone symptom of overactive bladder syndrome (OAB) (32); while with bladder pain, and frequency urgency are typical symptoms of interstitial cystitis or bladder pain syndrome (33). However sometimes patients with lower urinary tract symptoms may not be able to differentiate between normal urge (desire) to void and urgency (difficult to postpone) (4), furthermore, with history only it may be difficult to define the severity, duration and frequency of urgency(34, 35). Thus, it is important to have appropriate tools that allow accurate diagnosis, to establish tailored therapy and to assess the effectiveness of treatment. Severity questionnaires and scales have been developed specifically to assess urinary urgency, to help the patient to define the symptoms and severity and the physician to establish the therapy and its effects. Table 2 and table 3 show the validated questionnaires and scales respectively, used to assess the urinary urgency.

1.4. Urinalysis

“Urinalysis is a fundamental test that should be performed in all urological patients. Although in many instances a dipstick urinalysis provides the necessary information, a complete urinalysis includes both chemical and microscopic analysis.” (44). Urine dipstick testing, as opposed to microscopy, is satisfactory for urinalysis in the diagnosis of acute uncomplicated cystitis (45, 46). In relation to urinary incontinence, dipstick urinalysis is not a diagnostic test, but a screening test, utilised to detect haematuria, proteinuria, glycosuria, pyuria and bacteriuria.

Haematuria can indicate important pathology such as urothelial carcinoma in situ, leading to lower urinary tract storage symptoms including incontinence (47). Glycosuria is relevant, as a potential indicator of diabetes mellitus. This can cause symptoms via several mechanisms including polyuria secondary to osmotic diuresis. Diabetic peripheral autonomic neuropathy affecting bladder innervation may be associated with impaired bladder emptying. The clinician should note that a patient does not generally demonstrate glucose into the urine until the blood glicemia is >180 mg/dl. Consequently, a dipstick urinalysis may fail to reveal intermittently high sugars or mild diabetics. If diabetes is suspected, then a random or fasting blood sugar is preferred (48-50).

Pyuria and bacteriuria, detected from urinary dipstick leukocyte esterase and nitrite tests respectively, are important signs of urinary tract infection. The specificity and sensitivity of these latter tests for UTI is increased when used together compared to either individual test (50, 51). Even in the absence of controlled studies, there is general consensus that the benefits of urinalysis clearly outweigh the costs involved, although the use of urinalysis should always be associated with prognostic significance (52). A positive dipstick urinalysis will prompt formal urine microscopy and culture to detect UTI prior to antibiotic treatment and/or the use of additional tests such as endoscopy and urinary tract imaging.

Urinalysis negative for nitrite and leukocyte esterase reliably excludes UTI in people with UI (53) and should be included, with urine culture when necessary, in the evaluation of all patients with UI (Le1:GR A based on expert opinion). Urinary incontinence may occur during symptomatic UTI (level 3) (54) and existing UI may worsen during UTI (level 3) (55).

The importance of urinalysis in the basic assessment of patients with urinary incontinence and lower urinary tract symptoms is not dependent on gender, age or aetiology. Indeed, it has been recommended in the evaluation of geriatric patients including nursing home residents who are incontinent (56), in peri- and postmenopausal women (57), and in older women reporting urinary incontinence (58). In the latter context, it has even been observed that clinically significant urine samples can even be obtained from disposable diapers in elderly incontinent women (59). The clinical relevance of asymptomatic bacteriuria (without pyuria) and pyuria (without bacteriuria) in the elderly is controversial as the rate and severity of UI was unchanged after eradication of asymptomatic bacteriuria in nursing home residents (level 2; Grade B) (56, 60, 61).

Recently, bacterial communities (microbiota) have been discovered in the female bladder and consequently, the sterile urine paradigm is no longer valid. Emerging evidence suggests that the female urinary microbiota may contribute to symptoms of urinary incontinence in women (62). Several bacterial species are more common in women with urgency urinary incontinence than in asymptomatic controls (63, 64). For these reasons new approaches are being developed: the 16s rRNA sequence analysis and the expande quantitative urine culture protocol (64).

1.4.1 Urinalysis - Recommendation

1. It is considered standard to perform a urinalysis by either using a dipstick test or examining the spun sediment in incontinent patients. (Level 4 - Grade D)

2. If a dipstick test is used, it is recommended that a "multi-property" strip that includes fields for haematuria, glucose, leukocyte esterase and nitrite tests be chosen. (Level 4 - Grade D)

3. Additional tests available on urine dipstick strips, such a protein, bilirubin, ketones and pH, may be helpful in the broader medical management of patients. However, they are not essential in the context of evaluation of the patient with urinary incontinence or lower urinary tract symptoms. (Level 4 - Grade D)

4. Do not routinely treat asymptomatic bacteriuria in elderly patients to improve urinary incontinence. (Level 2; Grade B)

1.4.2 Future Research

Emerging evidence challenges the long-held paradigm that the healthy bladder is sterile and evidence indicate that the human urinary tract contains microbial communities; however, the role of these communities in urinary health remains to be elucidated. Interesting findings suggest that previously undetected bacteria in the bladder of women may have a role in UI that will provide new opportunities for prevention and improvement in the treatment approaches for UI (65).
On this basis, traditional tools for urinary bacterial assessment (Urinary dipsticks and standard urine cultures) seem to have significant limitations because they are not able to detect slow-growing bacteria. New diagnostic tools are developing: expanded quantitative urine culture and 16S ribosomal RNA gene sequencing and could give allow a greater insight into many lower urinary tract disease including incontinence (66).

1.5. Post voiding residual in the female and male patient

Post-void residual (PVR) volume (also known as residual urine, bladder residual) is the amount of urine that remains in the bladder after representative voiding. It indicates poor voiding efficiency, which may result from a number of contributing factors. It is important because it may worsen symptoms and, more rarely, may be associated with upper urinary tract dilatation and renal insufficiency. Both bladder outlet obstruction and low bladder contractility contribute to the development of PVR. PVR measurement can be accomplished within a few minutes of voiding either by catheterisation or by calculation of bladder volume using a portable ultrasound scanner.

It is difficult to determine the normal value of post-void residual determination in the initial assessment of urinary incontinence since most studies with data on PVR have not been performed in patients with UI. However, the populations studied have included some women with UI, and incontinent patients with neurogenic bladder disease.

Several studies have compared volumes measured with portable ultrasound scanners versus catheterisation and found portable scanners to be 85-94% accurate (67, 68). A study has imaged the bladder volume after catheterisation and found that the volume of urine remaining in the bladder after catheterisation accounted for most of the difference between the two measurements (67). Bimanual palpation cannot reliably estimate the post-void residual urine volume (69). Since PVR may vary, one measurement of PVR may not be sufficient (70). PVR should probably be measured several times to increase its reliability. In geriatric patients, Griffiths et al found a significant variability in PVR measurement depending on the time of the day, with the greatest volume occurring in the morning (71). A non-representative PVR is particularly common if the patient's bladder is not full enough to yield an urge to void. Special consideration is required in male patients with incontinence and bladder outlet obstruction, incontinent neurogenic patients who may demonstrate combined disorders of storage and emptying (72), and preoperatively in female patients being considered for incontinence surgery.

An increased PVR alone is not necessarily a problem, but if combined with high pressures it can lead to upper tract problems. If related to UTI’s, PVR needs to be treated since UTI’s cannot be eradicated in the presence of an infected residual. A significant PVR also decreases the functional bladder capacity and thus contributes to urgency/frequency, urgency incontinence and nocturia. However, a Scandinavian study in nursing home residents found that an elevated PVR was not associated with bacteriuria and incontinence (73). Since recurrent UTI’s [due to elevated PVR] can be associated with urinary incontinence it remains necessary to measure PVR in incontinent patients with UTI.

Review of the literature fails to show an evidence-based specific maximum PVR that is considered normal, nor is there a minimal PVR that is considered abnormal. The amount of residual urine that precedes treatment by various therapies has also not been determined. The AHCPR guidelines state that, in general, a PVR less than 50 ml is considered adequate bladder emptying and over 200 ml is considered inadequate emptying (expert opinion of the panel members) (74).

“Normal values” of PVR have been determined in several groups of non-incontinent and incontinent women. Gehrich et al studied 96 women (mean age 60 ± 11 yrs) that were seen in a well-women clinic. These women had no history of incontinence, retention, symptomatic prolapse or neurologic disorders. Most (97%) had a minor (asymptomatic) degree of prolapse, 80% were post-menopausal and 30% had had a hysterectomy. The median PVR was 19 ml (range 0-145 ml; mean 24 ± 29 ml); only 5% had PVR > 100 ml. Only, age > 65 yrs was associated with higher PVR. This study gives some indication on what might be considered normal or relatively normal (75). Tseng et al studied 107 women with urodynamic stress incontinence. They found a mean PVR of 62.5 ml by bladder scan and 38.5 ml by catheterization. Only 15.9% had a PVR greater than 100 ml. The PVR determined by bladder scan offered a sensitivity of 64.7% and a specificity of 94.3% in detecting PVR greater than 100 ml (76). Haylen et al studying women with lower urinary tract dysfunction found that 81% had a PVR of less than 30 ml (77). Fitzgerald et al studied women with urgency, frequency and urge incontinence: 10% had an elevated PVR of > 100ml. These women had no history of incontinence, retention, symptomatic prolapse, and were excluded. Of the 297 "asymptomatic" patients, 21.5% had PVR volumes of 150 mL or more. Patients with elevated PVR (> 150 ml) were significantly more likely to have a urinary tract infection at admission and have urine incontinence on discharge (80). Millemann et al retrospectively reviewed 201 women (mean age 55%; range 20-90) who presented with complaints of urinary frequency, urgency and/or urge incontinence. 19% had an elevated PVR of more than 100 ml (mean 211 ml; range 100-997 ml). On multivariate analysis the following independent predictors...
of raised PVR were identified: age > 55 yrs [OR 3.71], prior incontinence surgery [OR 4.32], a history of multiple sclerosis [OR 15.32] and pelvic organ prolapse grade 2 or greater [OR 3.61] (81). In summary, an elevated PVR > 100 ml was found in 5% of women visiting a well-women clinic, in 10-19% of women with OAB, in 11% of women with pelvic floor disorders and in 15.9% of women with urodynamic SUI. Overall, incontinent women have a slightly higher risk of elevated PVR compared to asymptomatic subjects. Does a significant PVR have an impact on the outcome of treatment in patients with incontinence? Nager et al studied the predictive value of urodynamic measures on stress continence outcomes after surgery for stress urinary incontinence. They found that urodynamic measures do not predict outcomes. However, since women with PVR > 150 ml were excluded in this study, one can only conclude that PVR volumes < 150 ml did not have an adverse impact on stress continence outcomes (82).

A PVR measurement is recommended in men with symptoms suggestive of bladder outlet obstruction. It is a well known clinical principle that chronic urinary retention can be associated with overflow incontinence [ischuria paradoxa]. Apart from this there are unfortunately insufficient data on the role of PVR and its significance in male urinary incontinence. Consequently, there are insufficient data to draw conclusions about the association of PVR and urinary incontinence in men as well as the association of PVR and the outcome of incontinence treatment in men.

In the geriatric patient, a PVR should always be measured since it decreases functional bladder capacity and contributes to urgency/frequency, urge incontinence and nocturia.

PVR should probably be measured several times to increase its reliability. In elderly patients, Griffiths et al found a significant variability in PVR measurement depending on the time of the day; the greatest volume occurred in the morning (71). Counter-intuitively, a Scandinavian study in nursing home residents was unable to show an association between an elevated PVR and bacteriuria and incontinence (73).

1.5.1 Recommendations

1. Varying degrees of decreased bladder emptying or urinary retention may be a cause of LUTS that are associated with symptoms of decreased urinary storage. The decision to perform a PVR in disease specific sub-groups of incontinent patients should be based on an association of the condition with poor bladder emptying (Grade D), whereas in individual patients this decision may be based on symptoms or physical findings. (Grade C)

2. Female patients who present with storage specific symptoms, with normal sensation and no complaints of decreased bladder emptying, and no anatomical, neurological, organ-specific, or co-morbid risk factors for retention may be assessed for bladder emptying by history and physical examination alone, depending on the potential morbidity of the failure to diagnose and the nature of the intended therapy. (Grade B). Due to the increased possibility of bladder outlet obstruction due to prostatic obstruction being increased in the male patient, the threshold for investigating residual urine in the male is significantly lower (Grade D).

3. A PVR should be performed in incontinent patients when decreased bladder emptying is suspected, especially if treatments that decrease bladder contractility or increase outlet resistance are being considered. (Grade D)

4. Non-invasive ultrasound measurement of PVR is as accurate as measurement by catheterization and is therefore the preferred method. (Grade A)

5. A palpable bladder on physical examination is an indication for referral to a specialist (Grade D)

1.5.2 Future Research

1. Development of more specific indications for PVR testing for diagnosis and prior to instituting therapy based on history, physical examination, and disease specific findings.

2. Further development of low cost, minimally invasive, and accurate means of measurement of PVR that do not require catheterisation.

V. SPECIFIC POPULATIONS: EVALUATION OF THE FEMALE PATIENT

1. ESTABLISHING THE TYPE OF URINARY INCONTINENCE IN WOMEN

The aims of the assessment of women with urinary incontinence are the documentation and characterisation of type of incontinence, its timing and its severity, the differential diagnosis, prognosis evaluation and planning of treatment (83). The classification of subjective diagnosis of urinary incontinence into stress, urgency and mixed incontinence is basically clinical. Assessment should include history, symptom assessment, and physical examination. A careful urological history may be helpful to make a first subjective differentiation between the types of incontinence. Infact as shown in Holroyd-Leduc’s meta-analysis (16) simple questions to diagnose stress or urgency urinary incontinence have high reliability in women, with the percent agreement between repeated questioning estimated at 90% for stress, urgency and mixed urinary incontinence sub-types (16). Further questioning on the frequency, severity of leakage and degree of bother, is essential for planning treatment and counseling of the women. The leakage should also be quantified if possible by using voiding diaries (84, 85), pad tests (the 1-hour pad test the most used)
other metabolic conditions (96), neuropsychiatric dis-
continence are: obesity(94)  (95, 96), diabetes and
success. The main factors associated with urinary in-
all comorbidities that could affect the lower urinary
tract infections (RUTI), no prior extensive pelvic sur-
gery or prior surgery for stress incontinence and no
medical conditions that can affect the lower urinary
tract (87). Complicated SUI doesn’t fulfil the uncom-
plified when the presenting history of SUI has been
present for at least 3 months, the post-void residual
urine volume is < 150 ml, urinalysis or urine culture is
negative and clinical assessment of urethral mobil-
ity,with an expressed desire for surgery for SUI, and
a positive provocative stress test. Conversely compli-
cated SUI has been defined as incontinence in
women with previous surgery for incontinence, his-
tory of pelvic irradiation, pelvic surgery within the pre-
vios 3 months, and anterior or apical pelvic-organ
prolapse of 1 cm or more distal to the hymen (88).
Nevertheless several studies (11, 88) have shown that
patient history alone is not completely accurate
in determining the type of incontinence. Symptom as-
essment by validated questionnaires can provide a
very helpful complement to the patient history, to as-
sess the impact of urinary incontinence on quality of
life, and the symptoms (89-93). In the literature there
are no studies that prove the usefulness of physical
examination to typify the urinary incontinence. How-
ever, it is recommended to identify risk factors as well
as significant associated or underlying pathology,
such as significant prolapse, obstruction, neurological
disease and malignancy(16).

2. GENERAL MEDICAL HISTORY

The main goal of the general medical history in
women with urinary incontinence is trying to identify
all comorbidities that could initiate or worsen UI as
well as those which could negatively impact treatment
success. The main factors associated with urinary in-
continence are: obesity(94)  (95, 96), diabetes and
other metabolic conditions (96), neuropsychiatric dis-
orders (97-100) , heavy occupational work, smoking,
previous pelvic surgery and constipation (100, 101)

Neurologic diseases, pelvic neoplasms (malignant or
benign) and radiotherapy can also lead to inconti-
nence. Therefore, a careful surgical history should be
taken and specific attention should be given to pain
and other neurological symptoms, especially over the
sacral nerve dermatomes, which could suggest neu-
rologic disease or an intrapelvic nerve entrapment.

Pelvic pain can also be associated with apical support
defects, endometriosis or pelvic congestion syn-
dromes. The latter two can be associated with neuro-
genic urgency, depending on localization of lesions and
varicosities, and require specific approaches.

Anorectal dysfunction, such as anal incontinence and
obstructed defecation must also be carefully as-
essed and treated simultaneously, as these symp-
toms are strongly associated with urinary inconti-
nence and may share a common aetiology and be as-
associated with a pelvic support defect.

A careful surgical history should be taken, especially
for pelvic surgery and other continence procedures,
as the former can disrupt the endopelvic fascia (102)
or result in intrapelvic nerve entrapment, thus gener-
ating secondary UUI (103) (104, 105). For recurrent
SUI, there seems to be a trend for better results with
retropubic and/or adjustable slings; however, there is
still not enough data to recommend or refute any of
the different management strategies for recurrent or
persistent stress incontinence after failed suburethral
tape surgery (105).

3. SYMPTOM ASSESSMENT

As classification of Urinary incontinence is clinical, a
careful symptom assessment is mandatory and it is
particularly important to plan the appropriate treat-
ment. Furthermore, it is important to quantify the de-
gree of leakage before and after therapy to evaluate
the impact of the disease on quality of life, and to iden-
tify patients with complicated incontinence that
need to be referred for specialised management (87).
To achieve these objectives there are several tools
including history and clinical assessment together
with validated questionnaires, voiding diaries and pad
tests. Many validated questionnaires have been de-
veloped to assist in the evaluation of urinary symp-
toms and to help in diagnosing the type of urinary in-
continence (89-93). They may be used in combina-
tion with history and clinical examination. The Inter-
national Consultation on Incontinence (ICI) has de-
veloped an ICI questionnaire (ICIQ) to assess pelvic
floor function in both clinical practice and research
settings (106, 107). It includes many modules about
both female and male urinary symptoms or pelvic
dysfunctions in particular urinary incontinence (ICIQ-
UI). Franco et al (108) and Karantanis et al(109) showed that the short form (ICIQ-SF) correlates well
with the 1-hour and 24-hour pad test for evaluation of
the severity of SUI. The severity of SUI seems to be
correlated to Intrinsic sphincter deficiency, although
the diagnosis is possible only by urodynamic study
(Urodynamic valsala leak point pressure (VLPP) <
60 cm water believed to be diagnostic) (110).

The Modified Gaudenz-Incontinence questionnaire
increases the likelihood of accurately diagnosing both
stress and urge incontinence, however this question-
naire is validated only in the Japanese language (16)
, while the Bladder Instability Discrimination Index
(91) and Versi’s questionnaire (111), although useful
to diagnose urgency and stress incontinence, are
complex and sometimes not easily used in the practical clinical setting. The patient-completed Questionnaire for Urinary Incontinence Diagnosis (112) contains 6 questions, of which 3 are intended to predict stress incontinence and 3 are intended to predict urgency incontinence. It appears to increase the likelihood of correctly diagnosing urgency incontinence (positive LR, 3.7; 95% CI, 1.6-9.0; negative LR, 0.27; 95% CI, 0.17-0.42), but is not as helpful in the diagnosis of stress incontinence (positive LR, 2.8; 95% CI, 1.6-4.9; negative LR, 0.21; 95% CI, 0.12-0.37) (16). The Urogenital Distress Inventory (113), that is a widely used symptom tool, is a questionnaire helpful to assess LUTS bother, including incontinence, in women. The Questionnaire for Urinary Incontinence Diagnosis is a reliable 6-item questionnaire able to diagnose stress urinary incontinence and urgency urinary incontinence in a referral urogynecology patient population with accuracy (93). Overactive bladder symptom scores are also very useful for women with storage symptoms including urgency incontinence (32) (34-42) (114) (115).

4. PHYSICAL EXAMINATION (FEMALE)

The main objective of physical examination is to detect signs, defined as any abnormality indicative of disease or a health problem, detectable on examination of the patient; an objective indication of disease; or a health problem. No studies were found to support evidence that clinical examination improves care for diagnosing the type of urinary incontinence (UI) in women. Nonetheless, there is a wide consensus recommending clinical examination as an important part of assessment women with UI, including: abdominal, neurological, gynaecological and pelvic examination, with the purpose of detecting associated or underlying pathology that may explain lower urinary tract symptoms (LUTS). Height and weight should be recorded so that the body mass index can be calculated (Kg/M2) as obesity is an important risk factor for UI (112, 115, 116).

a) Abdominal examination. Observation of the abdomen may yield evidence of scars from previous surgery or abdominal striae. Increased abdominal striae may be found in association with other markers of abnormal collagen metabolism, and are more likely in patients with prolapse and stress incontinence (117, 118).

Bladder fullness or retention may be identified by abdominal palpation or by suprapubic percussion. In one study designed to look at the clinical utility of basic assessment in elderly women, palpable enlargement indicated a post-void residual volume of at least 300ml (119). Other abdominal masses or abdominal distension (e.g. ascites) can also be detected by abdominal examination. Tenderness or a mass in the renal area must be excluded by examination.

b) Neurological examination. Neurological signs related to S2-4 can suggest a possible neurogenic lower urinary tract or pelvic floor dysfunction. Saddle anesthesia will occur with lesions affecting S2-S4. Assessment of gait, abduction and dorsiflexion of the toes (S3) and sensory innervation to the labia minora (L1-L2), sole and lateral aspect of the foot (S1), posterior aspects of the thigh (S2), and cutaneous sacral reflexes bulbocavernosus and anal reflexes) are additional features of the neurological exam that may be assessed. A rectal examination will provide a subjective assessment of resting and voluntary anal tone (S2-S4). For patients with possible neurogenic lower urinary tract dysfunction, a more extensive neurological examination is indicated. In the elderly, full cognitive and mobility assessments are also recommended. An evaluation of hand dexterity should be performed when self-catheterisation is being considered as a treatment option for incontinence associated with chronic urinary retention.

c) Gynaecological examination (vulva and vagina). There are few scientific data documenting the parameters of a normal pelvic examination in women of various ages and with various obstetrical histories. The components of the examination have not been universally agreed upon. Gynaecological examination should include: inspection of the vulva, perineum and vagina, as well as vaginal palpation, with the evaluation of pelvic floor muscle tone, muscle mass and defects. The location of any vaginal pain should be noted and any tenderness over the course of the pudendal nerve. Bimanual pelvic examination is also part of the gynaecological examination, with the assessment of the size, location, and mobility of the uterus and the adnexal structures. Palpation of any pelvic mass or unusual tenderness is possible by vaginal examination together with suprapubic palpation.

Vulval inspection allows a description of the skin and the presence of any abnormal anatomical features (atrophic changes, scars, erythema of the vulva, lichen sclerosis, cysts, other tumors). With inspection of the external genitalia a urethral caruncle may be noted (a small, soft, smooth friable red outgrowth along the edge of the urethra) or urethral mucosa prolapse (smaller eversion of the urethral urothelium, generally involving the posterior lip).

Another important aspect of the examination is the observation of the perineal movement when the patient is asked to cough or Valsalva. This is a way to evaluate the pelvic floor muscles function. We can observe a perineal elevation as the inward (cephalad) movement of the vulva, perineum, and anus and a perineal descent as an outward (caudal) movement of the vulva, perineum, and anus. During cough or Valsalva maneuver the perineum should show a ventral movement due to the contraction of the pelvic floor muscles; a downward movement might indicate a weak pelvic floor.

With vaginal examination we obtain information of the vaginal length and mobility, presence of scarring.
and/or pain, and level of oestrogenisation. Vulvar and vaginal atrophy (VVA) is a common condition and is a consequence of reduced oestrogenisation of urogenital tract that results in a loss of vaginal elasticity, dryness, decreased lubrication, with associated irritation, dyspareunia, and urinary symptoms (120). Vaginal atrophy can be treated with vaginal estrogen application and this should be considered as an adjunctive treatment in the management of common pelvic floor disorders in postmenopausal women (121, 122)

A urethral diverticulum presenting as a palpable suburethral mass, can also be detected on vaginal examination. The most common finding is a tender anterior vaginal wall mass and if the sacculation communicates with the urethra, it may be possible to express a purulent exudate from the urethra. Occasionally, a stone may develop within the diverticulum. Many patients with urethral diverticula are asymptomatic and need no treatment although symptomatic patients report swelling of the urethra, recurrent cystitis, dyspareunia, urinary incontinence, urinary dribbling after passing urine and voiding difficulties (123-125). Rectal examination. Anal sphincter tone and strength can be classified as good or poor, in the absence of any quantitative assessment. Ano-rectal abnormalities can be found by inspection and digital examination; hemorrhoids, fissure, intussusception; rectovaginal or anocutaneous fistula or tumor. Anal sphincter tear may be recognized as a clear “gap” in the anal sphincter. The presence or absence of fecal impaction may also be assessed.

d) Rectal examination. Anal sphincter tone and strength can be classified as good or poor, in the absence of any quantitative assessment. Ano-rectal abnormalities can be found by inspection and digital examination; hemorrhoids, fissure, intussusception; rectovaginal or anocutaneous fistula or tumor. Anal sphincter tear may be recognized as a clear “gap” in the anal sphincter. The presence or absence of fecal impaction may also be assessed.

e) Specialised tests for diagnosis UI in Women

Three special manoeuvres can be performed during the initial assessment of women with urinary incontinence: the stress test, the Q-tip test, and the pad test.

Stress Test. The stress test involves observation for urine loss when women, with a full bladder, are coughing forcefully or during a Valsalva manoeuvre. If the patient leaks with the onset of the cough and terminates with its cessation, the test is positive and confirms stress incontinence. It is an easy test to perform in a single visit and the results are immediately available. The stress test performed with coughing appears to be reliable. Reliability data are not available for tests performed using the Valsalva manoeuvre. This procedure can be performed while the patient is in the lithotomy position, if no leakage is observed, the test should be repeated in standing position [2]. A negative supine cough test does not exclude incontinence. Rimstad et al found that in the supine position only 49% of the women leaked during the stress test (126). Earlier studies have also found that the supine cough test has low sensitivity (127). A positive stress test is helpful in diagnosing the type of urinary incontinence. When stress incontinence is suspected by the symptoms, the cough stress test is the most reliable clinical assessment for confirming the diagnosis (128). When compared with multichannel urodynamic studies, the cough stress test demonstrates good sensitivity and specificity for stress incontinence (129-131). A detrusor contraction may occasionally cause leakage during a stress test and thus the possibility of a detrusor overactivity. Kulseng-Hanssen et al have demonstrated that only 5 of 100 stress and mixed incontinent women had a detrusor contraction simultaneously with stress leakage, and in none was detrusor over-activity the sole cause of leakage (132). Lagro-Janssen et al noted that the presence of urgency incontinence in the absence of stress incontinence excluded the possibility of SUI and had a high specificity for the diagnosis of detrusor overactivity (DO) (133). Holroyd- Leduc et al. reviewed existing evidence on the diagnostic accuracy of the stress test for stress urinary incontinence (16). Results from the meta-analysis revealed that a positive stress test increases the likelihood of a diagnosis of stress urinary incontinence (summary LR, 3.1; 95% CI, 1.7-5.5), while a negative test result decreases the likelihood (summary LR, 0.36; 95% CI, 0.21-0.60).

The main limitations of this test is the variability in the intensity of cough and bladder volume. However, in women complaining of stress urinary incontinence, cough stress test is important as an objective measure to confirm the diagnosis, particularly when surgical treatment is planned.

Pad test. A pad test it is a non-invasive diagnostic tool, involving the continuous wearing of a containing pad for a set period of time. The objective of pad testing is to quantify the volume of urine lost by weighing a perineal pad before and after some type of leakage provocation. It is as an optional test for the evaluation of urinary incontinence, to distinguish continent, from incontinent women, but is not diagnostic of the type of urinary incontinence (134, 135). Holroyd-Leduc et al. reported that a positive pad test increases the likelihood of an incontinence problem (LR, 3.3; 95% CI, 2.0-5.4), while a negative pad test makes an incontinence problem much less likely (LR, 0.11; 95% CI, 0.05-0.27) (16). Price and Noblet have demonstrated that in women with symptoms of predominant stress urinary incontinence, the cough stress test is more reliable than the pad test (131). Pad tests can be divided into short term tests, usually performed under standardized office conditions, and long-term tests, usually performed at home for 24–48 hours. Pad tests are generally performed with a full bladder or with a fixed known volume of saline instilled into the bladder before beginning the series of exercises. Only the “1 hour pad test" has been standardized by the International Continence Society (ICS-pad test) (136). This short test is appropriate in routine evaluation of patients during initial evaluation, however it can be affected by many factors, if either the patient or physician have doubts about the accuracy of the initial test, evaluation should be extended by an additional hour or repeated. The 24-hr test is more reproducible than a 1-hr test, but longer testing requires more preparation and a greater commitment on the part of the patient. A pad weight gain >1 g is considered positive.
for a 1-hour test, and a pad weight gain >4 g is positive for a 24-hour test. These values may need to be modified in situations of increased perspiration (137). There is wide variation in the pad weight gain in incontinent women participating in clinical trials. Although some studies have found high test-retest correlations in pad tests (136, 138), some other studies have reported low inter-subject and intra-subject reliability (139, 140). The correlation coefficient between total leakage during two long-term tests appears to exceed that of a standard 1-hour test (141, 142).

A pad test is a good instrument for evaluating severity of urinary incontinence, however, it is not a perfect "gold standard" for UI severity. A pad test should always be interpreted in conjunction with standard self-assessment questionnaires including the bother index. In the analysis of 1-hr pad test, an increase of 1–10 g is classified as representing mild incontinence, 11–50 g moderate and >50 g severe incontinence. Good correlation has been reported by Abdel-Fattah et al. between the self-assessment questionnaires and the 1-hr pad test (141). The King's Health Questionnaire showed a 96% sensitivity and 93% specificity of a 1-hr pad test in identifying incontinent patients(141). The good correlation between self-assessment questionnaires and 1-hr pad test, but not the 24-hr pad test supports the value in standardization. In addition there is also good correlation between the 24-hr pad test and the International Consultation on Incontinence Questionnaire—Short Form (ICIQ-SF) (109). The values for 24-hr pad test are classified as follows: Mild (4–20 g/24 hr), moderate (21–74 g/24 hr), and severe (>75 g/24 hr) incontinence (143). However these values have to be considered with caution and they may change depending on the sample characteristics (eg, proportion of women with more severe incontinence, etc.). In another study comparing pad-weighing test with the Incontinence Severity Index (ISI), the mean padweights (grams per 24 hours, 95% confidence intervals), were: 7 for slight, 39 (26-51) for moderate, 102 (75-128) for severe, and 200 (131-268) for very severe UI. Spearman's correlation coefficient for pad weighing results and severity index was 0.58 (p < 0.01), and bother increased significantly with increasing severity (144).

The main limitation of the pad test as a diagnostic tool for UI is the value for the cutoff of a positive test and the inability to distinguish between types of incontinence. This limitation is especially important when this test is used as an outcome measure, when surgical treatment of stress urinary incontinence is evaluated, as these women can suffer "de novo" urgency urinary incontinence.

Q-tip test. Stress urinary incontinence (SUI) may be classified based on urethral mobility. Urethral hypermobility is associated with greater surgical success after suburethral sling placement. Assessment of urethral mobility is an essential part of pelvic examination in women with symptoms of SUI, especially when surgery is planned. The Q-tip test has traditionally been used to assess the mobility of the urethro-vesical junction. The test involves placement of a lubricated cotton swab or Q-tip in the urethra to the level of the bladder neck while the woman is in the lithotomy position. The degree of rotation of the free end of the swab is then measured while the woman performs a Valsalva manoeuvre. The free end should remain horizontal if no anatomical defect is present. If the free end moves above the horizontal, urethral hypermobility is suspected, this can occur in patients with stress urinary incontinence. A straining angle of 30° or greater relative to the horizontal during Valsalva or cough has been considered clinically relevant and defined as hypermobility (145, 146). In a meta-analysis by Holroyd-Leduc et al. that examined the accuracy of the Q-tip test for diagnosing stress urinary incontinence, only two relevant studies met the inclusion criteria(16). Results of the analysis suggested that a positive Q-tip test does not accurately predict the diagnosis of stress urinary incontinence in women.

Although the Q-tip test is a useful tool, it may be uncomfortable for many women due to the insertion of a rigid cotton tipped swab into the urethra. The identification of visual examination tool to determine urethral hypermobility would help to eliminate this uncomfortable test. A study has compared the diagnostic accuracy of the Q-tip test with visual urethral mobility examination (VUME) and concluded that VUME is a diagnostic alternative to Q-tip test for the initial assessment of urethral hypermobility when performed by an experienced operator and is preferred by women(147). A recent publication comparing a vaginal swab test with the urethral Q-tip test has demonstrated that the vaginal swab test, with a cotton-tipped swab placed in the vagina 3 cm proximal to the external meatus in the midline at rest, is equivalent to the standard Q-tip test in measuring urethral mobility with less discomfort for patients (148).

Another noninvasive method to identify women with urethral hypermobility is translabial ultrasound (149, 150). This more specialised testing with pelvic floor ultrasound and other imaging techniques appears to be gradually replacing the Q-tip test for a more advanced assessment of bladder neck hypermobility, however they are limited to their cost, availability and special training required.

## 5. PELVIC ASSESSMENT: PELVIC FLOOR STRENGTH AND PELVIC ORGAN PROLAPSE

### 5.1. Assessment of Pelvic Floor Muscle Strength

Pelvic floor muscles (PFM) play an important role in continence and support of the pelvic organs. Voluntary pelvic floor muscle contraction and relaxation should be evaluated during the initial assessment. Pelvic floor muscle function can be clinically as-
sessed by several different methods, including inspection, visual palpation, ultrasound, electromyography (EMG), dynamometry and manometry (151-154).

Due to the location of the PFM inside the pelvis, the evaluation of the PFM function is difficult only by observation. Vaginal palpation is an accepted method to evaluate muscle tone and strength and is perhaps the most accessible and valid measure of PFM function (155, 156). PFM contractility measured by digital vaginal palpation can be scored according to the Modified Oxford Scale (MOS)(157). According to the joint guidelines published by IUGA/ICS in 2010, pelvic floor muscle strength is qualitatively defined by the tone at rest and the strength of a voluntary or reflex contraction as strong, normal, weak or absent, or by a validated grading symptom (2). Any or all of the following factors can be assessed including muscle strength (static and dynamic), voluntary muscle relaxation (absent, partial, complete), muscular endurance (ability to sustain maximal or near maximal force), repeatability (the number of times a contraction to maximal or near maximal force can be performed), duration, coordination, and displacement. If possible, it is desirable to document findings for each side of the pelvic floor separately to allow for any unilateral defects and asymmetry. The ICS report into the standardization of terminology of pelvic floor muscle function and dysfunction (158) classifies the pelvic floor muscles according with the ability to contract in:

a) Normal pelvic floor muscles: Pelvic floor muscles which can voluntarily and involuntarily contract and relax.

b) Overactive pelvic floor muscles: Pelvic floor muscles which do not relax, or may even contract when relaxation is functionally needed, for example, during micturition or defaecation.

c) Underactive pelvic floor muscles: Pelvic floor muscles which cannot voluntarily contract when this is appropriate (155).

d) Non-functioning pelvic floor muscles: Pelvic floor muscles where there is no action palpable.

The morphology and integrity of the pelvic floor muscles, including the puborectalis muscle, may be also assessed by palpating its insertion on the inferior aspect of the os pubis. If the muscle is absent 2–3 cm lateral to the urethra, i.e., if the bony surface of the os pubis can be palpated as devoid of muscle, an “avulsion injury” of the puborectalis muscle is likely (159). This finding is significantly associated with a reduction in MOS, as disconnection of a muscle from its insertion results in functional impairment. Studies in symptomatic women have showed an association between avulsion and reduced contractile strength (160, 161). All these studies demonstrated that MOS grading is strongly associated with subjective and objective measures of pelvic floor dysfunction, both clinically and sonographically, however it appears that MOS obtained by simple digital palpation might be a more valid measure of PFM contractile function than ultrasound measures of tissue displacement (154, 162).

5.2. Assessment of Pelvic Organ Prolapse

Assessment of pelvic organ prolapse described in this section is in accordance with the joint guidelines produced by IUGA/ICS in 2016 (163, 164). Pelvic organ prolapse (POP) as a sign is defined as the descent of one or more of the anterior vaginal wall, posterior vaginal wall, the uterus (cervix) or the apex of the vagina (vaginal vault or cuff scar after hysterectomy). Urinary incontinence and pelvic organ prolapse are separate clinical entities that often coexist. It is important to assess pelvic organ prolapse in a woman with incontinence, because repair of one pelvic support defect without repair of concurrent symptomatic pelvic support defects can predispose to accentuation of unrepaird effects and new symptoms. Significant pelvic organ prolapse can obstruct voiding and defaecation. The term stress incontinence on prolapse reduction (occult or latent stress incontinence) describes the development of stress urinary incontinence after the reduction of co-existent prolapse by surgical repair or pessary insertion (163, 164). The presence of any sign of POP should be correlated with relevant POP symptoms, commonly this correlation would occur when the prolapsed organ reaches the level of the hymen or beyond (165, 166). All examinations for pelvic organ prolapse should be performed with an empty bladder (and if possible an empty rectum). An increasing bladder volume has been shown to restrict the degree of descent of the prolapse (167). The choice of the woman's position during examination, e.g. left lateral (Sims), supine, standing or lithotomy is that which can best demonstrate POP in that patient and which the woman can confirm as the maximal extent she has perceived e.g. by use of a mirror or digital palpation (168). The degree of prolapse may be worse after a lengthy time in the upright position.
Pelvic organ prolapse staging. Each aspect of POP, uterine (cervical) prolapse, anterior vaginal wall (compartment), posterior vaginal wall (compartment), vaginal vault (cuff scar) prolapse can and should be subject to a clinical staging. The hymen always remains the fixed point of reference for prolapse description. According with the IUGA/ICS guidelines for POP in 2016 (163, 164), the following stages are considered:

Stage 0: No prolapse is demonstrated.

Stage I: Most distal portion of the prolapse is more than 1 cm above the level of the hymen.

Stage II: Most distal portion of the prolapse is situated between 1 cm above the hymen and 1 cm below the hymen.

Stage III: The most distal portion of the prolapse is more than 1 cm below the plane of the hymen but everted at least 2 cm less than the total length.

Stage IV: Complete eversion or eversion at least within 2 cm of the total length of the lower genital tract is demonstrate.

Uterine/cervical prolapse: Observation of descent of the uterus or uterine cervix.

Anterior vaginal wall (compartment) prolapse: Observation of descent of the anterior vaginal wall (compartment). Most commonly this might represent a bladder prolapse (cystocele). Higher stage anterior vaginal wall prolapse will generally involve descent of uterus or vaginal vault (if uterus is absent). Occasionally, there might be an anterior enterocele (hernia of peritoneum and possibly abdominal contents), most commonly after prior hysterectomy or reconstructive surgery.

Posterior vaginal wall (compartment) prolapse: Observation of descent of the posterior vaginal wall. Commonly, this would represent rectal protrusion into the vagina (rectocele). Higher stage posterior vaginal wall prolapse after prior hysterectomy will generally involve some vaginal vault (cuff scar) descent and possible enterocele formation. Enterocele formation can also occur in the presence of an intact uterus.

Vaginal vault (cuff scar) prolapse: Observation of descent of the vaginal vault (cuff scar after hysterectomy.

Pelvic organ prolapse quantification (POP-Q). The need for an objective, site-specific method of quantifying and staging POP led to the design and validation of the POP-Q system. The original description of the POP-Q was by Bump et al in 1996 and is shown in figures 1, 2 and 3 (169). This standardised system, which represents a reliable and internationally accepted tool for describing the anatomic position of the pelvic organs, has been validated in the dorsal lithotomy, standing, upright and lateral position (170-172).

Figure 1: The six sites (Aa, Ba, C, D, Bp and Bp), the genital hiatus (gh), perineal body (pB) and total vaginal length (TVL) used cm above or proximal to the hymen (negative number) or cm below or distal to the hymen (positive number) with the plane of the hymen being defined as zero (0). Alternatively, a three by three grid can be used to organize concisely the measurements as noted in Figure 2.

Figure 2: Grid presentation of POP-Q measurements

The POP-Q records defects relative to the hymeneal remnants in centimetre gradients. These measurements are further staged according to the most distal defect. The POP-Q system for POP considers the anatomic position of six defined points (two on the anterior vaginal wall, two in the superior vagina, and two on the posterior vaginal wall) measurement are in centimetres (cm) above or proximal to the hymen (negative number) or cm below or distal to the hymen (positive number), with the plane of the hymen being defined as zero (0). For example, a cervix that protruded 3 cm distal to the hymen would be +3 cm. All...
points are measured on maximal straining (except total vaginal length). The POP-Q as a system for quantitative prolapse description defines also other landmarks and measurements: The genital hiatus (GH) is measured from the middle of the external urethral meatus to the posterior margin of the hymen. The total vaginal length (TVL) is the length of the vagina (cm) from posterior fornix to hymen when Point C or D is reduced to its full normal position. The perineal body (PB) is measured from the posterior margin of the hymen to the mid-anal opening.

Anterior vaginal wall prolapse is defined as descent of the anterior vagina so that the urethra-vesical junction (a point 3cm proximal to the external urinary meatus) or any anterior point proximal to this is less than 3cm above the plane of the hymen. On vaginal examination, there is a loss of the transverse crease between the lower and middle thirds of the anterior vaginal wall and descent of the anterior vaginal wall. Anterior vaginal wall prolapse may represent unilateral or bilateral detachment of the pubocervical fascia allowing protrusions of the small bowel (enterocele) and/or rectum (rectocele). Normally, the anterior vaginal wall lies upon the posterior vaginal wall. For example, distal loss of support in the posterior segment may result in a bulge that compresses the urethra and bladder that lie upon the anterior vaginal wall. Point Ap is located in the midline of the anterior vaginal wall three (3) cm proximal to the hymen. By definition, the range of position of Point Ap relative to the hymen is −3 to +3 cm.

Point Ba that represents the most distal (i.e., most dependent) position of any part of the upper anterior vaginal wall from the vaginal cuff or anterior vaginal fornix to Point Aa. By definition, Point Ba is at −3 cm in the absence of prolapse and would have a positive value equal to the position of the cuff (Point C) in women with total uterine prolapse or post-hysterectomy vaginal eversion.

Prolapse of the apical segment of the vagina is defined as any descent of the vaginal cuff scar (after hysterectomy) or cervix, below a point that is 2cm less than the total vaginal length above the plane of the hymen. In some women, the intravaginal portion of the cervix may become elongated and cause the cervix to extend into the lower vaginal canal, simulating prolapse; however, the uterine fundus may have good support. In other women, the uterus may prolapse fully outside the hymen as uterine procidentia. Following hysterectomy, the vaginal cuff may be well supported or may prolapse fully outside the hymen, along with other vaginal segments. The two superior vaginal points are as follows:

Point C that represents either the most distal (i.e., most dependent) edge of the cervix or the leading edge of the vaginal cuff (hysterectomy scar) after total hysterectomy.

Point D that represents the location of the posterior fornix in a woman who still has a cervix. It is included as a point of measurement to differentiate suspensory failure of the uterosacral-cardinal ligament "complex" from cervical elongation. When the location of Point C is significantly more positive than the location of Point D, this is indicative of cervical elongation which may be symmetrical or eccentric. Point D is omitted in the absence of the cervix.

Posterior vaginal wall prolapse is defined as any descent of the posterior vaginal wall so that a midline point on the posterior vaginal wall 3cm above the level of the hymen or any posterior point proximal to this, less than 3cm above the plane of the hymen. Posterior protrusions into the vaginal canal are most commonly caused by defects in the recto-vaginal fascia allowing protrusions of the small bowel (enterocele) and/or rectum (rectocele). Normally, the anterior vaginal wall lies upon the posterior vaginal wall. Therefore, protrusions of the posterior vaginal wall can affect the function of the urethra and bladder that lie upon the anterior vaginal wall. For example, distal loss of support in the posterior segment may result in a bulge that compresses the urethra and affects voiding. The two posterior vaginal wall points are as follows:

Point Ap is located in the midline of the posterior vaginal wall three (3) cm proximal to the hymen. By definition, the range of position of Point Ap relative to the hymen is −3 to +3 cm.

Point Bp represents the most distal (i.e., most dependent) position of any part of the upper posterior vaginal wall from the vaginal cuff or posterior vaginal fornix to Point Ap. By definition, Point Bp is at −3 cm in the absence of prolapse and would have a positive value equal to the position of the cuff in women with total post-hysterectomy vaginal eversion.

The POP-Q system has not been widely adopted in clinical practice particularly by non-urogynaecologists; owing somewhat to difficulty in learning the assessment (173, 174). A simplified version of the POP-
of the POP-Q, reproducibility and reliability of the assessment system have been demonstrated (178, 179). Hall et al demonstrated that the examination could be completed within four minutes by new learners and two minutes by clinicians experienced with the assessment (70). With experienced practitioners, POP-Q staging performed using the measurement technique and estimation based on clinical examination are not significantly different (180). Parnell et al have described a POP-Q model in order to teach the technique and estimation based on clinical examination (181). Despite the difficulties highlighted with the adoption of the POP-Q, reproducibility and reliability of the assessment system have been demonstrated (178, 179). Hall et al demonstrated that the examination could be completed within four minutes by new learners and two minutes by clinicians experienced with the assessment (70). With experienced practitioners, POP-Q staging performed using the measurement technique and estimation based on clinical examination are not significantly different (180). Parnell et al have described a POP-Q model in order to teach the POP-Q examination (181).

The relationship between anatomical defects measured by the POP-Q and lower urinary tract symptoms or other pelvic floor symptoms in women with pelvic floor disorders has been investigated and the symptom feeling of a bulge in the vagina is the only symptom that correlated with POP-Q in all vaginal compartments (182-185). A recent published study demonstrates that the sensitivity and specificity of this symptom were 60% and 83% when point Ba was 1 cm below the hymen. Whereas they were 55% and 83% when point C was 3 cm above the hymen (186).

The correlation between posterior compartment prolapse measured by POP-Q and obstructed defecation symptoms has been also investigated; the best-designed studies utilizing validated measures show a significant association between presence of posterior compartment prolapse and specific obstructed defecation symptoms, most significantly splitting, straining, and incomplete emptying (187, 188). A retrospective study by Collins et al showed that a point Bp value of >-5 on the POP-Q, was found to be strongly correlated with defaecatory dysfunction with symptoms of stool trapping and incomplete evacuation according with the CRADI-8 score (189).

The POP-Q has been used for the linguistic validation of condition specific health related quality of life questionnaires such as the Prolapse Quality of life (P-QOL) (190, 191), Pelvic Floor Distress Inventory (PFDI) (192-194), Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ12) (195), Pelvic Organ Prolapse/Incontinence Sexual Questionnaire, IUGA-Revised (PISQ-IR) (196-202), and validation of the Patient Global Impression of Improvement (PGI-I) for urogenital prolapse (202).

An advantage of the widespread adoption of the POP-Q system is the capability to compare results and surgical outcomes of different studies. The POP-Q has been used to define improvement in POP after surgical interventions in a number of studies; including vaginal mesh or abdominal mesh (203-236), laparoscopic techniques (237-240), colpoposies (241-244), sacrosinous fixation (244-246), and collagen coated mesh repairs (247-249).

The quantification of POP using the POP-Q was compared with dynamic MRI; the results showed that correlations of the anterior compartment were good to moderate, compared with central and posterior compartment that were poor to moderate. Correlations were independent of the POP-Q staging measurements (250-253). The agreement of MRI-based POP staging with the POP-Q is excellent, but the added clinical value is questionable due to poor association with clinical findings and pelvic floor symptoms (251). The relationship between clinical assessment of female pelvic organ prolapse using the POP-Q and dynamic 2D transperineal ultrasound (TPUS) has been also investigated. It was observed that the accuracy of pelvic floor US staging was limited and that clinical assessment remains the gold standard (252). An observational study using POP-Q and pelvic ultrasound for the assessment of the type of cystocele, analysed the agreement between physical POP-Q and the Green radiological classification of cystocele. Kappa co-efficients ranged between 0.56-0.54 and 0.32-0.79 for clinical and ultrasound diagnosis respectively. The clinical utility of these findings has not been established (253, 254). A recent study compared clinical examination and imaging findings, especially regarding cut-offs for the distinction between normal pelvic organ support and prolapse. The conclusion was that the proposed cut-offs for ‘significant prolapse’ on ultrasound and POP-Q (Ba >-0.5 and cystocele ≥ 10 mm below the symphysis pubis, C ≥ -5 and uterine position of 15 mm above the symphysis pubis, are plausible and mutually consistent (254, 255).

General recommendations in the female patient

A global evaluation for women is essential for an effective treatment and prevention of recurrence of UI, especially in patients with other comorbidities. Identifying and treating those symptoms are directly related to treatment success and resolution of symptoms, as well as their recurrence.

Pain and urgency must be carefully assessed, as they may indicate that incontinence can be secondary to a neurologic or other functional conditions.
Urethral mobility can be assessed using the Q-Tip test and predict success/failure of TOT.

A ring pessary test, VLPP and MUCP have been advocated to elucidate pelvic support-related incontinence/symptoms and predict the outcome of a surgical procedure, but their predictive values still need to be assessed.

VI. SPECIFIC POPULATION: EVALUATION OF THE MALE PATIENT

1. CHARACTERISTICS OF MALE LUTS

In the male population, Lower Urinary Tract symptoms (LUTS) may present with dysfunction of the storage and emptying phase as well as with post micturition signs or symptoms. These symptoms can be non-specific in presentation and are multifactorial in origin. LUTS are a progressive and age related but not sex or organ-specific. They cause significant bother and impair quality of life (256, 257). Traditionally LUTS were thought to be secondary to bladder outlet obstruction due to prostatic enlargement; however, recent scientific evidence failed to show this relationship (257). Often, LUTS are unrelated to changes in prostatic size. Current research is aimed at understanding the impact of the bladder itself in LUTS. Bladder dysfunctions, such as Detrusor Underactivity, Detrusor Overactivity and other functional abnormalities can contribute significantly to LUTS (258).

In vitro as well as in vivo animal studies show a correlation between oxidative stress and ischemia with changes in bladder contractility in animals (259, 260). LUTS are strongly associated with ageing and represent a major health burden for the patient and the society. Several epidemiological reports have demonstrated that storage symptoms (including urinary urgency and urinary urgency incontinence) defined as overactive bladder syndrome also increases with age in men. LUTS are often under-diagnosed and undertreated and still unfortunately often accepted as part of ageing. In regards to urinary incontinence, epidemiological studies have shown that obesity is an independent risk factor for incontinence. Several studies indicated that each 5-unit increase in body mass index (BMI) above normal weight is associated with a 40% to 70% increased odds of urinary incontinence in a 5 to 10 year timeframe period (296). There is a gender disparity as the correlation between obesity and urinary incontinence is higher in women, with 60 to 70% of incidence of urinary incontinence among severely obese women. Although the incidence appears lower in men, is still quite relevant, as 24% of severely obese men have urinary incontinence (261). Obesity is a potentially modifiable condition. A recent meta-analysis confirmed that weight loss is associated with a reduction on incidence and severity of urinary incontinence among women and men. Specifically, in male population, obesity appears to be more frequently associated with urgency incontinence (261).

Chronic prostatic pain syndromes (e.g. non-bacterial chronic prostatitis) and other pelvic floor dysfunctions can also present with a component of symptoms compatible with a component of symptoms compatible with storage symptoms. In younger men, primary bladder neck dysfunction is a common cause of LUTS, with or without pelvic pain. Functional abnormalities of striated sphincter relaxation may also occur in young men. The complexity of the presenting symptoms and the various differential diagnoses mandate a thorough basic assessment of the lower urinary tract in men to plan optimal therapeutic intervention.

Recent epidemiologic studies and meta-analyses confirm a high prevalence of LUTS in the community. There is an increased prevalence of LUTS with age (262). The incidence appears to be of 3.5% in men in the fourth decade of life, while in men over age of 85 the incidence is higher than 30%. These epidemiologic data are confirmed by the finding that in the time period from 1992 to 2001 there was an increase of medical treatment for male LUTS from less than 2% to more than 10%. In the same timeframe, there was also an increase in the time between the first diagnosis of LUTS and the time to surgery. The Multi-national Survey of the Aging Male (MSAM-7) surveyed over 12,000 men age 50 to 80 in major countries of Western Europe and USA (297). Across all countries, prevalence increased from 22% in men aged 50–59 years to 45% in men aged 70–80 years. 31% of men reported moderate-to-severe LUTS (34% in the USA and 29% in Europe). Interestingly, despite the fact that 19% of men with LUTS present with complaints, only 10% received and appropriate medical treatment (263).

Based on the Integrated Health Care Information Solutions (IHCIS) database, LUTS are among the most frequent reasons for medical consultation among the male population over 50. The fourth most common diagnosis in this population is BPH, after coronary artery disease, hyperlipidemia, hypertension and diabetes mellitus (264).

LUTS have a significant impact on quality of life but also on potentially life-treating conditions such as falls in elderly population. As reported by Parsons et al. moderate and severe LUTS independently increase the 1-year risk of falls, particularly recurrent falls, in community-dwelling older men (265). In their study of 5,872 participants in the Osteoporotic Fractures in Men study were assessed for LUTS, using the AUA symptom score. Patients with moderate LUTS were found to have 11% higher risk of at least one fall, while the risk of fall increased to 33% in subjects with severe LUTS (265). Falls in the elderly population...
might have serious consequences and screening elderly patients for LUTS by primary care providers should be assessed routinely.

2. MALE INCONTINENCE

Improvement in early detection of prostate cancer has led to an increase of men treated for this condition. The rate of post-prostatectomy incontinence (PPI) is difficult to determine because of the varying definitions of incontinence, but approximately one in five men require the use of pads in the long term after radical prostatectomy (RP)(266). Incontinence has a significant negative impact on quality of life. This potential complication is also patients’ greatest fear, especially in the youngest subset of patients (65 years or younger), requiring RP(267). Robot-assisted laparoscopic prostatectomy (RALP) was introduced with the aim of improving surgical outcomes, but controlled or randomized studies on the long-term effects are few and present knowledge of effectiveness is based mainly on case series or registry data(268).

The Swedish LAP PRO trial brings some very useful insights into answering the question of true incidence of PPI and whether there are any differences across techniques. In summary, this trial focused on the primary end point of urinary incontinence 12 months after RALP, as reported by the patients (to reduce the potential bias of Surgeon-Patient relationship)(269). Notably, this study recruited only patients for high volume surgeons, those with more than 100 procedures done, to avoid the bias of the single surgeons learning curve. The study recruited 4000 patients and the final analysis included 2625 patients. 778 patients underwent an open retropubic radical prostatectomy (RRP) and 1847 underwent RALP. The study showed that patients classified as having urinary incontinence ranged from 20% to 56% after RRP and from 21% to 57% after RALP. The percentage of incontinence was even higher if a definition of dryness was combined with no use of pads and zero leaks(269).

Catalona et al. showed that incontinence after prostate surgery was primarily dependent on the age of patients(270). The older the patient, the more likely he is to be incontinent and to never regain urinary control. For 40-49 year olds only 3% (12/358) had long term incontinence but that increased to 8% (48/632) in 50-69 year olds 8% (48/632) and 13% (38/282) in men over age 70; for an overall prevalence of 7.7%(270).

Special consideration is needed for irradiated patients as the success rate and incidence of post-incontinence surgery differ significantly from non-irradiated patients. The revision rate of Artificial Urinary Sphincter (AUS) surgery, a procedure done for PPI, was significantly higher in irradiated versus non-irradiated men (mean 37.3 versus 19.8%; p < 0.007) after a mean follow-up of 38.4 months(271). Revision is typically performed for infection, erosion or urethral atrophy. Persistent urinary incontinence was also more than twice as likely in irradiated versus non-irradiated men (29.5 versus 12.1%; P = 0.003) with an odds ratio of 2.08(271). Radiation induced changes involving the bladder neck and urethral tissue, such as fibrosis, are considered to be the primary etiology for the development of incontinence. Surprisingly, the timing of radiation therapy does not seem to have any influence on the incidence of urinary incontinence. Similar rates of incontinence are reported in early and late radiation therapy after radical prostatectomy. Sowerby and colleagues reported the incidence of urinary incontinence to be 24.5% in men who underwent radiation less than 6 months from surgery and 23.3% in men with radiation greater than 6 months after prostatectomy(271).

Urgency incontinence is a failure of bladder storage usually due to the underlying pathology of detrusor overactivity (DO). Urgency incontinence commonly presents as part of the overactive bladder (OAB) syndrome. OAB is described as urinary urgency, with or without urgency incontinence, usually with frequency and nocturia, in the absence of infection or other obvious pathology [1]. In men, OAB symptoms often coexist with emptying phase LUTS. Men with emptying phase LUTS such as poor flow and hesitancy are often assumed to have benign prostatic obstruction, though research has shown they may not.

3. SYMPTOM ASSESSMENT

Symptom assessment in men with incontinence should identify and exclude patients with complicated incontinence, who need to be referred for specialised management. Complicated incontinence comprises patients with recurrent incontinence after failed previous surgery, with total urinary incontinence, and/or with associated symptoms such as pain, haematuria, recurrent urinary tract infection, voiding symptoms, and/or a history of previous pelvic radiotherapy or radical pelvic surgery(272).

Because the occurrence of LUTS in men does not necessarily indicate concomitant prostate enlargement and/or obstruction, specific modalities should be used to ascertain the potential for the aetiological role of these entities. A variety of symptom scores have been described to assess male patients with LUTS. It is important that symptom scores have a wide applicability across a number of different cultures and languages. Ideally, symptom scores should also help to determine the underlying etiology of LUTS (for example, BOO, DO, impaired detrusor contractility); however, this is made difficult by the fact that different conditions can produce similar or even identical symptoms. Each symptom score has advantages and disadvantages, but it is clear that the worldwide use of such scores has helped in evaluating symptoms, treating patients, and communicating findings globally. Symptom scores have been used in male LUTS for a variety of the purpose. 1) to assess
Three questionnaires with a high level of psychometric validity and reliability are the IPSS, the ICS’s ICS-male questionnaire (now known as the ICIQ-MLUTS), and DAN-PSS. Although each was designed with the same purpose, only six symptoms are common to all three, including incomplete emptying, urgency, decreased stream, frequency and nocturia.

In men, the American Urological Association symptom score for BPH (AUA-7) is most commonly used in North America for assessment of subjective symptoms. However, equally reproducible data can be obtained from the International Prostate Symptom Score (IPSS)(273), the ICSmale questionnaire (now renamed the ICIQMLUTS, long and short forms, as part of the ICIQ modular questionnaire: www.iciq.net).

The IPSS has been the most widely used (in many countries and languages), but one of the major criticisms of the IPSS is the fact that it is not disease or condition specific. In addition, it neglects the symptom of urgency incontinence, a symptom that produces significant bother. Urgency incontinence is an important symptom, particular in regard to therapeutic outcome in BPO patients. The prevalence of this symptom was also reported as common by the ICS-“BPH” study group and was higher in men with BOO than in those without (274).

ICIQMLUTS (ICSmale-SF) is slightly longer (14 questions), but takes into account the symptom of urgency incontinence, and in fact may be divided into voiding (ICS-male-VS) and incontinence (ICS-male-IS) sub-scores (275). Thus, it is particularly a questionnaire for assessment of the occurrence and bothersomeness of a wide range of LUTS in man. However, to date, it has not been as widely used as the IPSS, but may be more widespread use as part of the ICIQ Modular Questionnaire.

As the concept of OAB has become widespread, a simple symptom questionnaire to quantitatively assess OAB symptoms, the OABSS, was developed and psychometrically validated. Overactive bladder symptom scores are also very useful for male patients with storage symptoms including urgency incontinence(276, 277). Other new symptom questionnaires to assess male-LUTS include UWIN and the CLSS.

Ten LUTS (increased daytime frequency, nocturia, urgency, urgency incontinence, stress incontinence, slow urinary stream, straining, a feeling of incomplete emptying, bladder pain, and urethral pain) were selected as core symptoms from 25 LUTS defined by the ICS committee, and symptom questionnaire to assess the core symptoms we developed as the CLSS (277). Symptoms were scored according to their frequency and severity. The CLSS questionnaire was confirmed to show good test-retest reliability. The CLSS was compared with IPSS in men with LUTS, and it was suggested that the CLSS is more comprehensive than IPSS for symptom assessment of men various diseases and conditions (278). The CLSS provides overall assessment of relevant symptoms without omission, and may be useful for new patients, patients with multiple diseases, and patients without a definite diagnosis, as well as before and after intervention that may cause other symptoms.

Among LUTS, urgency, nocturia, and hesitancy are most bothersome, whereas weak stream, urgency, and frequency are the most prevalent in pooled populations being evaluated for BPH(279). Postmicturition dribbling is often provoked by an obstructing disease such as BPH or urethral stricture but can also be a symptom of a urethral diverticulum. As yet there is no validated symptom questionnaire that assessed post-micturition symptoms (post-micturition dribble and post-micturition incontinence).

To determine the cause of post-prostatectomy incontinence, many studies have stressed the lack of reliability of symptoms and emphasized the important role of urodynamic testing(280, 281). Nevertheless, valuable information can be gained from a careful history with regard to incontinence, especially when related to sphincter dysfunction. The symptom of stress incontinence is highly predictive of the presence of sphincter dysfunction. Chao and Mayo found that 67 of 71 men with post-prostatectomy incontinence secondary to sphincteric dysfunction complained of the symptom of stress incontinence(282). Similarly, Ficazzola and Nitti found 95% positive predictive value and a 100 % negative predictive value for symptom of stress incontinence(283). Urgency incontinence as a predictor of bladder dysfunction doesn’t seem to be as valuable, and the presence of bladder dysfunction cannot be determined accurately without urodynamic testing(282, 283).

An important aspect of the assessment of male incontinence should be a description of the type and severity of incontinence and precipitating events, Severity
may be determined by the number of episodes per day, the need for protection (e.g., pads, penile clamp, external catheter), and the impact of incontinence on activities of daily living. Bladder diaries and pad tests can quantify severity.

A bladder diary (or frequency volume chart) kept for 3 to 5 days may be useful in almost all male patients, especially in those with OAB. The time and voided volume are recorded for each micturition during several 24-hour periods. Bladder diary completion by the patient provides useful evidence about the normal urinary habits of the patient, including giving some estimate of bladder capacity and diurnal and nocturnal frequency, urgency and stress incontinence. It also helps to identify patients with nocturnal polyuria or excessive fluid intake which are common in the aging male. The data obtained from frequency-volume chart provide a strong correlation to cystometric capacities and are reasonably immune to the effect of detrusor overactivity in men with LUTS(284).

The 24 hour pad test is an excellent test to quantitate the amount of urine leakage in men. Since most patients use different size and type of pads, it is difficult to compare number of pad/day per patient. Furthermore, some patients are very disturbed by any leakage at all and change the pad very frequently, before they are saturated. The other distinction to be made is between a safety pad and true urinary incontinence. In general, the each 1g weight equals 1 ml urine loss. It is proposed to use a cut-off value of 250 g of urine to categorize minor from more troublesome or severe leakage(285). Recently, Machold et al. suggested that the technical feasibility of the 20-min pad test to evaluate post-prostatectomy incontinence was excellent. The results correlated significantly with both the self-assessment via questionnaire (r =0.63; p <0.001) and the 1-hour pad test (ICS; r =0.66; p < 0.001). Moreover, it was highly reliable (r = 0.74; p <0.0005) with excellent patient acceptance (286).

4. PHYSICAL EXAMINATION

The assessments focus on general physical examination, digital rectal examination (DRE) and neurological testing of the perineum and lower extremities.

In a general physical examination, specific attention should be placed on the evaluation of surgical scars, the presence or absence of a distended bladder and excoriation of the genitals secondary to urinary incontinence. Abdominal palpation should be performed to evaluate bladder distension, especially in elderly incontinent men, who may have overflow leakage due to obstruction. In patients suspected of urinary retention, post-void residual volume should be measured. The examination should also include external genitalia, location of the urethral meatus, retractability of the foreskin and evidence of congenital malformation. The evidence of urethral discharge after abdominal straining (a Valsalva manoeuvre) or coughing in either the supine or upright position should be evaluated so that the presence of stress incontinence can be ascertained.

A focused neurological examination is also highly recommended. In a patient suspected of neurogenic bladder, evaluation of perineal sensation and lower extremity neuromuscular function, and anal sphincter tone, which is often decreased in neurogenic patients is important (287). A focused neurogenic examination should also assess the patient’s general mental status and ambulatory status.

DRE should include palpation of the prostate to assess size, symmetry and consistency of the gland and its relation to the pelvic sidewall and the rectum. Enlarged, indurated and painful prostate may imply BPH, prostate cancer and prostatitis, respectively. The locally advanced prostatic cancer can also produce OAB-like symptoms including incontinence. DRE may exclude prostatic cancer, although its specificity and sensitivity is low(288). The DRE is 53% sensitive and 85% specific for identifying underlying prostate cancer when abnormalities (i.e. induration or nodule) are present(289). Furthermore, abnormal rectal tone can raise suspicion of an occult neurogenic disorder that may be contributing a patient’s symptoms. DRE tends to underestimate the true prostatic size: if the prostate feels large by DRE, it usually also is found to be enlarged by ultrasound or other measurement technique(290, 291). Prostate volume has been associated with the risk of BPH progression (292) and response to treatment (293). It has been reported that men with BPH with idiopathic detrusor overactivity showed a significantly higher incidence (54%) of intravesical protrusion of the prostate(294). This finding suggests that intravesical protrusion may in some way increase afferent impulses from the prostate and alter the stability status of the bladder. Occasionally tumors of the anal canal can be diagnosed while performing DRE of the prostate.

4.1. Urinalysis and Urine Cytology

All patients undergoing an evaluation for LUTS due to BPH should have a urinalysis performed to evaluate for UTIs or other uropathology. The most significant findings would include evidence for pyuria, bacteruria, and/or hematuria. Bladder cancer, carcinoma in situ of the bladder, urinary tract infections, urethral strictures, and bladder stones can cause OAB-like symptoms including incontinence in aged men. Although haematuria or pyuria is not universally present in those conditions, urinalysis is important to rule out these conditions. Urinalysis is not a single test; complete urinalysis includes physical, chemical, and microscopic examinations. Dipstick urinalysis is certainly convenient but false-positive and false negative results may occur. It is considered an inexpensive diagnostic test able to identify patients with urinary tract infection as indicated by the presence of leucocyte esterases and nitrites. A substantial proportion of older patients with chronic OAB-like symptoms have significant bacteriuria, sometimes accompanied by
pyuria. In men, recent urinary tract infections were associated with OAB without urgency incontinence (prevalence ratio=2.9; 95% CI: 1.6-5.0) (295). However, infection may exist in the absence of pyuria and, in the elderly population, pyuria may develop in the absence of urinary tract infection.

Microscopic haematuria can be easily identified by dipsticks because of the presence of haemoglobin. The detection of haematuria is important because the condition is associated with a 4-5% risk of diagnosing urological disorder or malignancy within 3 years.

A systemic review and economic evaluation of diagnostic tests and algorithms used to investigate haematuria concluded that the evidence based on which to determine the ideal means of investigating haematuria was insufficient (296). However, because of the high prevalence of urinary tract infection and the increase of LUTS in the presence of urinary tract infection, various guidelines on the management of patients with LUTS suggestive of BPO, and urinary incontinence, endorse the use of urinalysis in primary care management (297, 298).

Urinary cytology is also recommended in male patients with haematuria and a predominance of storage symptoms, especially with a history of smoking or other factors, to aid in the diagnosis of bladder carcinoma in situ and bladder cancer

4.2. Measurement of the Serum Creatinine

Epidemiological studies in community dwelling men have shown the absence of any association between BPO/BPE and chronic kidney disease (297, 299) suggesting that screening for renal function is not justified in male patients. Diabetes and arterial hypertension appear to be the most important causes of elevated serum creatinine in men with BPH and renal failure (297). Data from the MTOPS study showed that the risk of developing de novo renal failure in men with LUTS is low (less than 1%) suggesting that it is not necessary to monitor renal function in patients with LUTS / BPO (292). However, a study examining the association between (299) LUTS and glomerular filtration rate (GFR) in men concluded that in older men without obvious enlargement of the prostate, as LUTS became more severe, GFR fell (300).

4.3. Measurement of the Serum Prostate Specific Antigen (PSA)

In most patients, a normal DRE may be sufficient to exclude locally advanced cancer as a cause of LUTS or OAB. There is no consensus as to the measurement of prostate specific antigen (PSA) in patients with LUTS. The rationale for measuring PSA is twofold: to screen for prostate cancer (337) and to measure a parameter with prognostic value for the progression of BPH and the response to treatment (328, 329). Because prostatic cancer is one of the potential causes of LUTS or OAB in men, PSA (together with DRE) is a relatively sensitive way to exclude prostatic cancer as a diagnosis (301, 302). PSA measurement is recommended in men with LUTS and a life expectancy of over 10 years in whom the diagnosis of prostate cancer would change the management of patient’s symptoms. Given the uncertainties surrounding prostate cancer detection physicians must use clinical judgment in determining which patients should or should not undergo transrectal ultrasonography and prostate biopsy in response to a particular PSA (303).

However, it is important to understand that about 25% of men with BPH have a serum PSA greater than 4 ng/ml. Because of the overlap between serum PSA values in men with BPH and those with clinically localised prostate cancer, other parameters (PSA velocity, free/total PSA ratio, complexed PSA and PSA density) will assist diagnostic specificity (304, 305). It has been suggested that a relationship between initial PSA level and subsequent prostate cancer detection with a stepwise increase in cancer detection rate (from <1% to 58%) in patients with <1.0 ng/ml, 1.1-2.5, 2.6-4.0, 4.1-10.0 and >10 ng/ml PSA value in over 26,000 patients enrolled in a screening program (306, 307). In addition, Thompson reported data on prostate cancer prevalence from the prostate cancer prevention trial (307) confirming a stepwise increase in the risk of having a prostate cancer in patients with serum PSA from 0.5 to 4.0 ng/ml but showing the limitation of the current threshold of 4.0 ng/ml. Change of PSA threshold from 4.0 to 2.0 ng/ml has been proposed but currently no consensus exists (308).

In addition, serum PSA is a reasonable predictor of prostate volume in men with LUTS and can be used in this capacity in clinical decision making (303). It has been reported that the role of IPSS score in the assessment of BOO is questionable, and that the grade of obstruction is more related to prostate volume, PVR, and Qmax (309). It has been demonstrated that moderate-to-severe LUTS in men can result in urinary retention. The incidence of retention in men with untreated LUTS in community-based trials is 6.8 per 1000 during longitudinal follow-up of 4 years (310). If only patients with moderate-to-severe symptoms are considered, the rate of retention increases to 25 per 1000 (311). In a meta-analysis of predictors of retention in pooled groups of placebo patients from clinical trials of men with LUTS undergoing active interventions (4300 patients), Roehrborn et al. found PSA and prostate volume to be strong independent predictors of urinary retention and the need for surgery in men with LUTS followed up longitudinally in clinical trials (291, 312).

Laniado et al have also tested the hypothesis that PSA level could be used to predict the presence or absence of BOO, evaluated by pressure flow studies (313). In patients with LUTS, those with a PSA more than 4 ng/ml are significantly more likely to have some degree of BOO. Conversely patients with PSA less than 2 ng/ml have a 33% risk of BOO.
**Recommendations**

A variety of symptom scores have been described to assess patients with Male-LUTS. The IPSS, ICIQ-MLUTS, and DAN-PPS have been the most tested and were found to reproducible, valid, and sensitive for initial assessment. (Level 2). However, the IPSS neglects of symptom of incontinence.

Urinalysis is recommended in patients with male-LUTS. There are currently insufficient evidences to recommend routine measurement of serum creatinine and post-void residual urine in male patients with incontinence.

In addition to DRE, PSA measurement is recommended in selected male patients with OAB.

**Future Research**

1. Improve the understanding of the underlying pathophysiology and contributory clinical factors involved in the development and treatment of detrusor overactivity in the male patient, especially in differentiating the condition from female patients.

2. Development of simple, non-invasive, cost-effective methods to determine the contribution of bladder storage and bladder emptying abnormalities in male patients.

INTRODUCTION

The last update of the International Consultation on Incontinence report broadened the scope of this review to include all patient-reported outcomes, not just health-related quality of life. This chapter updates the previous literature reviews of Patient Reported Outcome Assessments (PROs), for lower urinary tract symptoms (LUTS) and bowel incontinence outcome measures, in addition to providing recommendations for questionnaire selection for use in clinical practice and research. In addition, this summary will review the purpose and content of the ICI questionnaire (ICIQ) modules. The expansion of this review to include all types of patient reported outcomes (PRO) is an important step in recognising the conceptual differences of various PROs each with different assessment goals. A PRO is defined as “any report of the status of a patient’s health condition that comes directly from the patient, without interpretation of the patient’s response by a clinician or anyone else”([1]1). PROs measure different aspects of disease and therapeutic impact such as: symptom frequency or symptom bother, health-related quality of life (HRQL), treatment satisfaction, or work productivity measures (Figure 1). An essential component of selecting a PRO for use is to ensure that the selected PRO is consistent with the objective of the study or clinical purpose. For example, if the goal is to assess treatment satisfaction, then a treatment satisfaction measure should be incorporated into the study design or as a clinical outcome. The matching of appropriate PRO selection with desired outcomes is critical to success when assessing PRO’s and will be reviewed further in this chapter.

Ultimately, the last decade has been one of tremendous growth in the area of PROs with influences from scientific and regulatory communities. As such, the ICI will endeavour to continually update the recommendations it offers on the basis of emerging data and published evidence based on the recommendations of the prior reviews.

1. SELECTING PRO MEASURES FOR CLINICAL TRIALS AND CLINICAL PRACTICE

How does a researcher choose which instruments are most appropriate for a particular research study and/ or clinical assessment? The following section provides general guidelines for use in conducting PRO assessments in clinical trials or other research investigations related to urinary or faecal incontinence. As there are many available PROs, it is of utmost importance to select the PRO measure that is relevant and applicable to one’s desired outcome. If an intervention is designed to reduce symptom bother, then a relevant PRO would be a symptom bother measure. Multiple PROs can be included in clinical practice or in a research study; however the designation of the PRO as a primary, co-primary, secondary, tertiary or exploratory endpoint must be noted. In addition, issues of staff and participant burden, time constraints, and resources should be considered in the selection of a PRO measure. Once it has been decided which outcomes are to be assessed it is important to choose a questionnaire that has been scientifically developed and validated. Principles of validation and questionnaires that have been validated are presented in this chapter.

“Outcomes” Claims Classification

Figure 1: Patient-Reported Outcomes Assessment Areas. Burke L, Evidence Review Branch DDMAC, FDA; DIA Workshop on Pharmacoeconomic and Quality of Life Labelling and Marketing Claims New Orleans October 3, 2000

2. SELECTING PRO MEASURES FOR RESEARCH STUDIES

2.1. Study Design

There are several protocol concerns that must be taken into account when using PRO measures in research studies, including the length of the study, the frequency of contact with the study participants, the timing of clinical assessments, the complexity of the study design, the number of participants enrolled, and participant and staff burden. The goal of the PRO assessment is to “fit” the PRO measures to the protocol without compromising either the study objective or design. For example, if the study design is complex with frequent participant contacts and multiple clinical measures, it may be necessary to keep the PRO measures at a minimum or to reduce the number of times the PRO is assessed (e.g. baseline and end of study rather than during all participant contacts) to minimise participant and staff burden. At the same time, however, PROs must be viewed as an important variable in the overall trial design and should not be devalued in the data collection process. Consequently, PRO measures cannot be altered or reduced to accommodate study design as such alterations may yield less reliable measures or may seriously diminish the integrity of the overall study design and yield useless information. Having well developed research
goals and questions regarding PROs will help to guide clinicians in the selection of measures for a study. The aim is to develop a conceptually adequate, yet practical PRO battery given the study population, the specific intervention, and the study design.

The frequency with which a PRO will need to be assessed in a research study will depend upon the nature of the condition or intervention being investigated and the expected effects (both positive and negative) of the treatment. At a minimum, as with all measurements collected in a research study, a baseline and end of study assessment should be completed. In addition, PRO assessments should be timed to match expected changes in functioning due to either the intervention, the condition or the disease itself. Timing follow-up assessments to coincide with typical patient follow-up visits, if appropriate, may also reduce the costs involved in the follow-up PRO assessments.

### 2.2. Study Population

It is critical to specify key population demographics that could influence the choice of instruments, the relevant dimensions of the PRO to be assessed, and the mode of administration. Thus, age, gender, educational level, language spoken, and cultural diversity should be carefully considered prior to selecting PRO measures. For example, a cohort of patients over the age of 70 may have more visual problems than middle-aged persons, making self-administered questionnaires potentially inadvisable. Ethnically diverse groups also require measures that have been validated across different cultures and/or languages.

In clinical trials, it is also important to consider how the disease or condition will progress and affect the outcomes of patients in the control group as it is to understand the effects of the study treatment. For example, in patients with incontinence assigned to a placebo-control arm of a study, one might expect a symptom to worsen and thus have an effect on daily functioning. The point is to select PRO measures that are sufficiently sensitive to detect changes in both the treatment and the control group patients. Use of the same measures for both groups will ensure an unbiased and comparable assessment.

### 2.3. Intervention

There are three major factors related to the intervention that are relevant to PRO assessment, and therefore require careful consideration: 1) the positive and adverse effects of treatment; 2) the time course of the effects; and 3) the possible synergism of the treatment with existing medications and conditions. It is crucial to understand how a proposed treatment can affect patient outcomes in both positive and negative ways. For example, some drug therapies may relieve LUTS but produce side effects like dry mouth or sexual dysfunction.

In addition, the time course of an intervention’s effects on PROs is also critical both in terms of the selection of measures and the timing of when PRO measures are administered to study participants. For example, in a trial comparing coronary artery bypass graft (CABG) surgery to angioplasty, an assessment of PRO one week post-intervention might lead to an interpretation that the surgical arm had worse outcomes than angioplasty for PRO since the individuals in this arm of the trial would still be suffering the effects of the surgical procedure (for instance, sore muscles and surgical site discomfort) which could overwhelm any benefits associated with CABG. However, at six months post-intervention, the benefits of CABG surgery such as, relief from angina might be more profound than the benefits received from angioplasty. Thus the timing of when PROs are assessed could influence how one interprets the benefits (or negative effects) of the interventions.

Finally, it is important to have a clear understanding of the current medications the patient population is likely to be taking prior to randomisation to the study treatment, and how these medications might interact with the trial intervention, (either a pharmacological or behavioural intervention), to influence patient outcomes.

### 3. TYPES OF PRO MEASURES

There are two types of PRO measures: generic and condition-specific. Generic measures are designed to assess outcomes in a broad range of populations (e.g., both healthy as well as ill individuals). These instruments are generally multidimensional, and assess at least the physical, social and emotional dimensions of life. An example of this type of instrument is the Medical Outcomes Study SF-36 Health Status Profile [2]. A second type of measure is condition-specific (e.g., instruments designed to assess the impact of specific diseases, conditions, age groups, or ethnic groups). Condition-specific measures can be similar to generic instruments in that they assess multiple outcome dimensions, but condition-specific measures also include items more specific to the particular condition or population being studied. Examples of condition specific instruments in urology and urogynaecology include the Incontinence Impact Questionnaire [3], the King’s Health Questionnaire [4], and the OAB-q [5].

In general, it is now common to include condition specific outcome measures in clinical trials due to their enhanced sensitivity to change and the need to minimise participant burden. Importantly, the type of instruments selected for inclusion in a research study will depend on the goals of the intervention and the specific research questions to be addressed. In practice, clinical trials that include PROs usually incorporate a combination of PRO measures most relevant to the study population and intervention, if applicable, being mindful of resource constraints and staff and participant burden.
3.1. Quality-adjusted Life Year (QALY)
Increasingly HRQL outcome measures are being used in the development of quality-adjusted life year (QALY) measures. A QALY is a universal health outcome measure applicable to all individuals and all diseases, which combines gains or losses in both life quantity (mortality) and life quality (morbidity) and enables comparisons across diseases and programs. QALYs are widely used for cost-utility analysis [6]. In the past decades, economic evaluation has been increasingly important for the decision maker to decide which treatment or intervention is more cost effective, in order to allocate limited healthcare resources soundly. Economic evaluation aims to compare interventions in terms of their costs and benefits, including their patient outcome impact. Health benefits can be quantified as QALYs which have become a standard measure and are now recommended in most of health economics guidelines as the method of choice [7]. The economic chapter contains additional information regarding QALYs, as do the following references: [8, 9].

### 4. LITERATURE SEARCH STRATEGY

For the current version of this chapter the previous literature search was updated. A number of databases were accessed, electronically, with specific search criteria, such as validation work from the period January 2006 through August, 2016. Age and gender limits were not specified. Databases used included Pub-Med/MEDLINE, and websites accessed included oab.com, proqolid.com, ncbi.nlm.nih.gov and mapi-institute.com.

The following key words were used separately and/or in combination: “urinary incontinence;”, “urinary symptoms;”, “urgency;”, “overactive bladder;”, “stress incontinence;”, “incontinence;”, “questionnaire;”, “epidemiology;”, “prostate;”, “prolapse;”, “faecal;”, “bowel;”, “anal;”, “quality of life;”, “sexual;”, “geriatric;”, “paediatric;”, “satisfaction;”, “symptom bother;”, “goal attainment;”, “screener;”, and “generic.” Questionnaires evaluated in this chapter were updated with any new information if new validation work was found. New questionnaires not in the previously updated resource tool were added to appropriate sections if they were validated and relevant with regard to the search terms specified above. Grades were evaluated for correctness, based on previous and new validation work, and modified if and when necessary to demonstrate any changes with respect to instrument validation.

### II. THE MEASUREMENT OF PATIENT- REPORTED OUTCOMES (PROS) OF INCONTINENCE, OTHER LOWER URINARY TRACT SYMPTOMS, AND BOWEL PROBLEMS

The symptom impact of urinary incontinence and other lower urinary tract symptoms (LUTS) as well as bowel problems and the treatment benefit of any modality in this field can be assessed in several ways. While taking a detailed clinical history is the most traditional method, patient-completed tools have gained more importance and proved their reliability in the symptom and outcome assessment such as voiding diaries and validated questionnaires.

Patient self-completed questionnaires or patient reported outcomes (PROs) build the basis of the patient-centered healthcare system and represent the most important clinical review of symptom impact and treatment benefit from a patient perspective [10, 11]. PROs or the synonymously used new term patient reported outcome measures’ (PROMs) provide a method for the standardised collection of data, or an objective assessment of subjective phenomena, from patients relating to incontinence, other LUTS, and bowel problems. Clinicians’ assessments of patients’ outcomes have often been shown to underestimate the degree of bother perceived by patients, and to focus on issues of lesser importance to patients [12].

### 1. BASIC DEFINITIONS AND TERMINOLOGY

It is important to understand the advances in terminology of outcome measures that are categorized in 3 groups: clinical, humanistic and economical [13]. The humanistic outcome measures may focus on role performance and emotional status, whereas economical outcomes on expenses and saving. The clinical outcomes measure cure or survival and they can be further sub-classified as clinician reported, caregiver reported, physiological (e.g. urodynamic improvement) or patient reported. If the patient is observed for the outcomes by a clinician, researcher or caregiver then the outcomes are termed observer reported outcomes (OROs) [14]. Proxy reported outcome is a measurement based on the report by someone other than the patient reporting as if he or she is the patient and are different from a PRO or ORO [15].

According to US-FDA, a PRO is any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else [15]. The European Medicines Agency’s (EMA’s) Reflection Paper on the Regulatory Guidance for the Use of Health Related Quality Of Life (HRQL) Measures in the Evaluation of Medicinal Products defines a PRO similarly as “any outcome directly evaluated by the patient and
based on patient’s perception of a disease and its treatment[s]” [16].

Although PROs are commonly used as an umbrella term to also include health related quality of life (HRQOL) some authors consider PROs to differ from HRQOL measurements for the following reasons. Firstly, HRQOL is multidimensional whereas a symptom is a one-dimensional property. Secondly, PROs are directly related to disease and treatment effect compared to HRQOL where there is an indirect relation to them. Thirdly, in the case of PRO concepts symptoms are often considered for behavioral objective measures but seldom for HRQOL. Thus, PRO concepts are simple whereas the concepts are complex in HRQOL [11].

The US-FDA has described the basic definitions related to PRO that are shown in Table 1 [15]. PRO instruments can also be classified as generic, disease specific, dimension specific, region/site specific, individualized, utility measures, and summary items having their own advantages and disadvantages [11,17].

Since the last ICI, electronic PROs (ePRO) have gained more importance since clinical trial managers and regulators prefer electronic collection of PRO data directly from the patient for PRO-based end points [18]. It has been suggested that ePRO leads to improved data quality, more complete data, less subject and administrative burden, as well as better implementation of skip patterns [19,20]. Furthermore, it has been shown that electronic data collection yields more reliable and accurate data, allowing a stronger test of the study objectives and a better picture of the patient’s experience [20].

### 2. PRO QUESTIONNAIRE DEVELOPMENT AND VALIDATION

PRO questionnaires can be used to record the presence and severity of urinary and bowel symptoms, as well as the impact of symptoms on everyday activities and health-related quality of life (HRQL) and satisfaction with treatment, etc. To ensure that the results obtained with PROs are clinically useful, data must be gathered using valid and reliable instruments. Prasanna et al have reported the characteristics of an ideal PRO instrument that are shown in Table 2 [11].

Questionnaire design and development is not a simple process. Developing such instruments requires a multistep, structured process that incorporates cognitive psychology, psychometric theory, and patient and clinician input. The process begins by determining the intent and purpose of the PRO and culminates in studies that demonstrate the measure’s validity, reliability, and responsiveness. The specific steps required for developing a PRO questionnaire are outlined in the following section and are shown in Figure 2 and each step is further detailed in Table 3 [15].

The development of a PRO is a rigorous, scientific process to provide confidence that the PRO is measuring what it is intended to measure, that it does this reliably, and is appropriate for use in the patient or population group under investigation. The final instrument must have demonstrated validity and reliability in the intended target population. PROs need to be

---

**Figure 2: Five-step development of PRO instrument (adapted from ref 6)**
developed with patient and clinician input and have the psychometric, or measurement, properties of the PRO evaluated to determine that it is a valid outcome measure. To be a useful measurement tool, a PRO instrument must also be easy to administer, reliable, and valid. Only PROs that have undergone this process and have published validation data are discussed in this chapter.

2.1. Determining Questionnaire Intent and Purpose

The first task in developing a PRO measure is to determine why the instrument is needed. Given the current number of disease-specific questionnaires available in the field of incontinence and related pelvic disorders, a new PRO measure must fill a need that has not already been met by an existing instrument. Once the need for the measure is recognized, its purpose and clinical usefulness need to be considered because the purpose dictates the validation design process. For example, a symptom and a treatment satisfaction measure would be developed and validated differently because the outcome is different.

The development stage would focus on the outcome of interest (e.g., symptoms patients experience and the significance of each symptom, or what issues patients consider when determining how satisfied they are with treatment) with the items derived from the patient perspective and relating to the outcome of interest. Validation efforts would include designing a study focused on the outcome of interest with the appropriate patient inclusion/exclusion criteria to enhance generalizability while maintaining internal consistency and providing opportunities to test—at a minimum—reliability and validity.

2.2. Developing the Items

Designing a clinically useful PRO measure involves more than just developing a series of questions. In addition to clinician input and literature review, questionnaire items must be generated from a patient perspective and include patient views. This is obtained through focus groups or one-on-one interviews to provide qualitative data on issues pertinent to patients and to identify the words patients use to describe their symptoms or disease impact. Focus groups and one-on-one interviews should be carefully planned to address the goals of the questionnaire being developed. For example, if a measure is intended to assess symptom bother, interview questions should pertain to the patient’s symptom experience. Importantly, rather than using clinical terminology which patients may not comprehend, the words used during the focus groups or interviews should be common to patients. The results of the qualitative patient interviews lead to item generation. After items are generated, the newly drafted questionnaire should be reviewed by other patients and experts to ensure its readability and content validity.

An alternative approach to questionnaire development is to adapt an existing measure to meet the needs of the desired questionnaire. Patients need to be involved in the questionnaire adaptation to ensure that the revised measure is pertinent to the population of interest. The adapted questionnaire must be validated on its own in the target population as the validity of the original questionnaire does not apply to the adapted measure.

For newly developed and adapted questionnaires, think out loud interviews or cognitive interviews should be used to ascertain the correctness and validity of the revised questionnaire. In a think out loud interview, patients are asked to review a question and describe what they are thinking as they cognitively process the question; the patients think out loud about what the question means to them and how they think through their response to the question. For a cognitive interview approach, patients review and respond to the questionnaire items, and then they are interviewed about what each item meant to them as they completed the questionnaire. Both approaches provide information about what patients consider when responding to each question.

2.3. Determining the Mode of Administration of a Questionnaire

When generating the PRO items, the mode of administration must be considered. Will the measure be completed by the patient (i.e., self-administered) or administered by an interviewer (i.e., interviewer-administered)? How the questionnaire will be completed needs to be determined before the validation stage because mode of administration can affect patient responses. For highly personal or intimate questions, a self-administered questionnaire is recommended to avoid response bias. Questionnaires that are self-administered are preferable to interviewer-administered questionnaires because the data collection burden is reduced and patients are more likely to provide unbiased information on self-administered questionnaires. Importantly, if a questionnaire has been validated for a particular mode of administration (self-administered pen and paper), this does not make the questionnaire valid for all modes of administration (e.g., electronic administration via web or hand held device). Should the mode of administration change from the original validation, processes must be undertaken to ensure no change in meaning or content have occurred with the format change. Guidelines for this type of adaptation are clearly outlined by Coons et al (2009) [211].

2.4. Questionnaires’ Psychometric Properties

All PRO measures must demonstrate reliability, validity, and responsiveness, which are described in detail below. This can be accomplished in several ways:
Perform a stand-alone cross-sectional study to validate the questionnaire in the patient population for which it was designed;

Administer the untested questionnaire in a clinical study and use the baseline data to perform psychometric validation (the end-of-study data can also be used to evaluate responsiveness); or

Perform a stand-alone longitudinal study with an intervention to determine the instrument's psychometric performance and responsiveness in a non-clinical trial setting.

The following psychometric properties must be tested for and demonstrated in a validated questionnaire.

Reliability refers to the ability of a measure to produce similar results when assessments are repeated (i.e., is the measure reproducible?). Reliability is critical to ensure that change detected by the measure is due to the treatment or intervention and not due to measurement error [22-25]. One measure of reliability is the questionnaire's internal consistency, which indicates how well individual items within the same domain (or subscale) correlate. Cronbach's alpha coefficient is used to assess internal consistency reliability, with higher alphas indicating greater correlation. Typically, Cronbach's alpha should be greater than 0.70 to indicate good internal consistency reliability [22, 23]. If the item-to-total alpha is less than 0.20, the question should be removed or rewritten.

Test-retest reliability, or reproducibility, indicates how well results can be reproduced with repeated testing. To assess test-retest reliability, the same patient completes the questionnaire more than once, at baseline and again after a period of time during which the impact of symptoms is unlikely to change (e.g., a few days or weeks) [22, 23]. The Spearman's correlation coefficient and intraclass correlation coefficient are used to demonstrate reproducibility. For group data, a Spearman's correlation coefficient or an intraclass correlation coefficient of at least 0.70 demonstrate good test-retest reliability [22, 23].

Inter-rater reliability indicates how well scores correlate when a measure is administered by different interviewers or when multiple observers rate the same phenomenon [22]. Demonstration of inter-rater reliability is not necessary for self-administered questionnaires but is necessary for instruments based on observer ratings or using multiple interviewers. A correlation of 0.80 or higher between raters indicates good inter-rater reliability [22].

Validity refers to the ability of an instrument to measure what it was intended to measure [22, 23]. A measure should be validated for each specific condition or outcome for which it will be used. For example, a measure designed to assess stress incontinence would not be valid for OAB unless it were specifically validated in patients with OAB symptoms.

Content validity, convergent validity, discriminant validity and criterion validity typically are required to validate a questionnaire [22, 23].

Content validity is a qualitative assessment of whether the questionnaire captures the range of the content it is intended to measure [22, 23]. For example, does a measure of symptom severity capture all the symptoms that patients with a particular condition have, and if so, is the measure capturing the items in a manner meaningful to patients in language patients can understand? To obtain content validity, patients review the measure and provide feedback as to whether the questions are clear, unambiguous, and comprehensive.

Convergent validity is a quantitative assessment of whether the questionnaire measures the theoretical construct it was intended to measure [22, 23]. Convergent validity indicates whether a questionnaire has stronger relationships with similar concepts or variables. Stronger relationships should be seen with the most closely related constructs and weaker relationships seen with less-related constructs [22, 23].

Discriminant validity indicates whether the questionnaire can differentiate between known patient groups (e.g., those with mild, moderate, or severe disease) [22, 23]. Generally, measures that are highly discriminative are also highly responsive.

Criterion validity reflects the correlation between the new questionnaire and an accepted reference, or gold standard [22, 24]. One difficulty in establishing criterion validity is that a gold-standard measure might not be available [22, 24]. When criterion validity can be established with an existing measure, the correlation should be 0.40 to 0.70; correlations approaching 1.0 indicate that the new questionnaire may be too similar to the gold-standard measure and therefore redundant [22, 24].

Responsiveness indicates whether the measure can detect change (for better or worse) in a patient's condition [25-27]. An aspect of responsiveness is determining not only whether the measure detects change but whether the change is meaningful to the patient. This can be done by determining the minimal important difference (MID) of the measure. The MID is the smallest change in a PRO questionnaire score that would be considered meaningful or important to a patient [26-28]. A treatment that is statistically significantly better than another may not necessarily have made a meaningful difference to the patient; the MID indicates whether the treatment made such a difference from a patient perspective.

Unfortunately, there is no scientific test for MID as it is an iterative process that involves two methodologies to determine the MID of a questionnaire: an anchor-based approach and a distribution-based approach [27, 28]. With the anchor-based approach, the MID is determined by comparing the measure to other measures (or "anchors") that have clinical relevance [27]. With the distribution-based approach, the
MID can be determined by the statistical distributions of the data [27], using analyses such as effect size, one-half standard deviation, and standard error of measurement [27, 28, 2929].

Another methodology to evaluate treatment benefit is to examine the cumulative distribution function (CDF) of responses between treatment groups. The CDF provides plots to examine the treatment effect and mean improvements by treatment group to see if the mean improvement varies by patient subsets [15, 29].

2.5. Linguistic and Cultural Validation

Increasingly, PRO questionnaires are required to be used in a number of different populations and settings, however, questionnaires and their psychometric properties are not necessarily transferable [3030, 3131]. A measure that is valid and reliable for a particular language and culture may not prove to be so after translation. Linguistic and cultural adaptation of a questionnaire can occur during the development phase before validation, or it can be done after the questionnaire is validated in the language in which it was initially developed, with the latter being the more common approach. Ensuring the linguistic and cultural validity of a questionnaire is especially important for measures used in multinational clinical trials [30, 31].

The principal steps in adapting a measure for different languages and cultures are as follows:

- two forward translations of the original instrument into the new language;
- quality-control procedures that may include a backward translation (translating the instrument back into the original language) [31];
- adjudication of all translated versions;
- discussion by an expert panel to ensure clarity of the translated questionnaire; and
- testing the translated instrument in monolingual or bilingual patients to ensure that it measures the same concepts as the original instrument [31, 3232].

However, if a backward translation of the measure does not produce a semantically equivalent instrument, then the instrument may need to be developed in the target language, rather than just translated [31].

After cultural and linguistic validation, PROs should also be psychometrically validated within the target language. Thus, reliability, validity, and responsiveness need to be assessed with each language translation to confirm the same measurement properties are present in the translated language(s) to ensure psychometric equivalence. If psychometric equivalence is not present (e.g., not achieving similar or better results in new language translation), the cultural and linguistic translations need to be reevaluated and perhaps a new instrument may need to be developed.

The ICIQ questionnaires and many of the other questionnaires discussed in this chapter have multiple linguistically validated versions making them useful for International implementation. It is also important to note that the step after linguistic validation, demonstrating psychometric equivalence, should also be demonstrated to ensure that the PRO performs equivalently in different languages and cultures (e.g., Coyne et al. 2008 [3333]).

2.6. Regulatory Oversight

As clinicians and scientists have begun to appreciate and accept PROs as appropriate outcome measures, regulatory authorities have issued guidance documents on current best practices in the development and implementation of PRO in clinical trial settings [15, 3434, 3535]. For PROs to be acceptable outcome measures for regulatory authorities, documentation of measurement properties must be present as well as evidence of inclusion of the patient perspective and understanding of the PRO and a cohesive conceptual framework that stipulates how the PRO is related to the intervention. While PROs within this document may have a "recommended" status, they may not meet all of the required regulatory guidelines and may require additional validation work either from a qualitative or quantitative perspective. It is strongly suggested that regulatory authorities be contacted early in the process of selecting a PRO for clinical trials to ensure regulatory acceptance of the PRO.

2.7. Questionnaire Development - Conclusion

PROs are the most suitable method for assessing the patient's perspective of their lower urinary tract, vaginal and bowel symptoms [2736]. Questionnaires may be long and detailed for use in research, but need to be short and easy to use to be relevant for clinical practice. In addition to being valid and reliable, they need to be easy to complete, and, if they are being used to measure outcome, sensitive to change. Developing a new questionnaire and testing it thoroughly takes a great deal of time and is only necessary if there is not an existing instrument available.

There are many questionnaires currently available for use and these have been reviewed and described with recommendations from the Committee for their use in the last four ICI reports.

The major purpose of the ICI has been to provide a definitive international review and consultative opinion regarding the recommended measures to assess patient reported outcomes within the area of urinary incontinence and LUTS. To this end since the First Consultation, the ICI has worked to develop a modular format for the various patient reported outcomes allowing clinicians and researchers to select internationally recommended questionnaires for the assessment of their patients in both clinical practice and clinical trials. In this sixth ICI review, the ICIQ modular
Questionnaires (supported by the International Consultation) are presented in detail and their use evaluated. Whilst some of the modular questionnaires are still currently under full evaluation their content and format are presented within this chapter.

III. RECOMMENDED PRO QUESTIONNAIRES

GRADES OF RECOMMENDATION FOR QUESTIONNAIRES 2016

As with previous Consultations, the Committee continues to use three grades of recommendation. However, we have added a + sign to indicate when published content validity is available for an instrument:

Questionnaires were 'highly recommended' and given a Grade A if the Committee found "Published data indicating that the questionnaire is valid, reliable and responsive to change following standard psychometric testing. Evidence must be published on all three aspects and questionnaires must be relevant for use with persons with incontinence. Grade A + indicates there is additional evidence of published content validity."

Questionnaires were "recommended" and given a Grade B if the Committee found "Published data indicating that the questionnaire is valid and reliable following standard psychometric testing. Evidence must be published on two of the three main aspects (usually validity and reliability). Grade B + indicates there is additional evidence of published content validity."

Questionnaires were considered to have "potential" and given Grade C if the Committee found "Published data (including abstracts) indicating that the questionnaire is valid or reliable or responsive to change following standard psychometric testing. Grade C + indicates there is additional evidence of published content validity."

The Committee decided that evidence published in abstracts or posters could be used to indicate a developing questionnaire's potential, but was not sufficiently peer-reviewed to provide the basis for a stronger recommendation.

As decided in the Fourth Consultation the recommendation will be to preferably utilize questionnaires from the ICIQ modules described in detail below. Many, but not all, of these questionnaires are Grade A or A+ questionnaires by previously stipulated criteria. Within the description of the ICIQ modules below the grade assigned to each module is indicated.

When no suitable instrument exists a Grade B or C questionnaire, performing additional validation as indicated prior to use if feasible, should be used.

For UI and UI/LUTS, the Committee examined the quality of the psychometric evidence. Only where published data were scientifically sound was the label 'with rigor' allowed. Where the Committee had concerns about the quality of evidence, this is noted in the descriptions of the questionnaires below. The Committee considered that the number of high quality questionnaires means that there are now sufficient questionnaires for most purposes and it is not necessary to encourage the development of new questionnaires, except for particular patient groups (see below).

IV. INTERNATIONAL CONSULTATION ON INCONTINENCE MODULAR QUESTIONNAIRE (ICIQ): WHAT IS THE ICIQ?

The ICIQ modular questionnaire was developed to meet the need for a universally applicable standard guide for the selection of questionnaires for use in clinical practice and clinical research for lower pelvic dysfunction [37, 38]. It was recognised that there were many good validated questionnaires each developed for a specific purpose and each subtly different. Although developers of the questionnaires were familiar with their content and use, the increasing number of questionnaires made appropriate selection difficult and limited the ability to compare similar clinical and research data due to different data collection methods.

The decision to develop standard questionnaire modules was taken by the Committee after the first ICI meeting in 1998, and resulted in the development of the ICIQ core questionnaires discussed in this section.

An international advisory board was established to continue the development of the modular ICI questionnaire outside the limits imposed by triennial convening of the ICI Committee. The advisory board consisted of clinicians and researchers with experience in the design and use of questionnaires representing the major societies involved in the assessment and research of lower genital tract, lower urinary tract and bowel function. The ICIQ modular questionnaire was then established. Researchers who have developed questionnaires that they would like to be reviewed by the advisory board for inclusion should send the questionnaires and relevant publications to www.iciq.net. The project is a series of living documents that will be continually updated.

1. AIMS AND OBJECTIVES

The ICIQ’s objective is to provide international consensus on the use of patient completed questionnaires for the assessment of lower pelvic symptoms and their impact on patient’s lives. Three aims underpin the ICIQ in order to achieve clarity over questionnaire use:

To recommend high quality self-completion questionnaires according to evidence of validation as stipulated by the five prior ICI Committees;

To promote wider use of questionnaires to standardise assessment of lower urinary tract and pelvic dysfunction and its impact on patients’ lives, in order to;

Facilitate communication in different patient settings and different patient groups both in clinical practice and wider clinical research.

The ICIQ recognised that many high quality published questionnaires already existed and, with permission from the authors, those instruments were adopted into the modular project. It was not possible to adopt all available questionnaires and where more than one option existed, the most appropriate questionnaire for the purpose was included. Where high quality questionnaires were not available, the need to develop a new questionnaire was acknowledged. Questionnaires are developed according to rigorous methodology which complies with industry-standard guidance for PRO development [1]. Collaborative efforts to develop new questionnaires are welcome and encouraged.

The ICIQ’s international nature requires that linguistically validated translations are available. More than 50 language versions of various modules have been validated to date and conducted according to established protocol [39].

Sixteen ICIQ modules/questionnaires are currently available for use, with further modules in development (discussed in detail below). Clinicians or researchers are able to select module(s) to meet the particular requirements of their study or clinical practice. In order to simplify this selection process, modules have been categorised as shown in Figure 3. It must be stressed that although multiple questionnaires can and probably should be used they must be used in the format in which they were originally designed and the questionnaires cannot be merged together as this may affect their measurement capability.

In recent years, increasing advances have been made in the area of electronic documentation, particularly with regard to patient care. It is recognised that questionnaires requiring written completion by hand may lack versatility and therefore prevent uptake of the ICIQ, hampering attempts to promote standardisation of evaluation. Evaluations of electronic ICIQ modules have been completed, indicating equivalence of their measurement properties and acceptability to the target audiences [40].

Cognitive interviewing was conducted with participants representative of potential respondents, namely men and women with lower urinary tract symptoms of varied cause and of varying age. Further participants completed electronic and paper versions of the questionnaires, in a randomised order, to provide comparison data and the opportunity to compare completion over the telephone was also included. Electronic versions demonstrated excellent equivalence with their paper counterparts, supporting use of these formats as long as they are prepared in the specific ICIQ format. Telephone completion was found to produce slightly poorer correlations although acceptable equivalence was still observed. This is as expected as these questionnaires are intended for self-completion but this

*In development

A study has provided reassurance that their use over the telephone is acceptable if self-completion is not practicable.

In this chapter, questionnaires forming part of the ICIQ modular format are referred to as those preferred for usage. Although many of the modules are Grade A or A+ questionnaires, others are still under various phases of development and are graded appropriately. Questionnaires that are in early stages of development and have yet to reach Grade C are described as "in development". Where an ICIQ module is not available it is recommended that a Grade A+, A,B or C questionnaire is used.
2. ICIQ MODULES

2.1. Core Modules

Questionnaires to assess the core symptoms and impact on health related quality of life (HRQL) of lower pelvic dysfunction are contained in this section, in addition to impact on sexual matters. Core modules (Table 4) provide evaluation of:

- Lower urinary tract symptoms
- Urinary incontinence
- Vaginal symptoms
- Bowel symptoms

Each symptom module is intended for the comprehensive yet succinct measurement of symptoms and associated ‘bother’. The bother item attached to symptom items, where applicable, enables the individual to indicate areas that cause the greatest negative impact on HRQL as perceived by them. This can be a more sensitive indicator of treatment goals than frequency of symptoms alone. The HRQL questionnaires cover specific issues that are a consequence of symptoms, such as life limitations and emotional impact. Sexual matters modules specifically evaluate the impact of lower urinary tract symptoms on this aspect from the male and female perspective.

A further core module has been added that moves away from the retrospective questionnaire format in the form of a bladder diary. This is a fully validated prospective tool for the measurement of bladder events as they occur.

2.2. Specific Patient Group Modules

Questionnaires to assess specific conditions or symptom complexes such as nocturia, overactive bladder and underactive bladder, in addition to management strategies such as long term catheter and pad usage are contained in this section along with HRQL modules for these specific symptom complexes where available. This category also includes specific patient groups, for example, children. These instruments contain only question items characteristic of the symptom complex or have been developed specifically for use in a diverse group, which defines their context of use making the items/questionnaire only utilisable in that population.

- Nocturia
- Overactive bladder
- Underactive bladder
- Neurogenic
- Inflammatory bowel disease
- Lower urinary tract symptoms in children
- Individuals using long term catheters
- Individuals using absorbent pads

2.3. Optional Modules

This category lies within the core symptoms and includes lengthier questionnaires for more in-depth evaluation of lower pelvic dysfunction. Whilst these questionnaires are suitable for use in clinical practice, they have not been shortened for clinical efficiency and are therefore more widely used in research studies where exploration of broader associated symptoms may be desired.

- Lower urinary tract symptoms
- Urinary incontinence

2.4. Post-treatment Module

The ICIQ module for post-treatment satisfaction is in the early stages of development. Assessment of a patient’s satisfaction with treatment (behavioural, surgical or medication) provides information on treatment impact on their condition and life and includes their perception of effectiveness, tolerability and convenience. It is not yet clear if satisfaction following treatment can be characterised by a set of common question items that are applicable to all lower pelvic health conditions. As with HRQL, there are generic and disease specific questionnaires that assess satisfaction. Ongoing studies will provide further evidence on which to make suggestions regarding post treatment evaluation but it is likely that this will encompass both generic and condition specific measures. Ultimately, the development of post treatment modules will also rely on advice from regulatory authorities (e.g. FDA, EMA) to ensure that measures capture a recognised multidimensionality of satisfaction.

3. GUIDANCE FOR USE OF THE ICIQ

The ICIQ recommends the use of a symptom and HRQL module that match the intended purpose of a study in order to provide a comprehensive evaluation of these two perspectives. The extent of burden placed on the respondent and the study or clinical outcomes must be considered however and ultimately guide questionnaire selection. The characteristics of each module are summarised below, although more extensive information can be found on the project website, www.iciq.net. Modules currently under development are summarised in Table 5.

4. ICIQ QUESTIONNAIRE IMPLEMENTATION

The ICIQ modular questionnaire has attracted considerable attention from both clinicians and researchers worldwide since its structure was finalised in 2004. More than 2000 requests for use of the various modules have been documented and over 350 published studies were identified up to June 2016. The most widely applied module is the ICIQ-UI Short Form, particularly to evaluate female urinary incontinence. Reports on further validation and translations of the ICIQ and related educational projects are growing in number. This is essential in order to achieve standardised evaluation of pelvic floor dysfunction, which is a primary aim of the initiative.

The ICIQ has also been applied to clinical and general practice settings, and has been adopted in national guidelines for the management of urinary incontinence in:

- women (NICE clinical guideline 171)
- primary care (SIGN 79)(www.sign.ac.uk/pdf/sign79.pdf)
- included in a primary care resource pack by the British Society of Urogynaecology

5. CONCLUSION

The ICIQ modular questionnaire project (www.iciq.net) provides a growing series of standardised questionnaires for the patient reported assessment of lower pelvic dysfunction symptoms and their impact on patients lives. The ICIQ provides clarity over the selection of questionnaires by recommending only those with evidence of high quality and robust psychometric validation including validity, reliability and sensitivity to change. Testing psychometric equivalence of the ICIQ electronic formats also provides reassurance of their rigorous measurement capabilities in specific alternative formats. This assurance provides the user with confidence in the results obtained, which is important in clinical practice and research where treatment decisions or trial outcomes depend on this evidence. Increasing awareness of the ICIQ aims to promote increased use of standardised questionnaires and further evaluation of existing modules in order to advance the evidence base supporting use of these tools. These efforts aim to increase communication between clinicians and researchers and enable more wide-spread comparisons between different treatments and patient groups worldwide. Collaboration with the ICIQ is encouraged among clinicians and researchers in order to further develop new and existing ICIQ modules and translations.

V. PATIENT-REPORTED OUTCOME (PRO) QUESTIONNAIRES TO ASSESS THE IMPACT OF URINARY INCONTINENCE, OAB AND LOWER

1. URINARY TRACT SYMPTOMS

There are a variety of PRO measures available for use in clinical practice and research that assess a range of concepts (e.g. HRQL, patient satisfaction, symptom bother, etc). Encouragingly, PROs awarded the highest ICI grade are being used widely in studies, with short forms that are easily accessible being preferred.[55] This section provides an overview and assessment of these measures. Importantly, clinical practitioners and researchers need to clearly determine their clinical and research objectives before selecting a PRO as it is these objectives and the target patient population that will help determine which validated PRO is appropriate to use. Tables 6 to 10 provide a brief overview of all current PRO measures for urinary incontinence and LUTS, their purpose, psychometric properties, translation availability, and recommended ICI grade.

Please note, as instrument development and validation is an ongoing process, the tables below contain publications through June 2016. As additional work may have been performed on a instrument, it is always prudent to conduct a further literature search and/or contact the instrument developer prior to selecting an outcome measure for your clinical practice or study. Further study-specific testing should also be considered to ensure a tool’s appropriateness for the intended purpose. When using a questionnaire in a patient group other than the group in which it was initially developed, cognitive interviews with the new patient population should be held to review the applicability of the questionnaire to the new patient group. Several of the main questionnaires to be discussed below have now had modified versions published in the literature. The Committee’s view is that although it may be appropriate to modify established questionnaires for use with some populations, it is advisable to keep such modifications to a minimum, and to use the original versions whenever possible. Any modifications of established questionnaires may result in changes (sometimes substantial) in the psychometric performance of the instrument, and thus all modified instruments should be subjected to the same psychometric testing as that employed in developing a completely new instrument. Specifically, modified instruments should report information regarding the instrument’s construct validity, reliability, and test-retest reliability, at a minimum, and sensitivity to change, in intervention studies.
2. HEALTH-RELATED QUALITY OF LIFE MEASURES

Health-related quality of life (HRQL) measures help to assess the impact of disease and treatment on those aspects of quality of life related to health. UI is a symptomatic condition that has been shown to affect many aspects of a patient's life - physical, emotional, and social relations and cause concern and burden. As such, it is important to assess HRQL in clinical research and practice. Table 6 provides a quick overview of the variety of HRQL measures available and their validity and characteristics to determine which measure is suitable for your objectives.

3. PATIENT SATISFICATION AND GOAL ATTAINMENT SCALING

Patient satisfaction and Goal Attainment Scaling are two important but separate types of PROs that allow for individualised assessment of disease impact and treatment. Patient satisfaction is the subjective, individual evaluation of treatment effectiveness and/or the service provided by the healthcare system. Goal attainment scaling (GAS) is a method developed to ascertain individual patient treatment goals and using those to facilitate patient-provider interaction and tailor the treatment plan based on those individual's goals [56].

Measures of patient satisfaction can include evaluation of accessibility/convenience, availability of resources, continuity of care, efficacy, finances, humaneness, information gathering and giving processes, pleasantness of surroundings and perceived quality/competence of health care personnel [57]. At its most basic level, satisfaction is a comprehensive evaluation of several dimensions of health care based on patient expectations and provider and treatment performance. As an outcomes measure, patient satisfaction allows health care providers to assess the appropriateness of treatment according to patient expectations. In chronic diseases, where patients must live with treatment, patient satisfaction may be the distinguishing outcome among treatments. In order to improve the detection of incontinence, OAB and other LUTS, several screening tools have been developed (Table 8). These tools help patients self-describe symptoms and facilitate diagnosis of LUTS by the clinician. Only the B-SAQ has been designed to screen for general lower urinary tract symptoms (LUTS) rather than solely symptoms of one condition. The majority of patients with LUTS have mixed urinary symptoms, and therefore a questionnaire which can detect more than one symptom complex may be more functional as a screening tool in clinical practice than a highly specific questionnaire. The Leicester Impact Scale (LIS), OAB-V8, OAB-SS and QUID are all Grade A, short, simple to understand and complete, and easy to interpret. However the LIS is interviewer, not patient administered. Importantly, with screeners, responsiveness is not assessed, however the sensitivity and specificity of each tool is critical.

4. SCREENING TOOLS

In order to improve the detection of incontinence, OAB and other LUTS, several screening tools have been developed (Table 8). These tools help patients self-describe symptoms and facilitate diagnosis of LUTS by the clinician. Only the B-SAQ has been designed to screen for general lower urinary tract symptoms (LUTS) rather than solely symptoms of one condition. The majority of patients with LUTS have mixed urinary symptoms, and therefore a questionnaire which can detect more than one symptom complex may be more functional as a screening tool in clinical practice than a highly specific questionnaire. The Leicester Impact Scale (LIS), OAB-V8, OAB-SS and QUID are all Grade A, short, simple to understand and complete, and easy to interpret. However the LIS is interviewer, not patient administered. Importantly, with screeners, responsiveness is not assessed, however the sensitivity and specificity of each tool is critical.

5. ASSESSING SYMPTOM BOTHER AND OVERALL BOTHER

Measures that can be used to assess how bothered patients are by urinary symptoms are included in Table 9. The Patient Perception of Bladder Condition (PPBC) and the Urogenital Distress Inventory are the only Grade A recommend instruments. However, there are several Grade B and C measures which assess bother for incontinence and LUTS.

6. ASSESSING THE IMPACT OF URGENCY

Several instruments have been developed specifically to assess urinary urgency, which is defined by the International Continence Society as “the complaint of a sudden compelling desire to pass urine
which is difficult to defer[66]. Urgency is the driving symptom of OAB [67,68], thus assessing the effect of treatment on this symptom and its impact on HRQL is important. With any measure designed to evaluate urgency, patients must be able to distinguish between the normal desire to urinate (urge) and the difficult-to-postpone need to urinate (urgency) [68,69]. Wording thus becomes critical in the development of urgency assessment measures. Chapple and Wein [70] make a case for describing urgency as a “compelling desire to void in which patients fear leakage of urine” as a means of distinguishing this abnormal sensation from the normal need to void. However, some patients may have a sensation of urgency without fear of leakage, further complicating attempts to define urgency. Importantly, with some of these scales, patients have the option of indicating that they experienced UIUI (an event) rather than the strongest feeling of urgency (a sensation) itself. Several instruments have been developed to assess urinary urgency these are summarised in Table 10.

VI. QUESTIONNAIRES FOR SPECIFIC PATIENT GROUPS

Most studies and questionnaires have been developed for use with members of the general population or urology/gynaecology patients with incontinence or POP. However, some specific patient groups may experience particular problems with incontinence (for example, children, frail elderly or those who are severely disabled), which may require independent investigation and potentially the development of more specific measures or the addition of a new subset of items on already developed instruments. The Committee advises that researchers should use existing highly recommended or recommended questionnaires if possible as this aids comparison and to reduce the increasing proliferation of questionnaires. Many of the questionnaires developed below for particular conditions (e.g. prostate cancer) pre-dated the development of highly recommended questionnaires, and highly recommended questionnaires should be used preferentially.

1. OLDER PEOPLE

Urinary incontinence symptoms play an influential role on the overall HRQL in older people (>65) and causes a significant decrease in HRQL, as severe as that of many chronic disease states. Since the elderly commonly have a number of associated co-morbid conditions, it may be difficult to measure the impact of urinary incontinence with generic HRQL measures. The use of incontinence specific tools to measure patient-reported outcomes in the elderly, therefore, is of considerable importance. Validated incontinence-specific PRO questionnaires, such as IQ, I-QOL or KHQ, are used for clinical trials or research on urinary incontinence including elderly people, but their validity has not been specifically assessed in this age group. Okamura assessed symptoms and HRQL in older people (men and women) with lower urinary tract symptoms including incontinence, using the KHQ and IPSS. They demonstrated that symptoms and HRQL in the elderly with LUTS could be assessed by IPSS and KHQ and that urinary incontinence appeared to be more associated with a decreased HRQL in elderly women [71].

On the other hand, there are a variety of factors affecting older people, including physical, social, mental, economic or environmental conditions, which are different from those of the young. In frail elderly people with dementia or physical impairment, it may be difficult to assess the impact of urinary incontinence alone. Questionnaires specifically developed for the elderly may be of great importance in this respect. However, there is little relating to the development or validation of particular questionnaires for older people with urinary incontinence. Two questionnaires dealing with older people were found and are described below. No questionnaires dealing with patient outcomes specifically for frail older incontinent people were found.

1.1. The Urge Impact Scale (URIS) [Grade B]

The Urge Impact Scale (URIS) was designed and tested specifically for older persons with urgency incontinence. The URIS was developed and validated by DuBeau et al. [72] and included 32 items, reduced to 24 items (URIS-24). The URIS-24 was psychometrically assessed for validity and reliability in community-dwelling older (>65y) men and women with urgency incontinence. Cronbach’s alpha was 0.84 for the URIS-32 and 0.94 for the URIS-24. In assessment of test-retest reliability, interclass co-efficient (ICC) was 0.88. The URIS-24 had modest but nearly significant correlation with the number of urgency incontinence episodes (rho=-0.39, p=0.05). Factor analysis revealed 3 component structures corresponding to physiological burden, perception of personal control and self-concept. There was no analysis for responsiveness. They showed that the URIS-24 is an internally consistent, highly reproducible tool for the assessment of the QOL impact of urgency incontinence on older persons.

1.2. Caregivers

The Overactive Bladder Family Impact (OAB-FIM) scale was developed to assess the impact of OAB on family members of patients with OAB. This 19-item tool consists of 6 subscales [73]. Four subscales (Irritation, Activities, Travel, Concern) could be used for all family members; however 2 additional subscales (Sleep, Sex) should only be administered to spouses/significant others. The OAB-FIM was highly discriminating between OAB and control family members, with all OAB family members indicating significant impact (all p<0.0001). Internal consistency reliability (Cronbach’s alpha >0.71) and 2-week test-retest reliability (intra-class correlation coefficients >0.73) were high for all subscales. Concurrent validity of the OAB-FIM was demonstrated through statistically significant
(p < 0.001) Spearman correlations with the OAB-q (coefficients ranging from 0.35 to 0.58) and the PPBC (0.31 to 0.56). No differences were noted on the OAB-FIM by patient incontinence status (none, urge vs. mixed). OAB-FIM scores also discriminated by family member perceptions of OAB severity, particularly among the Irritation, Activities and Travel subscales. Correlational analyses among the OAB-FIM and relationship quality measures suggest that greater OAB symptom impact on the family member was associated with increased problems in the patient–family member relationship. The responsiveness of the OAB-FIM is yet to be assessed. This measure can be found at www.pfizerpatientreportedoutcomes.com.

2. CHILDREN

Some questionnaires have been developed specifically to assess issues for children and can include parent and child versions of the questionnaire. Enuresis is a particular focus in addition to specific disorders such as Spina Bifida (ISI-P). See Chapter 9 (Children) and section on ICIQ modular questionnaire.

3. SPINAL CORD INJURED / NEUROLOGICAL IMPAIRMENT

Individuals who have a spinal cord injury or are neurologically damaged can experience particular difficulties with incontinence and the use of various devices. It would be useful to investigate whether Grade A questionnaires, developed for people without neurological damage, can be used in this group, or whether additional modules or instruments are required. New instruments available in this area are detailed below.

3.1. QUALAS-A: Quality of Life Assessment in Spina Bifida for Adults

The QUALAS-A was developed to evaluate quality of life associated with bladder and bowel disorders in adults with Spina Bifida [74]. Items were generated through interviews and a focus group and refined to develop the 53 item pilot instrument. International recruitment achieved a sample of 532 participants to evaluate validity and reliability to assist item reduction. The resulting 15 item questionnaire provides a comprehensive assessment organized within three domains: Health and relationships, Esteem and sexuality, and bladder and bowel.

3.2. IUI: Incontinence Utility Index

The IUI is a condition-specific preference-based measure for urinary symptoms related to neurogenic detrusor overactivity that provides population based utility scores to value health states [75]. The instrument was developed from the I-QoL and neurogenic module by applying Rasch modeling. 442 participants were interviewed to estimate social preferences and explanatory models identified that demonstrated adequate predictive validity.

3.3. Qualiveen: Quality of Life Related to Urinary Problems in Spinal Cord Injury [Grade A]

The Qualiveen was developed to evaluate the specific impact of urinary dysfunction on the quality of life of spinal cord injury patients in France [76]. The initial items were developed following patient interviews, and were then assessed for validity and reliability in 281 spinal cord injury patients with urinary difficulties. The Qualiveen contains 30 items and has demonstrated good reliability and validity [76]. Further validation of the Qualiveen has occurred in multiple sclerosis patients and it has been translated and validated into English [78], German [79], and Portuguese [80]. The Qualiveen has demonstrated responsiveness in multiple sclerosis patients and has a suggested MID of 0.5 [81].

4. PROSTATE / BLADDER CANCER

Many PRO questionnaires are available for assessment in this area: Post-radical prostatectomy questionnaire [82, 83], Cancer Rehabilitation Evaluation System - Short Form (CARES-SF) [84], Prostate Cancer Treatment Outcome Questionnaire (PCTO-Q) [85], Prostate Cancer Specific Quality of Life Instrument (PROSOLI) [86], Modified Southwest Oncology Group (SWOG) [87], Functional Assessment of Cancer Therapy - (FACT-G), Bladder form (FACT-B) and Prostate form (FACT-P) [88], Functional Assessment of Cancer Therapy Vandervlet Cystectomy Index (FACT-VCI) [89], EORTC metastatic prostate cancer [85], Changes in Urinary Function [90], Prostate-targeted Health Related Quality of Life [91]. While it is beyond the scope of this chapter to review and recommend PROs in this area, the principles and guidelines discussed herein apply to selecting a PRO related to prostate and bladder cancer.

5. LOWER URINARY TRACT SYMPTOMS/BENIGN PROSTATE DISEASE

Many questionnaires have been developed to assess LUTS and benign prostate disease; however, most do not contain a full evaluation of UI. Perhaps the most widely known urology PRO is the AUA Symptom Index [92], I-PSS (International Prostate Symptom Score) [92, 93]. The IPSS has been utilised internationally to assess symptoms of prostate disease with documented reliability, validity and responsiveness. More recently a Visual Prostate Symptom Score [94] has been developed and an app version of the IPSS has been evaluated, providing alternative approaches to the assessment of symptoms associated with prostate disease [95]. Additional PRO
measures for BPH are as follows: Patient-completed modification of the Boyarsky[96], BPH Impact Index [97][98] and BPH Health-related QoL survey [99].

Although the number of HRQoL questionnaires available for use in the subjective assessment of women with prolapse is now a number of validated questionnaires to use in conjunction with the clinical assessment and standardised measurement of urogenital prolapse which is reported elsewhere in this section. In addition, given the number of conservative and surgical management options available for women with symptomatic prolapse, standardisation of subjective outcome measurement is increasingly important.

This section will review the standardised symptom assessment tools for pelvic organ prolapse and, whilst the questionnaires described do not allow the clinical staging or planning of prolapse treatment they should be used alongside more objective tools to measure the subjective outcome of treatment. Evidence from previously reported studies has shown the importance of patient-reported outcome measures and subjective assessment may provide a more meaningful assessment tool when compared to more traditional objective measurements. The use of these subjective outcomes has been shown to be robust and correlated with objective assessments during long term follow up.

Although the number of HRQoL questionnaires available for the assessment of urogenital prolapse is not as great as those associated with lower urinary tract dysfunction, there are now a number of recommended and validated questionnaires available. However, it is important to consider that where specific problems associated with urogenital prolapse need to be considered, such as lower urinary tract symptoms or sexual function, then it may be preferable to consider the use of one of the questionnaires designed specifically for that purpose. In addition, as prolapse is often multidimensional, selecting questionnaires in the modular format of the ICIQ may be more useful in clinical practice.

Women who have symptomatic urogenital prolapse may also complain of sexual dysfunction and the Pelvic Organ Prolapse Urinary Incontinence Sexual Questionnaire (PISQ) is now available in short form (PISQ-12) and has been validated in Turkish and has been developed and reported. The Patient Global Impression of Improvement (PGI-I) was initially developed for lower urinary tract symptoms and has more recently been validated for use in patients with urogenital prolapse. The use of a simple one answer patient reported outcome measure has also been used in studies using composite endpoints with the validated HRQoL questionnaires.

When reviewing the available HRQoL questionnaires the committee examined the quality of the psychometric evidence and only where published data were robust were the instruments considered for recommendation. [Box 1].

For this current report the previous literature search was updated using the Pubmed/Medline databases from January 2013 – August 2016 in addition to the website mapi-institute.com. The following key words were used either separately or in combination; ‘questionnaire’, ‘prolapse’ and ‘quality of life’. The grading of questionnaires was also reviewed and updated if new information had become available.
The Austrian Pelvic Floor Questionnaire (AFPQ)209
Pelvic Floor Symptom Bother Questionnaire (PFBQ)210
Electronic Personal Assessment Questionnaire-Pelvic Floor (ePAQ-PF)211

There are now a number of patient reported outcome measures which have been developed for the assessment of patients with Anal Incontinence (AI) and Faecal Incontinence (FI). Due to the considerable overlap between faecal incontinence and other forms of pelvic floor dysfunction questionnaires used for urinary and prolapse symptoms may also contain domains for anal and faecal incontinence. Likewise, items relating to faecal incontinence may also be included in questionnaires used to evaluate colorectal disease. In addition, due to the wide variation in normal bowel function within, and between individuals, some of these questionnaires may lack sensitivity and specificity for more specific bowel disorders such as Irritable Bowel Syndrome (IBS), Irritable Bowel Disease (IBD) evacuation disorder and constipation. Since anal incontinence, faecal incontinence and bowel evacuation are closely related to pelvic floor function it may be inappropriate to consider bowel function simply in terms of continence and constipation. Constipation and evacuation disorders may result from a number of different pathologies such as outlet obstruction and slow transit in addition to other mechanical, pharmacological, metabolic and neurogenic causes [214].

Anal incontinence is known to occur in both men and women with the prevalence depending on age and the symptoms are known to be important in terms of the underlying pathophysiology. Faecal urgency and faecal urgency incontinence are thought to be associated with the loss of voluntary control due to impaired external sphincter function whereas passive faecal incontinence is thought to be associated with impairment of the smooth muscle of the internal anal sphincter [215].

This update of the last triennial report has again examined the quality of the psychometric evidence and only where published data were scientifically sound were the questionnaires included in the overall report.

For this current report the previous literature search was updated using the Pubmed/Medline databases from January 2013 – August 2016 in addition to the website mapi-institute.com. The following key words were used either separately or in combination; ‘questionnaire’, ‘faecal’, ‘anal’, ‘bowel’ and ‘quality of life’. The grading of questionnaires was also reviewed and updated if new information had become available.

The updated search found no new HRQoL instruments for the assessment of anal or faecal incontinence and, in addition there were no further validation studies reported on those questionnaires which were ungraded. Consequently the recommendations of this triennial report remain unchanged.

The grades of recommendation are as outlined in previous sections. Box 2 summarises the questionnaires reviewed and grades of recommendation.

Analysis

For this current report the previous literature search was updated using the Pubmed/Medline databases from January 2013 – August 2016 in addition to the website mapi-institute.com. The following key words were used either separately or in combination; ‘questionnaire’, ‘faecal’, ‘anal’, ‘bowel’ and ‘quality of life’. The grading of questionnaires was also reviewed and updated if new information had become available.

The updated search found no new HRQoL instruments for the assessment of anal or faecal incontinence and, in addition there were no further validation studies reported on those questionnaires which were ungraded. Consequently the recommendations of this triennial report remain unchanged.

The grades of recommendation are as outlined in previous sections. Box 2 summarises the questionnaires reviewed and grades of recommendation.

| Ungraded |
| Postpartum Flatal and Faecal Incontinence Quality of Life Scale [174] |
| Bowel Function Questionnaire [217] |

Tables 11, 12 and 13 provide details of the specific psychometric properties and development of each questionnaire.
 Sexual dysfunction affects many people and may be caused by psychological, emotional or physiological factors, often with multifactorial and interrelated etiologies. Sexual function may be regarded as a dimension or aspect of overall HRQL, for which a number of dimension-specific measures have been developed and validated. There is a wide choice of available instruments, the selection of which will depend on the clinical or research setting where the instrument is to be employed. Established and widely used measures that have been shown to be valid, reliable and responsive are clearly desirable, however the feasibility and appropriateness of using a particular instrument in a particular setting must also be considered. A large number of different instruments exist in this field, which aim to evaluate specific aspects of sexual function and sexual health.

While the importance of investigating male sexual health as part of a normal male urological assessment is established, this has not been established for female evaluation. Many physicians underestimate the prevalence of female sexual dysfunctions and do not routinely perform an assessment of sexual wellness as a part of their practice [218], despite evidence that many women with LUTS have sexual problems.

In a comprehensive assessment of women with pelvic dysfunction, sexual function should be investigated. However it may be a difficult issue to discuss during a consultation because of discomfort or embarrassment. Female discomfort may stem from personal embarrassment, a sense that sexual dysfunction is not a medical problem and this may be compounded by a lack of time during health care visits.

In addition many physicians report a lack of training in how to appropriately address sexual function with patients [221]. Clinicians who treat sexual problems often prefer to use unstructured rather than structured interviews or questionnaires in clinical practice as an unstructured approach allows the tailoring of questions to suit the couple or the individual being assessed. Unstructured interviews enable the clinician to support patients who feel vulnerable and encourage discussion. In this setting, vocabulary can be modified, as can the level of assertiveness and the depth of questioning to suit the needs of the individual. This flexibility is not readily achievable with questionnaires which individuals may also find difficult to complete due their impersonal nature or because of physical or mental impairment, cultural or language differences. However, some patients find the discussion of intimate issues with clinicians very difficult and questionnaires may allow these issues to be measured in private, at ease and more effectively before subsequently exploring questionnaire responses in the clinical interview itself. Therefore there is a wide choice of available instruments, which could help the physician during history taking and the selection of an instrument will depend on the clinical or research setting where the instrument is to be employed.

Table 14 and Table 15 outline sexual health measures with a Grade A, B, C rating based on the criteria provided above, and the linguistic validations of each questionnaire are also documented.

This table includes the questionnaires useful to assess female and male sexual function in patients with any pelvic dysfunction and urinary symptoms. Questionnaires obtaining an A+ rating demonstrate reliability and validity and also that content was derived with patient input and responsiveness to treatment has been shown.

**A Rated group:** the Female Sexual Function Index (FSFI) [178,222,223], the Female Sexual Distress Scale (FSDS) [224], the International Consultation on Incontinence Questionnaire-Vaginal Symptoms (ICIQ-VS) [45] and the Derogatis Sexual Functioning Inventory (DISFI) [225]. These questionnaires assess female sexual function and measure the quality of a patients current sexual functioning. The Menopausal Sexual Interest Questionnaire (MSIQ) [226] is also included in this group but only two domains. For male patients the International Index of Erectile Function (IIEF) [227] is recommended to assess men with erectile dysfunction. Most of the identified measures are self-reported, easy and quick to administer and many have various language versions available. The majority have also been previously used in incontinence populations.

**B Rated group:** the Daily Log of Sexual Activities (DLSA) [228], the Female sexual distress scale-revised (FSDSr) [229], the Index of Sexual Functioning for women (BISF-W) [230], the Change in Sexual Functioning Questionnaire (CSFQ) [231,232], and the Sexual Interest and Desire Inventory Female (SIDI-F) [233]. They assess the sexual dysfunctions in women with sexual desire disorder and functional sexual arousal disorder. The Pelvic Organ Prolapse Urinary Incontinence Sexual Question (PISQ-12) [179] assesses sexual function after surgery in women with Pelvic Floor Dysfunction and has been validated in women with urinary incontinence and pelvic organ prolapse. The Sexual Quality of Life–Female (SQoL-F) [181] is useful to assess the impact of female sexual dysfunction on quality of life, while the Sexual Satisfaction Scale for Women (SSS-W) [234] measures the women’s sexual satisfaction and distress in patients with pelvic floor dysfunction. The Sexual Function Questionnaire (SFQ) [180] is an instrument for both partners. This questionnaire also addresses some of the consequences of female sexual dysfunction for the woman, her partner and their relationship. Both the physical and the
cognitive aspects of sexual response are evaluated within the SFQ items. The Male Sexual Health Questionnaire (MSHQ) [235] assesses sexual function and satisfaction in older men with urogenital symptoms of LUTS and sexual dysfunctions.

**C Rated group:** The Women's Sexual Interest Diagnostic Interview--Short Form (WSID-SF) [228] is used to assess sexual function in adult women with hypoactive sexual desire disorder, The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire, IUGA-Revised (PISQ-IR) [236], and the Sexual Health Outcomes in Women Questionnaire (SHOW-Q) [237] to assess the impact of pelvic problems on sexual desire, frequency, satisfaction, orgasm, and discomfort.

The choice of which tool to use will be dependent on the type of patient, age, type of pelvic dysfunction and on research hypothesis. For instance, if you wanted to assess impact of OAB on sexual function e.g. arousal in women then the FSFI should be used rather than the SQOL-F because the FSFI has a specific arousal domain whereas the SQOL-F assesses sexual quality of life.

INTRODUCTION

This chapter is based on the 'Urodynamic Testing' chapter from the previous (ICI2013) consultation. The fifth consultation, ICI2013, updated the evidence for the technical performance, clinical utility and responsiveness to treatment of UDS for patients with UI. Testing for faecal incontinence was not included in the dynamic testing ICI2013. This ICI2016 chapter starts with a summary of the ICI2013 recommendations and conclusions in each of the paragraphs and
then provides relevant updates where from where we have evaluated the current evidence. Finally, the updated ICI2016 conclusions and recommendations are presented. Outdated references have been removed and new literature references are added. Publications less than one year before the consultation were deemed not to have stood the ‘test of time’ and so have not been included.

The primary aim of this chapter is to present what tests might be performed to elucidate the mechanism that causes UI in the individual and to make recommendations for practice. To this end, we present an overview of the best available recent scientific evidence about the role of UDS in clinical practice for patients presenting with UI. Based on the above, we provide recommendations, and the strength of the recommendation (A to D), for the current state of diagnostic assessment of the patient, or groups of patients with UI.

Each of the recommendations of the preceding consultation is re-evaluated and the discussion ends with new or renewed conclusions (with a level of evidence that follows the Modified Oxford Scale). Following on from that we present our new (ICI2016) graded recommendation(s) where necessary after considered judgement of the evidence (discussion). Where deemed useful we suggest topics(s) for research. Conclusion, recommendation and suggestions for research are highlighted in the text and are therefore suitable for ‘express reading’.

The chapter considers the evidence around UDS for patients with signs and symptoms of UI by reviews of the literature regarding clinical UDS of diverse patient groups with UI; which include the following discrete groups; Women, men, children, neurogenic lower urinary tract dysfunction (NLUTD) and the frail elderly. UDS of voiding dysfunction is not addressed specifically and only described where deemed relevant (more specific: when related to the UI).

I. WHAT ARE URODYNAMIC STUDIES AND WHAT SHOULD, IN GENERAL BE THE ROLE OF URODYNAMIC STUDIES IN CLINICAL PRACTICE?

INTRODUCTION

Urodynamic testing should be performed to objectively measure and document the entire LUT function and/or dysfunction. UDS should be done only when it can have therapeutic consequences; will change the patient’s management and/or when part of a surveillance or a research program. For this, the individual patient’s symptoms, including their impact in terms of bother and degree of hinder they cause as well as the impact of other relevant circumstances (like e.g. comorbidity or operability) should be kept in mind. UDS can show signs, not presented, such as e.g. (significant) postvoid-residual urine (PVR) or detrusor underactivity (DU), which may be relatively unnoticed by the patient, even when neurologically intact. UUT signs (dilatation) can exist or develop without any (new) symptoms, especially, but not uniquely in patients with relevant neurological abnormalities. Furthermore, the patient can present with complaints such as, ‘urinary frequency’, ‘nocturia’ or ‘recurrent UTIs’, which are difficult or impossible to reproduce in the usual UDS-laboratory. Nevertheless, in the usual setting of a UDS a feature of LUT function or dysfunction may be observed/measured that is relevant to these unnoticed phenomena and (therefore) explaining the person’s symptoms. Finally, UDS may provide a basis for the prevention of (signs or) symptoms to arise that are at the time of the testing not presented by the patient; e.g. urinary retention or UUT dilatation or deterioration.

UDS allows direct assessment of LUT function by the measurement of relevant physiological parameters (ICS-ST2001 1) and invasive UDS is defined as any test that is invasive, i.e. involving insertion of one or more catheters or any other transducers into the bladder and/or other body cavities, or insertion of probes or needles, for example for (needle-) EMG measurement1 (ICS-GUP2016).

The point of a clinical /biological test is that it will show a result on a continuum between what is considered normal physiology and pathology; and UDS is no exception to this. The key to determining the cause of the signs and/or symptoms of LUTD will be to reproduce the function and the dysfunction of the LUT of the individual patient. The implicit consequence of this is also that ideally at least one complete filling (storage) and pressure-flow (voiding) cycle, that adequately represents the patients problem (e.g. with regard to volumes) including post voiding features, (PVR, or after contraction) should be tested, analysed, and documented, even if only storage or only voiding signs or symptoms have been expressed by the patient. Last but not least: when LUT sensation is altered, as is frequently in patients with NLUT, the symptoms are even less reliable than those of patients with intact sensation, making UDS as an objective evaluation to advise or justify a specific management even more important.

The role of UDS in broad clinical perspective can be:

a. To identify all factors that contribute to the LUT-dysfunction signs (e.g. UI) and/or are the origin of the symptoms (e.g. frequent voiding) and assess their relative importance;

b. To obtain information about all other aspects of LUT function or dysfunction; whether or not expressed as a symptom or recognisable as a sign;
c. To allow a prediction of the possible consequences of LUTD for the UUT;
d. To allow a prediction of the outcome, including undesirable side effects, of a contemplated treatment;
e. To confirm the effects of intervention or understand the mode of action of a particular type of treatment for a LUTD; especially a new and/or experimental (not routine) one;
f. To understand the reasons for failure of previous treatments for UI, or for LUTD in general (after unsatisfactory treatment).

UDS is the gold standard to assess LUT function and dysfunction. Some studies have challenged UDS with a clinical diagnosis as the comparator. Specifically, the ‘clinical diagnosis of SUI’ was used as a predictor of outcome of suburethral tapes in a very selected group of patients.\(^4\) When this clinical diagnosis – not standardized in general and not for these trials- had been compared with one specific element (filling-cystometry) of the –not (always ICS) standard- UDS diagnosis (and also including patients with DO\(^6\)) neither way of diagnosis has been superior for the patients recruited in this study with signs and/or symptoms of SUI-S. The question remains whether the overall outcome of the surgery (or alternatives for some of the patients) could have been better than the ±65% overall success rate (dry, without other symptoms e.g. frequent voiding), when a more structured clinical as well as UDS diagnosis and/or analysis had been used in these studies.\(^4\)\(^6\)

### UDS in clinical practice evaluates a person’s LUT function with at least one complete and representative filling-voiding-post voiding cycle by testing with relevant pressures and flowmetry. UDS includes quality control, subsequent analysis, and systematic documentation.

#### 1. UROFLOWMETRY

This is the non-invasive measurement of urine flow rate applicable for both women and men, as well as for children. The general principles are identical although voiding position is relevant,\(^7\) and a small series of young men voiding in the healthy range shows that time after ejaculation may play a role.\(^8\) Uroflowmetry is also relevant for patients with neurological abnormalities, when they are able to (and do) use a toilet in the daily life situation. The patient voids into a flow meter in private, ideally with a normal to strong (but not uncomfortable) desire to empty their bladder.\(^9\)\(^10\) Urine flow rate is continuously measured and displayed graphically. Various parameters from the trace are automatically calculated and printed out together with the trace. After control for artefacts in automated calculations, the maximum flow rate, the volume voided and shape of the curve are usually the principal determinants of whether or not the patient is emptying their bladder in a normal way. Flow rate-volume dependency should be considered. If an abnormal voiding occurs, it is good clinical practice to repeat the assessment to attempt to reproduce normal behaviour. Several factors, such as patient apprehension, can give an abnormal recording in patients who have no voiding difficulty. Asking the patient about what she or he thinks about the voiding; whether the voiding was an adequate representation of their usual voiding, (if possible: comparison with the usual voiding diary -volume) must be regarded as good urodynamics practice. Repeating the assessment can remove such confounding factors. Unambiguous and careful instruction of the patient, privacy and a short meatus to flowmeter distance are all inherently relevant.\(^11\) The committee has not found any relevant technical changes or innovations to uroflowmetry equipment since 2013.

### 2. FILLING CYSTOMETRY

This is the measurement of the pressure inside the bladder to assess its storage capabilities. It is an invasive test which involves a catheter being placed into the bladder, usually transurethrally, and another catheter being placed rectally, vaginally or through an abdominal stoma to measure abdominal pressure. Subtracting the indirectly measured abdominal pressure \((p_{abd})\) from the pressure measured inside the bladder (intravesical pressure, \(p_{ves}\)) gives a representation of pressure changes due to the action of the detrusor smooth muscle, the detrusor pressure, \(p_{det}\) \((= p_{ves} - p_{abd})\). During this assessment, the bladder is usually filled with normal saline solution, or x-ray contrast solution in the case of VUDS, either through a separate catheter placed transurethrally or through the filling channel of a dual lumen catheter, if used. Usually the filling rate is much faster than physiological bladder filling (which is 1-2mL/min) and therefore referred to as non-physiological in ICS terms. The bladder will become filled in about 10 minutes when a 10% of ‘estimated usual capacity –based on voiding diary (taking into account the PVR whenever possible)’ is taken as the filling rate (mL/m).\(^3\)

The intravesical, abdominal pressure and the calculated detrusor pressure are monitored as the bladder is filled and before the patient has been given ‘permission to void’. The storage ability of the bladder is assessed in terms of the volumes required to elicit various sensations from the patient, its cystometric capacity, its compliance (passive muscle adaptation to volume stretch and detrusor muscle relaxation), and the presence or the absence of phasic detrusor pressure rises. The filling (storage) phase of cystometry is the when USUI can be assessed by means of coughing or straining, on the request of the clinician.\(^12\) Good urodynamic practice demands that all three of abdominal, intravesical and detrusor pressures are evaluated to diagnose urinary bladder storage function. The committee has not become aware of any
changes after 2013 in technique of cystometry. Pelvic muscle EMG during cystometry is not ICS standard and not further discussed in this chapter (see chapter on imaging and neurophysiological testing for this). Alternatives for ICS standard water (saline) filled catheters and tubing are being evaluated and will be discussed in a separate paragraph. Specific attention to artefact and errors merits attention and has been included in the update of the ICS Good Urodynamic Practices.\textsuperscript{13} \textsuperscript{14} \textsuperscript{15}

3. PRESSURE-FLOW STUDIES (VOIDING CYSTOMETRY)

This is a measurement of the mechanics of micturition. When the filling phase of cystometry is complete, the patient is given ‘permission to void’ and will empty their bladder into a flow meter whilst intravesical, abdominal and detrusor pressures are being recorded. The simultaneous measurement of flow rate and pressure enables voiding to be assessed and pressure flow analysis can help determine whether a slow urine stream is due to BOO or to DU or to a combination of both. Pressure-flow studies can also assist in the diagnosis of detrusor-sphincter dyssynergia and a clearer description of dysfunctional voiding and/or quantification of outlet dynamics during voiding. Similar precautions as for uroflowmetry must be taken regarding representativeness, artefacts and patient apprehension. Since 2013 no new studies have been published about the technique of pressure flow testing. Analysis of pressure flow regarding detrusor (underactive –DU-) contraction or ‘contractility’ during voiding has received increased attention and is suggested to be of future relevance.\textsuperscript{16} \textsuperscript{17}

4. URETHRAL PRESSURE PROFILOMETRY

This is a test to estimate the urethra and the surrounding structures’ ability to maintain a closed bladder outlet, allowing the body system to contain urine within the bladder. A catheter is placed transurethrally into the bladder and then withdrawn along the urethra (usually by a mechanical puller at a constant rate). Catheters that use water perfusion but also catheters with microtip pressure sensors or catheters with air filled (‘charged’) balloons are used to this aim. The pressure along the length of the urethra is measured and interpreted relative to the pressure inside the bladder or abdomen. The maximum pressure measured in the urethra is assumed to give an indication of the urethral closure function. The clinical relevance of UPP is frequently discussed in the literature and alternative technical systems to measure urethral pressure or function have been published and will be discussed in following paragraphs.

5. ABDOMINAL LEAK POINT PRESSURE

This test estimates the urethra’s ability to contain urine within the bladder. Intra-abdominal pressure is measured whilst the patient is asked to increase their abdominal pressure by Valsalva or by coughing. The abdominal pressure required to produce leakage from the bladder gives an indication of the closure function of the urethra. Diverse methods as well as reference pressures are used. New evidence (since ICI2013) for the relevance of LPP measurements and variants of LPP will be discussed in the specific paragraphs of this report.
ICI2013 also advised evaluation of how their system compares to the standard reference values for clinical relevant limits of pressures obtained with the ICS standard water-filled systems.

Studies comparing measurement of urethral pressure by air-filled catheters with measurement by microtip catheters have indicated that the values obtained are statistically significantly different, but are more reproducible with the air-filled systems. In laboratory bench-top studies, water-filled catheters were reported to act as an under damped system, while less sensitive to motion artefacts, whilst air-filled catheters acted as an over damped system; while less sensitive to artefacts, they were slower in response. Another report concluded however that the signal could be adjusted to compensate for this difference. Air-filled catheters have several practical advantages over water-filled pressure lines because there is no hydrostatic pressure effect (as is occurring in - the tubing of a water-filled system) to account for, so that there is no need to position external sensors at a standard reference level. (Which is the level of the symphysis pubis by ICS convention.) Air filled system have no requirement to fluid flush the system to exclude air, a process that is essential in a water-filled tubes pressure-sensing environment. Also, there are no pressure (tube wagging or knocking) artefacts produced when the patients move. In order to compare water-filled systems with the air-filled systems during live UDS, two studies conducted pressure measurements in female patients with both systems simultaneously, one study with 20 patients and one with 51 patients. Both studies reported that the systems were not interchangeable, since values obtained from each were significantly different, the larger study stating that values could vary between systems by up to 10 cmH2O (the 95% limits of agreement). Pressure offset, as observed, differences are not particularly relevant in (urodynamic graph) pattern analysis, however when absolute (subtracted) pressures become relevant as in pressure flow analysis or urethral pressure profiles the possibility of clinically relevant differences exists. Studies that refute or confirm this are not yet available. Thus, more recently, a review paper has recommended that further validation of measurement techniques with air-filled systems should be done before its clinical similarity can be established. Further research must be carried out in order to identify what has caused the observed differences in pressure readings obtained, by evaluating the potential sources in the air-filled system however also in the (ICS standard) water-filled system.

1.2. Conclusions

- Air-filled catheters may provide an acceptable alternative to other techniques for measuring the pressure closing the female urethra however normal –or reference- values have not been established. (level 3)
- Studies show that air-filled catheters record different pressure values to water-filled lines in UDS and are therefore not interchangeable. (level 2)
- Air-filled catheters have not been tested in men or in children, or in patients with NLUTD.

1.3. Recommendation (Grade C)

- Investigators planning to use air-filled catheters for intravesical and intra-abdominal pressure in UDS are advised to check for themselves that they have an equivalent performance to their current system for measuring pressure.
- Investigators planning to use air-filled catheters for intravesical and intra-abdominal pressure in UDS are advised to check for themselves how the performance of their system compares to the standard reference values for clinical relevant limits of pressures obtained with the classical systems.
- Clinicians using UDS should be well aware of the technical demands of measuring with a water-filled –external pressure system and should be able to (prevent and correct and) recognize these, also in post test evaluation.

1.4. Topic for Research

- Studies to compare the performance of air-filled catheters with (ICS- standard) water-filled pressure lines in the measurement of intravesical and intra-abdominal pressure during filling and voiding cystometry, to include ‘fast’ events such as coughing, in male, neurological and paediatric patients as well as analysis of test-retest reliability.
- Studies to determine the cause(s) of the earlier observed differences in pressure readings between water-filled and air-filled systems.
- Studies to determine the clinical relevance of difference in pressure readings between water-filled and air-filled systems.
- Studies to demonstrate the technical stability and clinical reliability of practice with the water-filled external pressure reference UDS systems.
- Studies to establish standard values for filling cystometry and pressure flow study in women.

2. OBJECTIVE ASSESSMENT OF BLADDER SENSATION

2.1. Conclusions and Recommendations 2013

Based on published results ICI2013 noted that there was a significant variation in clinical practice to determine bladder filling sensation landmarks and maximum cystometric capacity despite the standardisa-
tion of terms. The committee concluded that strategies to derive bladder filling sensation parameters in a more automated and objective way (with patient controlled electronic analogue scale registration), have been showing plausible and applicable results. ICI2013 stated that these were however not sufficiently tested with regard to reliability, relevance, investigator independency or test retest robustness.

Bladder sensation during UDS is usually recorded by the simple expedient of asking the patient to inform the investigator when they experience different sensations. This is ICS standardised, but subjective, measurement that can be confounded by the investigators inadvertently or deliberately distracting the patient whilst bladder filling is being carried out. Investigators can also bias the measurement by inadvertent prompting, or by causing too much ‘concentration’ and unrepresentative awareness of the patient. Bladder filling sensation has received increasing attention since urinary urgency and early filling sensations are clinically important and some treatments are believed to influence LUT sensation.27 28

A patient-activated, keypad 'urge score' device to measure sensations during bladder filling was introduced29 that provided reliable and repeatable measures of different bladder sensations, however this never found its way into clinical routine. Filling sensations during conventional UDS were marked on a body map and this study suggested that women's bladder sensations vary in relation to their bladder condition.30

Daily life bladder sensation can be evaluated by a sensation related bladder diary and during cystometric bladder filling. 185 women with SUI-S, OAB-S or mixed UI filled out a 3-day bladder diary grading bladder sensation and measuring VV at each micturition. The maximum cystometric sensation (FS and ND) volumes were significantly larger than the diary VVs for corresponding bladder sensations, and this in all groups, leading to the conclusion that symptoms relate more to the diary.31 In the development of the ICIQ bladder diary, the data from 264 patients diary recordings of urinary urgency showed weak agreement with questionnaire responses and UDS observations.32 Although cystometry is regarded the gold standard to assess bladder filling sensation there is a paucity of evidence regarding its clinical relevance; also the question whether cystometry or alternative (diary –like) evaluations are more relevant remains unanswered.

Research has provided some in vivo evidence of the specific brain areas that are involved in LUT sensation, control and modulation, but this type of observations cannot yet be regarded as a replacement of cystometry, because up to now no brain pattern has been found to correlate with a specific UDS abnormality.33 34

Many studies consistently show that the correlation between objective and subjective features of detrusor adaptation to volume increment, bladder proprioception and the subjective interpretation of filling is weak.35 36 37 38 39 40 41 In fact these observations also demonstrate that UDS is adding new and objective diagnostic information to what has been gathered with history, voiding diary and clinical investigation. Both UDS, as well as signs and symptoms, are relevant to select further treatment, for instance in the identification of DU.42

2.2. Conclusion (Level 3-4)

• Based on published results, a significant variation exists in clinical practice to determine bladder filling sensation landmarks and maximum cystometric capacity, despite the standardisation of terms.

• Strategies to derive bladder filling sensation parameters in a more automated and objective way, have been published and show plausible and applicable results, however these have not been sufficiently tested regarding reliability, relevance, investigator independency or test retest robustness.

2.3. Heart Rate Variability

Heart rate variability was evaluated to serve as a monitor of the autonomic nervous system as an objective measure (indicator) for LUTD and/or bladder filling sensation, without arriving at a clinical application yet.43 44 46

2.4. Conclusions (Level 3-4)

• None of the analysis or testing methods of the autonomic nervous system has, to date, shown any relevance for the objective diagnosis of LUT function in neurologically intact persons.

3. NON-INVASIVE PRESSURE (& FLOW) MEASUREMENTS

Non-invasive measurements of bladder pressure during voiding in men by the penile cuff or condom catheter have been shown to correlate with traditional invasive measurement of bladder pressure. ICI2013 concluded (grade B) that non-invasive measurements of bladder or detrusor ‘voiding- pressure’ can be considered in clinical experiments in order to evaluate voiding function when the male patient is not required to undergo an invasive assessment of the storage function of the LUT. The ICI2013 did not recommend condom or penile cuff pressure, nor near infra-red detrusor spectroscopy, for the diagnosis UI, or of LUTD. 46 47 Recently a device to measure isovolumetric (maximum) pressure during voiding at the location of the fossa navicularis. The pressures obtained correlated with BOOI based on detrusor pressure at maximum flow rate, but have not been tested for relevance for UI.48 49 Measurement of perineal noise during voiding as another way of non-invasively quantifying male BOO has been evaluated but has also not
demonstrated relevance for the diagnosis of (male) UI.\textsuperscript{50}

Transabdominal wall near-infrared spectroscopy was used to detect the haemodynamic changes that are associated with detrusor contractile activity. This has been demonstrable in a highly selective set of feasibility recordings and may lead the way for non-invasive detection of detrusor (over-)activity.\textsuperscript{51, 52} Another group has however not been able to replicate this.\textsuperscript{53} The use of perineal ultrasound to detect turbulent flow in the male urethra has been reported.\textsuperscript{54} Both near infrared spectroscopy and perineal ultrasound have not been tested, or are not applicable, for patients with UI.

3.1. Conclusions (Level 3)

- Non-invasive measurements of bladder pressure during voiding in men by the penile cuff or condom catheter have been shown to correlate with traditional invasive measurement of bladder pressure. None of these studies have shown any applicability in the diagnosis of UI.

- Near-infrared detrusor spectroscopy has in very selected recordings shown a relation with detrusor (over)activity but this has not been reproducible in an independent clinical follow up evaluation.

3.2. Recommendation (Grade B)

- The committee endorses that in clinical experiments non-invasive measurements of bladder or detrusor pressure may be considered in order to evaluate voiding function when the male patient is not required to undergo an invasive assessment of the storage (and continence) LUT functions.

- The committee does not recommend condom or penile cuff pressure, nor near infrared detrusor spectroscopy, for the diagnosis of UI, or of LUTD.

4. URETHRAL RETRO-RESISTANCE PRESSURE

In the measurement of urethral retro-resistance pressure (URP), a small metal plug is inserted just inside the female urethra and saline is pumped into the urethra until the pressure reaches the value sufficient to overcome the resistance offered by the urethra when the fluid flows into the bladder. The pressure required to achieve and maintain an open bladder outlet is taken to be a measure of urethral closure function. The basic principle behind the technique has its origins in 1923 when Bonney made an attempt to measure the efficiency of urethral closure.\textsuperscript{55} Slack et al studied 258 SUI-S women with the URP technique in comparison with MUCP and Valsalva LPP. The URP, in a group of 61 women, without symptoms of UI and who had negative standing UI tests, was significantly higher than in a group of women with SUI-S who had been tested previously.\textsuperscript{56} This study also provided some test-retest data, which showed that URP measurements were consistent in individuals. Measurements of URP on 165 women with various UDS diagnoses were published subsequently.\textsuperscript{57} Women with USUI had significantly lower URP than women with competent urethral sphincters. In the mixed symptoms group, URP mean values were not significantly different from those with DO competent sphincters, or those with USUI. The authors concluded that whilst there are significantly different URP measurements between women with DO and those with USUI, URP is not a diagnostic tool. An analysis of URP in 48 women with (clinical) SUI-S and also USUI, without pelvic organ prolapse (POP) before and after anti-UI surgery (colposuspension n = 8, TVT n = 6, TOT n = 34) and another study to compare URP with ‘established measures of UI severity’ showed that preoperative URP did not correlate with SUI-S in all women, had no predictive value and did not correlate with the outcome of anti-UI surgery.\textsuperscript{58, 59} As for women, retrograde pressures are obtainable for men also and have shown to correlate with 24-hour pad test volume.\textsuperscript{60}

4.1. Conclusion (Level 2/3)

- After positive first reports of urethral retro-resistance pressure measurements it was shown that this measurement does not give any better information about urethral closure function than the urethral pressure profile or Valsalva LPP.

4.2. Recommendation (Grade B/C)

- The committee recommends that urethral retro-resistance pressure measurements are not used in clinical routine as an alternative to cystometry or (when deemed necessary for) urethral pressure measurements made with conventional urodynamic equipment to diagnose female UI.

5. URETHRAL PRESSURE REFLECTOMETRY

Urethral pressure reflectometry was evaluated in an in vitro study for the simultaneous measurement of cross-sectional area and pressure in a collapsible biological tube to assess the female urethra.\textsuperscript{61} The team postulated that these parameters had the potential to provide more physiological information about the urethra than could be obtained from conventional urethral studies. These investigators compared UPR with urethral pressure profilometry (UPP) in 143 women (105 patients and 38 healthy volunteers).\textsuperscript{62} UPR was measured supine, both while relaxed and during “squeeze”, and while upright and relaxed, and compared with UPP using the perfusion technique, with the patient supine and relaxed. Short-term reproducibility and long-term reproducibility were also assessed. The authors showed that UPR measured the same pressure as UPP but the UPR was more reproducible, however clinical relevance of
this observation was not specifically discussed. Subsequently UPR parameters of in 30 SUI-S women and 30 volunteers (23 'continent' and 7 'nearly continent') were reported and compared with UPP. A feasibility study using the technique has now been reported in 10 male patients.

5.1. Conclusion (Level 3)
- Preclinical measurements of urethral pressure reflectometry opening pressure and cross sectional area (‘dynamics’) have provided some insight into urethral closure function and dynamics, but, as yet have no clinical relevance in the diagnosis of UI.

5.2. Recommendation (Grade C)
- The committee recommends that urethral pressure reflectometry is not used in clinical practice for the diagnosis of UI before clinical relevance, non-inferiority and/or superiority over current UDS has been demonstrated.

6. ULTRASOUND IMAGING

Imaging and ultrasound in relation to UI will be discussed in a separate chapter of this book. We will only give a short summary of ultrasound in relation with UDS observations.

The measurement of detrusor wall thickness has been used in several studies as a screening test for DO or for BOO with a variety of measurement techniques using transvaginal, transabdominal or transperineal ultrasound. Different protocols were used and measured different parts of the bladder. This has resulted in contradictory data. Some data showed a smaller cystometric capacity in OAB-S -wet or DO, and an association between increased detrusor wall thickness and DO on UDS. Also, observations of an association of ultrasound detrusor wall thickness and BOO have been reported. Most researchers conclude that overlap of the results and the relatively low predictive value should be improved before bladder wall thickness is used in clinical practice. Especially the specificity of detrusor wall thickness for UI (or DO) is not determined and probably unlikely. Studies of specific (other) patient groups have been reported. One, in SCI patients, concluded that detrusor wall thickness could not be used in such patients and another in nocturnally enuretic children suggested that detrusor wall thickness could be applied as a screening tool to select children with DO.

Twenty men (mean ± SD age 66 ± 6 years) with LUTS were included in a study to evaluate radio frequency ultrasound imaging -detrusor wall strain. This bladder wall strain correlated positively with detrusor pressure in some patients with a (urodynamic) isovolumic and/or voiding detrusor contraction. It has however been difficult to continuously measure the bladder wall in a large proportion of the patients.

6.1. Conclusion (Level 3)
- There is some evidence that detrusor wall thickness is related to BOO as well as to DO.
- There is no evidence that ultrasound detrusor wall thickness analysis can discriminate between DO (with or without UI) and BOO. Detrusor wall thickness has a relatively low predictive value to discriminate from normal LUT function.
- There is a large overlap between normal and abnormal values in detrusor wall thickness and a lack of standardisation in ultrasound detrusor wall thickness measurement.

6.2. Recommendation (Grade C)
- The committee recommends that ultrasound detrusor wall thickness not be used in routine clinical practice for the diagnosis of LUTD related to UI.

III. URODYNAMIC STUDIES: NORMAL VALUES, RELIABILITY AND DIAGNOSTIC PERFORMANCE; REPRODUCIBILITY AND RELIABILITY OF URODYNAMIC STUDIES (ESPECIALLY UROFLOWMETRY CYSTOMETRY AND PRESSURE-FLOW STUDY)

1. CYSTOMETRY: NORMAL VALUES AND TEST RETEST VARIATION

1.1. Conclusions and Recommendations 2013
The ICI2013 concluded that various studies have been helpful in giving normal values and test retest variation of UDS parameters in healthy volunteers. But also, that there has been some evidence that evaluation of filling sensation may be different between laboratories, (thus: ‘may be observer dependent’), making data exchange as well as generalization and interpretation of published data difficult. The ICI2013 recommended (Grade B) that investigators and clinicians bear in mind the results of UDS in healthy persons and to recognize ‘normal’ test-retest variation as well as the differences and/or variations between ‘usual lower urinary tract behaviour’, ambu-
latory monitoring and office UDS. The ICI2013 further suggested that clinicians should be sufficiently aware of the normal variation, and normal values of LUT function and UDS and recommended further standardisation and a practical objective means of recognizing and recording the parameters relevant to sensation during bladder filling.

The ICI2013 has reported that several studies have been showing test retest variation of ±10-15% for various parameters (volume, pressure or flow) and observations; It was concluded that this can be regarded as the physiological variation of UDS. However also was concluded that various studies demonstrated clinically relevant practice variation and inter-rater/observer variation. In ICI2013 the committee recommended (grade B) that investigators and clinicians consider the inherent physiological variability of UDS and furthermore that investigators and clinicians evaluate the representativeness of the tests (which is an evaluation based on the patient’s perception as to how well the tests have reproduced their usual LUTS and (dys)function, helped e.g. by the voiding diary. The ICI2013 had recommended that examiners strive towards maximal representativeness. Also, the ICI2013 recommended the sitting/upright position during cystometry to be most sensitive to reproducing DO. The ICI2013 recommended persistent attention to the standardisation of techniques, to education, and to practice quality evaluation, and consistency of interpretation of results, especially to reduce intra and inter-practice variation and inter–observer variability.

1.2. New Evidence 2016

The committee has not found new evidence regarding normal values of urodynamic tests.

The committee has also not found new evidence about test retest reliability of standard UDS. One health care system has proposed a national quality standard for UDS.80

1.3. Conclusions

The committee concludes that limits of normality of urodynamic tests are well established. (level 2)

The committee also concludes that precise limits for abnormal (reduced) compliance are not exactly known. (level 3)

The committee concludes that LPP has many variations (also without cystometry) and that standardization of technique(s) is lacking. (level 3)

1.4. Discussion

Normal function and physiology of the LUT is the basis for diagnosis of abnormality and dysfunction. Based on the commonly accepted limits of normality a specific dysfunction can be diagnosed.

There is a risk for UTI after UDS. A systematic review evaluated nine randomized controlled trials and concluded that prophylactic antibiotics did reduce the risk of bacteriuria after UDS but there was not enough evidence to suggest that this effect reduced symptomatic UTI.81

1.5. Recommendations (Grade C)

Persons diagnosing LUT function and dysfunction should be sufficiently aware of normal variation in the results of UDS. Persons should also be sufficiently aware of normal values and normal variation of LUT function and dysfunction.

Routine antibiotic prophylaxis should not be prescribed for UDS testing; the procedure should be performed sterile and aseptic as per good clinical practice.

2. REPRODUCIBILITY OF AMBULATORY URODYNAMIC STUDIES

2.1. Conclusions and Recommendations 2013

At the time of ICI2013 there has not been published data on the reproducibility or test retest differences of ambulatory UDS. Recently test-retest repeatability of the UDS parameters commonly utilized in ambulatory UDS for patients with NLUTD was evaluated on 64 consecutive patients with stable SCI who underwent two AM studies 24 hr apart. AM parameters were reliable for the reproduction of the main UDS parameters investigated in patients with NLUTD, except for the end filling detrusor pressure. Balancing (zeroing) the abdominal and vesical pressures was reported to be a problem in this study.82

2.2. Conclusion (Level 3)

One single centre study reported reproducibility of some parameters resulting from ambulatory UDS for patients with a NLUTD.

2.3. Discussion

Movement artefacts, pressure calibrating, and assessment of fill volume as well as prevention of urodynamic catheters to dislocate are challenging in ambulatory monitoring and standardization of the test is likely of relevance.83

2.4. Recommendations (Grade B-C)

- The committee does not recommend ambulatory UDS as a routine diagnostic test for patients with UI.
- The committee recommends greater attention to test retest differences of ambulatory monitoring
- The committee recommends standardization of the practice and the (technical quality-) analysis of ambulatory UDS.
3. INFLUENCE OF CATHETER ON VOIDING

3.1. Conclusions and Recommendations 2013

There is evidence that, in general, flow is reduced when voiding with a urodynamic catheter in the urethra and that this reduction is partially caused by the size of the catheter and it has been the opinion of ICI2013 that single catheters 6-8Fr incorporating both a filling channel and a pressure-sensing channel should be used for intravesical pressure measurement during cystometry (i.e. double lumen catheters in the case of using water-filled pressure lines). The ICI2013 recommended that investigators interpret pressure-flow voiding parameters and the subsequent PVR together with the free flow (not catheterised, representative) voiding parameters. Furthermore the ‘standard’ use of, as thin as possible, ‘one-catheter-systems’ (dual lumen if water-filled) for filling and pressure recording during UDS was recommended by ICI2013.

The committee found one new study that confirmed differences between free flow and UDS (catheterized pressure) flow. The differences were large and VV differences were not given, nor the voiding position or pressure flow. The differences were large and VV differences between free flow and UDS (catheterized) were reported.84 A small single centre series concluded that the effect of a 4Fr catheter has been negligible.85

3.2. Conclusion (Level 3)

Recent studies have confirmed that the transurethral catheter that is necessary for pressure flow caused an effect on voiding and flow rate that is more or less proportional to the size of the catheter.

3.3. Discussion

Both test retest variation as well as variation in circumstances (e.g. position; privacy; (pre) VV) play a role in ‘dynamic differences’ between two flow rates. And especially the potential effect of position (for men) and privacy has not been reported in flow-pressure flow study. Also, differences may be large, especially in relatively high flow rates (>15mL/s) without clinical relevance. The committee considered that a dual catheter system is disadvantageous because of the manipulation just before the voiding as well as for the need for re-catheterisation when a second test is deemed to be necessary. 6-8Fr catheters are ICS standard and pressure flow categories are based on measurements with catheters or this size, however only in male patients.

3.4. Recommendations (Grade A-B)

- The committee recommends that investigators interpret pressure-flow voiding parameters and the subsequent PVR together with the free flow (not catheterised, representative) voiding parameters when relevant in the diagnosis of concurrent LUTD, together with the complaint of UI.
  - Standard of, as thin as possible, ‘one-catheter-systems’ (dual lumen if water-filled) for filling and pressure recording during UDS are recommended. If such system is not available, a double catheter system with removal of the filling line, before voiding or while testing stress- or DO UI (-LPP) is acceptable.

4. URETHRAL PRESSURE MEASUREMENTS

4.1. Recommendations 2013

ICI2013 concluded that diverse studies have shown considerable test-retest variation of all urethral pressure measurements or parameters and that normal and pathological values of urethral pressure parameters are largely overlapping. Furthermore, it was concluded that urethral pressures depend on the pressure recording catheter used and its orientation within the urethra and depend on patient position, volume of fluid in the bladder and position of the patient. The ICI2013 recommended that investigators and clinicians recognize the poor sensitivity and specificity of urethral pressure measurements and their significant test retest variation. The committee did not recommend urethral pressure measurement as the only UDS in patients with UI either to confirm or to refute USUI and that these measurements are judged in relation to other UDS (such as cystometry) and to the clinical examination.

5. LEAK POINT PRESSURES

5.1. Introduction

5.2. Recommendations 2013

ICI2013 concluded that diverse (definitions and) techniques to determine (urine) LPP exist and also that there is a weak association between abdominal LPP and the patient experienced or measured severity of bother, or amount of UI. Studies have shown that different techniques and patient positions influence the results of LPP. Studies evaluated by ICI2013 showed that the parameters from abdominal LPP measurements are not very helpful as predictors of success from surgery with either tension free vaginal tape or transobturator tape in patients with SUI-S. The ICI2013 did not recommend abdominal LPP measurement as a single UDS in patients with UI either to reject the diagnosis of USUI, or to select treatment and recommended that the result of abdominal LPP, when performed on patients with UI, should be judged in relation to other UDS such as cystometry.
and to the clinical examination. The ICI2013 considers ‘detrusor leak point pressure’ in patients with NLUTD a relevant parameter. This is discussed in section III (neurogenic LUTD) and in section IV (patient evaluation: children).

### 5.3. New Evidence

Valsalva (abdominal) LPP was used in a study to evaluate the effect of urethral submucosal injection of bulking agent in patients with SUI-S (no –further- UDS was done) but no changes were reported although 50% of patients considered themselves as dry 1 year after the treatment. In another study, to relate though 50% of patients considered themselves as dry UDS was done) but no changes were reported alt-

LPP 60-90cmH2O (mean 75cmH2O). The overall sub-
tween intraoperative urethral circumference and arti-
valurinary sphincter cuff size affects postoperative

RRP UI, Valsalva LPP was evaluated as a predictor evance with regard to outcome. With regard to post

primary study questioned whether a difference be-
egression midurethral sling procedure in female

USIU, 112 patients were evaluated according to pre-

operative VLPP values were not predict-
gling outcomes of this treatment. With regard to post

RRP UI, Valsalva LPP was evaluated as a predictor of outcome in a retrospective cohort of 87 men. The primary study questioned whether a difference between intraoperative urethral circumference and arti-
ficial urinary sphincter cuff size affects postoperative

outcomes. But LPP before AUS did not show any re-

levance with regard to outcome. Valsalva LPP was

found to increase while an intravesical balloon was

placed but the amount of LPP change was not asso-
ciated with UI and/or pad-test volume urine loss in a

prospective study of 166 women with SUI-S of whom

one third received sham treatment.

### 5.4. Conclusion (Level 2-3)

New studies showed no evidence that (the height of) abdominal LPP is helpful as predictor of success of surgery in patients with SUI-S or patients with post RRP UI.

### 5.5. Recomendation (Grade B)

- The committee does not recommend abdominal LPP measurement as a single UDS in patients with UI.

### 6. FILLING CYSTOMETRY AND SENSITIVITY AND SPECIFICITY OF SYMPTOMS

#### 6.1. Recommendations 2013

Many studies evaluated by ICI2013 showed a weak correlation between symptoms and the result of UDS, especially filling cystometry, in patients with UI. The ICI2013 concluded that the sensitivity and the specificity of the symptoms, when systematically assessed and voiding diary is included, is at best and in the ‘most typical patients’, around 60-70%, in comparison with the result of the objective results of UDS.

In general, the ICI2013 committee considered the correlation of the SUI-S (expressed, or questioned) with the result of UDS is somewhat better than the correlation of urgency or UUI (expressed, or questioned) with UDS and concluded that especially when frequent voiding, urgency and/or UUI is part of the symptom complex of patients with UI, UDS is of value to obtain an objective (urodynamic) diagnosis, prior to invasive therapy. Taking into account the variation between various institutes and the test-retest variation, the ICI2013 considered it relevant that investigators and clinicians judge also how adequate the results of the performed tests represent the individual patients’ symptoms. The ICI2013 recommended (grade B) UDS in patients with UI when an objective diagnosis is warranted. This is commonly the case when symptoms do not exclusively direct to SUI-S, or when (for all types of UI) conservative measures have not been successful, or when relevant co morbidity exist or relevant previous surgery has been performed. The ICI2013 recommended interpretation of the results of the complete UDS in relation with the symptoms, signs from the clinical (or other) examinations in conjunction with the voiding diary in all pa-

#### 6.2. New Evidence 2016

UDS is the gold standard to assess LUT function and dysfunction. Some studies have challenged UDS with a clinical diagnosis as the comparator. Specifically, clinical diagnosis of SUI-S was used as a predictor of outcome of suburethral tapes in the VALUE trial. When this clinical diagnosis – not standardized for these trials- had been compared with one specific el-

ement (filling -cystometry) of the –not always ICS-

standard- UDS diagnosis, neither way of diagnosis has been superior for the patients recruited in this study with SUI-S. By doing UDS, it was reported in an abstract report) that a significant proportion of patients had DO demonstrating the poor specificity of the clinical diagnosis even in expert centres.

Distinguishing or defining characteristics of detrusor overactivity

#### 6.3. Recommendations 2013

Studies summarized in ICI2013 have not been able to show relevant differences in patterns or characteristics of DO whether the cause of overactivity (asso-
ciated with UI- or not) is neurogenic or idiopathic and diverse studies have not been unable to reliably quantify the severity of DO (with or without UI), in a clinically or scientifically applicable way. The ICI2013 recommended (grade C) that neither the cause (neu-
rogenic or idiopathic) nor the severity of DO is diag-
nosed on the basis of parameters from urodynamic investigation (cystometry).
6.4. New Evidence 2016

No further evidence about quantification or objective reproducibility of the detrusor filling phase pattern, related to the diagnosis of the LUTD leading to UI, has been published.

6.5. Recommendation (Grade C)

- The committee recommends that neither the cause (‘neurogenic’ or ‘idiopathic’) nor the severity of DO is diagnosed on the basis of parameters from urodynamic investigation (cystometry).

7. PROVOCATIVE MANOEUVRES

7.1. Recommendations 2013

A systematic review available at ICI2013 concluded that more DO is seen when the patient is in the sitting position during cystometry, when compared to the supine position. There has also been some evidence that moving to a toilet, and also hand washing, is strongly provocative of DO.

Evidence suggests that ice-water cystometry can be applied to elicit DO in patients with NLUTD and that a detrusor contraction during filling with ice-water can be interpreted as a sign of pathologic (existing only in patients with relevant neurology) C-fibre reflex activity. It has, however, also been shown in this regard that false-negative tests do occur.

The ICI2013 recommended that the results of provocative cystometry are interpreted in the light of the patients’ symptoms and to bear in mind whether the results obtained are representative. The ICI2013 recommended the performance of UDS in the sitting position whenever possible, because of the better sensitivity for filling phase abnormalities, but also because of the greater possibility of representative voiding and better patient comfort.

7.2. New Evidence 2016

The committee has not found new evidence regarding the position of the patient during cystometry.

7.3. Recommendations (Grade C)

- The committee recommends that the results of provocative cystometry are interpreted in the light of the patients’ symptoms and to bear in mind whether the results obtained are representative.

- The recommends the performance of UDS in the sitting position whenever possible, because of the better sensitivity for filling phase abnormalities, but also because of the greater possibility of representative voiding and better patient comfort.

8. CLINICAL APPLICATIONS OF URODYNAMIC STUDIES

8.1. Women with Urinary Incontinence

The diagnostic rationale for UDS in women with UI in association with the currently changing management paradigm has been debated for some time. The think tanks of the International Consultation of Incontinence Research Society (ICI-RS) have discussed this diagnostic rationale and suggest that the patients’ presentation can be more precisely delineated as syndromes. E.g. that the SUI syndrome (SUI-S), the overactive bladder syndrome (OAB-S), and the neurogenic LUT dysfunction syndrome (NLUTD-S) are suggested as more precise and descriptive terms that can be used to delineate categories of patients based on symptoms and signs. The diagnostic process for patients with LUTD should be carefully implemented and personalized to rationally select patients for invasive UDS and improve the outcome of initial management.

8.2. Urodynamic Evaluation is Recommended

- When a patient presents with symptoms and signs of LUTD (especially UI) that are not typically ‘SUI-S’ or ‘overactive bladder (wet) syndrome’ or not (typical) nocturnal enuresis (syndrome).

- When a patient presents with new or persisting symptoms and signs of LUTD after initial (or subsequent) management or when a patient, after initial management expresses the wish for alternative (and/or more invasive and/or irreversible) management.

IV. STRESS URINARY INCONTINENCE SYNDROME

1. URETHRAL PRESSURES AND SEVERITY OF STRESS URINARY INCONTINENCE

1.1. Recommendations 2013

Various studies have shown a weak association between UI severity and urethral function tests (LPPs and urethral closure pressures) and cohort studies have shown that UI volume and intravesical volume at leakages are poorly associated with symptoms’ severity and/or with patients’ quality of life. Furthermore, ICI2013 concluded that studies have shown that ure-
thral function tests (LPPs and urethral closure pressures) are of very little value in predicting the outcome of treatment with suburethral tapes. Studies to demonstrate any relevance of urethral function tests (LPP and urethral closure pressures) in predicting the outcome of non-surgical or other treatments for SUI-S are lacking.

The ICI2013 recommended (grade C) that urethral function measurements of LPPs and urethral closure pressures are not used as a single factor to grade the severity of UI and therefore did not recommend the use of contemporary urethral function tests for prediction the outcome of any surgical treatment for SUI-S.

1.2. New Evidence 2016

A new study published showed, validating the earlier evidence, that urethral pressure and/or LPP did not have a predictive value towards outcome after 6 months of TVT surgery, apart from the 6% patients with very low urethral pressures (<20cmH2O).91

Two expert opinion reviews have discussed the lack of evidence specifically for the management of patients with very low urethral, (leak point or closure) pressures and both have concluded that the many possible surgical solutions do not differ very much in outcome.92 93

1.3. Recommendation (Grade C)

The committee does recommend that LPP and urethral closure pressures are not used as a single factor to grade the severity of UI

The committee does not recommend the use of contemporary urethral function tests for prediction the outcome of any surgical treatment for SUI-S.

2. ASPECTS OF URODYNAMIC STUDIES RELEVANT TO THERAPY FOR STRESS URINARY INCONTINENCE

2.1. Conclusion and Recommendations 2013

ICI2013 reported that it has been concluded in a model study, based on a selected retrospective cohort that UDS is not cost effective in the primary health care setting for women with predominant SUI-S symptoms. The model demonstrated however also, that in a referred population UDS is the most accurate way to obtain an objective diagnosis in an individual patient with UI symptoms. The ICI2013 summarized that it has been concluded in retrospective and prospective cohort studies that symptoms of ‘pure SUI’ do not exclude other LUTD.

2.2. New Evidence 2016

Mixed UI has repeatedly been shown to have a poorer outcome than SUI-S alone in surgical trials.94 Despite this in one study OAB-S symptoms were reported to be more likely to improve rather than deteriorate after TVT in one study.95 However ‘de novo’ OAB-S symptoms were reported to arise in another.96 A study found in follow up of 200 patients after 10 years that persisting or new onset OAB-S is an important reason for dissatisfaction.97

The question is whether there is any role in predicting outcome other than differentiating mixed from pure USUI. Detrusor opening pressures have been investigated in outcome for colposuspension and fascial slings and found not to help whereas another study suggested opening pressures were predictive of outcome of retropubic tape surgery. These findings were supported by a further study the following year.100 A recent systematic review asked the question ‘does preoperative UDS improve outcomes of women undergoing surgery for SUI-S?’ 101 This review was importantly influenced by the VALUE study and concluded that the current evidence suggests that UDS does not influence the outcome of SUI-S surgery. The review supported the need for new properly constructed RCT’s for this. They highlighted the results of the VALUE study where, in a non-inferiority design, 93% of the 630 patients underwent surgery.4 They did demonstrate that 18 patients had the choice of surgery changed based on UDS, although the protocol design intended to omit the UDS results. A second study was again a non-inferiority design looking expressly at where the UDS findings were discordant with symptoms including 578 patients of which 268 were discordant. 126 women were randomised to surgery direct or individual tailored therapy.6 A further secondary analysis of the women VALUE study concluded that UDS did significantly change clinical diagnosis but that UDS – as was planned- infrequently changed treatment plan or influenced surgical decisions.102 This position has been further evaluated by the INVESTIGATE 1 study.103 This study was designed to demonstrate the feasibility of a RCT into the role of UDS for patients with SUI-S. The investigators concluded such a trial was feasible and their pilot data indicated that there was a change in practice based on UDS with 80% versus 95% undergoing surgery. The study wasn’t powered to demonstrate significance and the authors concluded that 450 patients would be needed in each arm to answer the question, which is more than the 2 (prospective) studies which have reported to date.

ICI2013 Initial assessment – committee has suggested ‘a simplified accurate and reproducible system for anatomic changes and establishing the likelihood or presence of SUI’ (p377-378: General recommendations in the female patient) as a research recommendation. In the absence of such system, to date, it is impossible to establish the need for UDS in a reliable manner. At present the predictive value of a clinical diagnosis towards the selection and the outcome of management are unknown. UDS can only be disputed (or discarded) as the gold standard when prospectively compared to its alternative; a reproducible systematically derived clinical assessment or
a well-defined ‘stress urinary incontinence syndrome’, and/or a precisely defined ‘urgency urinary incontinence syndrome’ (or ‘overactive bladder – wet syndrome’).

2.3. Recommendation (Level B)

The committee recommends that UDS is kept in mind when discussing costs (risks, harm) and benefit (objectivity of the diagnosis) of the various methods (clinical or UDS) of diagnosis for (LUTD and/or) UI, in relation to the method of treatment.

3. PREDICTION OF FAILURE OF SURGERY

3.1. Recommendations 2013

ICI2013 found that LPPs are reported not to correlate with failure (or success) rates of colposuspensions, transobturator and retropubic suburethral, bone-anchored suburethral slings and that there is conflicting evidence that low urethral closure pressures are associated with poorer success rates of sub-urethral slings. The ICI2013 recommended that measurements of urethral function (LPP and urethral closure pressures) are not used to predict the likelihood of success after surgical treatment for women with uncomplicated primary SUI-S.

3.2. New Evidence 2016

ICI2016 did not find any new evidence. The committee, however, reviewed some studies that commented on the new onset or persistence of OAB-S in women with mixed symptoms of UI. An extensive review of the outcome of all little invasive surgical techniques after minimal 2 years showed that ‘storage LUTS’ and ‘voiding LUTS’ had an overall similar prevalence of about 15%.104 A –very- long-time follow up study observed that the likelihood of being storage symptom- free declined steadily after each year until ±30% after 10 years, whereas voiding symptoms stabilised after the first year but further increased in prevalence after 6 years.105

4. VOIDING DIFFICULTIES AFTER SURGERY

4.1. Recommendations 2013

ICI2013 concluded that female voiding dysfunction has been defined in many ways throughout the many publications, with consistency in UDS criteria- and analysis lacking. ICI2013 also concluded that test methods have been unable to reliably predict which patients will develop voiding difficulties after surgery for SUI. In particular, normal UDS do not predict absence of voiding difficulties after sub-urethral tape. However, it was found that flow rates, if abnormal, may be useful in predicting post-operative voiding dysfunction and retention following retropubic and transobturator suburethral slings. ICI2013 recommended that patients are informed that it is difficult to predict who will develop voiding difficulty following surgery for SUI and recommended that patients with poor flow rates before (intended) surgery are informed that they have a higher likelihood of having voiding problems following suburethral tape placement for USUI.

4.2. New Evidence 2016

A review has confirmed the ICI2013 conclusions.106

5. POSTOPERATIVE URGENCY, MIXED SYMPTOMS OF INCONTINENCE, OR OVERACTIVE BLADDER SYNDROME

5.1. Recommendations 2013

The prospective studies that were available at ICI2013 indicated that OAB-S, mixed symptoms of UI and/or DO during UDS at presentation have a negative effect on the outcome of (all available) surgical interventions for SUI-S. ICI2013 concluded that test methods have been unable to reliably predict which patients will develop de-novo urinary urgency (OAB-S) after surgery for SUI-S. Post hoc evidence suggests that procedures for the treatment of SUI-S which are more ‘obstructing’ produce a higher chance of de novo urinary urgency (OAB-S).

The ICI2013 recommended (grade B) that patients with SUI-S are informed that the chance of developing urinary urgency (OAB-S) following surgery is unpredictable and recommended also that patients are counselled before surgical intervention regarding the possibility of a lesser success rate when OAB-S and/or (UDS) signs of DO (or reduced compliance and/or cystometric capacity) exist.

5.2. New Evidence 2016

A new study showed that also patients with ‘obvious’ symptoms of SUI-S may have DO, and that these patients are successfully managed without surgery.107 Another recent study demonstrated that when TVT-O was done only in patients with USUI without (UDS-) DO the cure rate after 10 years was markedly higher (95%) than the usual reported ±75-80%.108

6. THE ROLE OF URODYNAMIC STUDIES IN PREDICTING URINARY INCONTINENCE IN WOMEN AFTER
URGENCY URINARY INCONTINENCE AND OVERACTIVE BLADDER SYNDROME

1. FREQUENT VOIDING AND URGENCY; OVERACTIVE BLADDER SYNDROME

1.1. Recommendations 2013

Studies have not been able to show a strong association between OAB-S and DO. Various studies have directly or indirectly concluded that the individual prediction of the response to treatment for OAB-S, on the basis of the characterization or quantification of DO during UDS, is impossible. The ICI2013 recommended (Grade B/C) that investigators and clinicians discuss with patients with DO that neither the quantity nor specific characteristics of DO predicts the response to any of the therapeutic approaches.

1.2. New evidence 2016

A single centre retrospective study with good power confirmed the lack of association between subjective symptom severity and bother and objective measurements reinforcing the need for objective assessment, especially in proof of principle studies. However, it was also observed that UDS cystometric capacity, compliance as well as onset of first contraction were associated with perceived severity of symptoms. Another well powered multicentre study demonstrated that subjective symptom assessment for women with LUTS was not reliable to uncover the pathophysiology that caused the symptoms.
1.3. Recommendation (Grade B)

- The committee recommended that investigators and clinicians discuss with patients with OAB-S that neither the quantity nor specific characteristics of OAB-S predicts the response to any of the therapeutic approaches.
- The committee recommended that investigators and clinicians discuss with patients with OAB-S that when UDS is performed neither the quantity nor specific characteristics of DO predicts the response to any of the therapeutic approaches, but that the absence of DO is relevant for further management.

VI. URGENCY URINARY INCONTINENCE

1. RECOMMENDATIONS FOR URODYNAMIC DIAGNOSIS IN WOMEN WITH URINARY INCONTINENCE

1.1. Recommendations 2013

The ICI2013 recommended non-invasive UDS (voiding and UI diary, PVR, and possibly uroflowmetry) for all patients with UI and suggested that non-invasive and simply reversible treatment based on symptoms and signs is offered in situations where one of the two types of UI is likely to exist, without invasive UDS, if the patient accepts the uncertainty margins of the diagnosis and there is no symptom or sign for coexisting dysfunctions or complicating factors. The ICI2013 provided the following examples:

- Uncomplicated symptoms of SUI with normal bladder diary, normal uroflowmetry and without relevant PVR. (Symptomatic pure SUI with no symptoms or signs of voiding difficulties), for treatment with pelvic floor muscle training.
- Uncomplicated symptoms of UUI or OAB-S, with a bladder diary in accordance with these symptoms, with normal uroflowmetry and without relevant PVR. (Symptomatic pure UUI with no symptoms or signs of voiding difficulties), for treatment by bladder training with or without combined pharmacotherapy.

The ICI2013 has recommended that, whenever surgical intervention is planned, whenever there is doubt about the pathophysiology, or about whether the UI is uncomplicated or not, that invasive UDS should be performed in order to provide the knowledge on which rational treatment decisions and prognosis can be based. The ICI2013 also recommended UDS for patients that have had failed first therapies. The investigation should be tailored to the individual patient; typically, this means that it will be a comprehensive examination of multiple aspects of storage and voiding function, and not just of the UI itself.

1.2. New Evidence 2016

New studies have attempted to better define the role of clinical diagnosis in women with (predominant) symptoms and signs of SUI, but have regrettably not been very generalizable (or reproducible) because of little standardisation in both experimental arms (clinical diagnosis as well as UDS), because of preselection (inclusion) and also because of crossing over within the trial.

1.3. Recommendations (Grade B)

- The committee recommends that that invasive UDS should be considered for women with SUI-S or in order to provide the knowledge on which rational treatment decisions can be based.
- The committee recommends to perform UDS whenever there is doubt about the pathophysiology causing (UI, the SUI-S or) the LUTS, whether the UI is uncomplicated or not.
- The recommended UDS for patients that have had failed first (pragmatic) therapy.
- The recommended (complete, standard) UDS for women that have LUTS and or UI and representative ineffective voiding (significant PVR) and or reduced flow rate.

VII. PATIENT EVALUATION: MEN

1. URODYNAMIC TESTING OF MEN WITH SYMPTOMS AND SIGNS OF LOWER URINARY TRACT DYSFUNCTION

1.1. UDS for Male LUTS and / or UI

1.2. Conclusions and Recommendations 2013

Epidemiologic studies have shown that LUTS in men >50 years of age are highly prevalent and that storage LUTS are relatively more reported than voiding or post-micturition symptoms. Case series available at ICI2013 indicate that in male patients, OAB-S -wet is associated with a UDS diagnosis of DO. OAB-S dry might involve other LUTD or be the result of obstructed and/or ineffective voiding. Guidelines at that time suggested that the initial treatment for male LUTS could be based on the predominant symptoms, without UDS and recommend, on the basis of expert opinion, UDS when the initial management fails to resolve the storage LUTS.
Various studies indicate that male LUTS including UI may be due to detrusor dysfunction and/or BOO and that DO and urethral sphincter dysfunction should also be considered in young men with LUTS or in men with a small prostate. Mono and multi-centre cohorts show that although UDS do not unequivocally predict outcomes of pharmacological or surgical treatment, treatment results are, however shown to be better predicted in patients who have had objective UDS and objective evidence of BOO. ICI2013 recommended (grade C) that all elderly male patients with UI should receive a complete UDS when conservative measures fail, to understand the problem.

1.3. New Evidence 2016

OAB-S and LUTS associated with prostate enlargement and BOO in men increase with age. Coexistence of UI in men with BOO and DO increases with age and with the degree of BOO. In addition to BOO associated UI, other pathological conditions such as nocturnal enuresis and post-micturition dribble are also clinically relevant in men. Evaluation for men with LUTS and UI starts with symptoms assessment, further discussed in the diagnosis chapter of this book. The best independent predictors of USUI, apart from clinical history were the patient’s age and the ICIQ-UI-SF. ICI questionnaire and 3-day bladder diary have been shown to be valid, reliable, and responsive to change. Non-invasive investigations such as uroflowmetry and measurement of PVR are easy to perform but cannot distinguish BOO from DU.

Surgical intervention, to relieve BOO and associated LUTS, based on UDS diagnosis of outflow obstruction resulted in an improvement of flow rate and reduction of symptoms. Preoperative UDS diagnosis of DO is associated with significantly more storage symptoms than the patient without DO. Multivariate analysis revealed that a low MUCP at baseline UDS was the independent predictor of de novo UI after HoLEP (laser prostate enucleation) for BPH-BOO. In an expert group discussion, it was concluded that UDS is in all guidelines referred to as the gold standard for the diagnosis of bladder sensation, and this committee reported that each of the methods currently in use has limitations as to its use and proof of reliability.

Ambulatory UDS is sensitive for the detection of DO, however prone to artefacts and time consuming. Nevertheless, the method is considered valuable by some experts when all other diagnostic means have failed. This was demonstrated in patients with suspected detrusor acontractility on UDS and UI of unclear origin; however, the UDS graphs with this manuscript do also show significant technical flaws. Ambulatory UDS has been shown reliable for the reproduction of the main UDS parameters in patients with NLUTD-S, except for the end filling detrusor pressure.

1.4. Conclusions

UDS for (elderly) men with LUTS has demonstrated relevance for the diagnosis of bladder sensation, and volume adaptation (bladder compliance and detrusor relaxation) it has also demonstrated relevance in the quantification of BOO. UDS is in all guidelines referred to as the gold standard test to evaluate men with signs and symptoms of LUTD.

Most elderly men who present with OAB-S have voiding symptoms also and a consistently reported large percentage has – UDS - evidence of BOO.

BOO, DO, reduced cystometric capacity, PVR and/or DU can occur in any combination per individual, independent of the symptoms presented, and can all be quantified on the basis of UDS.

Specific evidence that UDS improves outcome is limited, and pragmatic or ‘symptom oriented’ management is demonstrated to be very well possible in many men. Nevertheless, UDS is the basis for therapy when it is desired to be directly aimed at the pathophysiology that is responsible for the symptoms if the patient and/or the physician consider that relevant.
1.5. Recommendations (Grade C)

- The committee recommends invasive UDS for a patient for which objective elucidation of the pathophysiology of the LUTD is deemed relevant.

- In general, this shall be relevant when invasive management is considered. But it may also be relevant in relatively symptomatic men with relatively young age and/or relatively small prostates and/or relatively good flow rates and/or with relatively large volume of PVR, when initial management fails.

- The committee recommends invasive UDS for patients that have experienced failure of surgery for LUTS.

2. LUTS AND OAB-S IN MALE PATIENTS

2.1. Conclusions and Recommendations 2013

ICI2013 concluded that symptoms and signs of “new onset” UI or nocturnal enuresis in men are unspecific with regard to the underlying dysfunction, also when large PVR or retention are excluded and recommended UDS of men with symptoms and signs of UI.

2.2. New Evidence 2016

OAB-S symptoms (with or without UI) are highly prevalent in men and the prevalence increased with age. LUTS, believed to represent bladder storage (dys)function were more prevalent than voiding symptoms or post-micturition symptoms in men. The most prevalent LUTS was nocturia. A longitudinal study showed that OAB-S and UI symptom severity progresses over time. The overall incidence of DO was 76% in male patients with OAB-S symptoms, 63% of men with urgency (OAB-S dry) had DO, while 93% of men with urgency and UI (OAB-S wet) had DO. Men who received invasive UDS were less likely to undergo surgery as treatment for LUTS. Urethral closure pressure had a significant association with BOO and also micturition urethral pressure profilometry, but not with UI in men. Most of patients with BPH and (urodynamically demonstrated) BOO have OAB-S which can be relieved after TURP, however, one study found that the presence of pre-operative terminal (end filling-) DO might be negatively associated with the improvement of BOO-S and UI. In patients who received vapourisation of the prostate for BPH-BOO, a study found the number of patients with moderate to severe storage LUTS decreased from 60% to 49% at week 6 to 12% at month 6 but DO has not been a predictor in this series.

UDS has been used to evaluate outcome of medical treatment for OAB-S in men and may demonstrate objective improved LUT function, or not. In a study including both genders, combined low and standard dose trospium and solifenacin has shown to provide good clinical effects associated with UDS changes. On the other hand, in evaluation of the therapeutic efficacy of once daily tadalafil in men with LUTS, a randomised, placebo controlled 12-week clinical trial revealed that, although there had been a symptom response, no objective UDS changes were found. Especially no change in any of the relevant cystometric (DO) or pressure flow study parameters (BOO) was observed.

Systematic review of percutaneous tibial nerve stimulation (PTNS) concluded that PTNS has been efficacious for symptoms of frequency and/or UI in most cohort studies. 77% of participants with an initial positive response to 12 weekly PTNS treatments safely sustained symptoms improvement to 3 years with an average of 1 treatment per month. PTNS treatment also leads to improvement in open label uncontrolled studies patients with multiple sclerosis which was observed to persist for one year in one recent study. A review shows that UDS proof of (PTNS-) effects is observed (evaluated) in a very limited number of studies and patients and has demonstrated some improvement of cystometric capacity and occasionally reduction of DO.

In a systematic review of the mean outcomes for the use of BoNT-A in the management of LUTD it was shown that the cystometric capacity increased 60% and maximum filling phase pressures reduced by 40%, with its clinical relevance demonstrated in voiding (emptying) diary parameters. EAU guideline advised initial treatment of LUTS and OAB-S is conservative and of empirical nature, including lifestyle interventions, physiotherapy, physical therapy, pharmacotherapy.

AUA/SUFU guideline for diagnosis and treatment of non-neurogenic OAB-S in adults has provided expert opinion supplement from the 2012 original version to 2015 version with recommendations for refractory OAB-S however with an undefined role of UDS, and with ambiguous definitions of “treatment resistance”.

2.3. Conclusions

LUTS in men >50 years of age are highly prevalent and storage LUTS are frequently reported. In male patients, OAB-S wet symptoms are associated with DO. UI in elderly male may be due to DU /urinary retention and/or BOO.

UDS has been demonstrated to be able to differentiate storage dysfunction (DO reduced compliance) and outflow dysfunction (bladder neck obstruction, DU and BOO) or combinations of these, in men with LUTS.

LUT-S –storage symptoms, with or without (U)UI, diminished gradually over time after vapourisation of the prostate. Patients with preoperative terminal DU might have lesser rapid improvement of OAB-S symptoms after TURP.
Epidemiology shows that non-urologic causes for nocturia are prevalent and nocturnal polyuria can be diagnosed with a 24 h frequency-volume chart.

UDS in elderly men indicate however that DO and BOO with ineffective voiding may play a role in a proportion of patients with nocturnal enuresis and/or UI. UDS has shown that use of a phosphodiesterase inhibitor initiates no objective changes of the LUT function in men, although it does affect symptoms.

New onset, night time UI, in an elderly male, warrants urgent urodynamic pressure-flow analysis.

2.4. Recommendations 2016

- The committee recommends UDS for objective diagnosis of male LUT function, especially in elderly men with UI or in (young) men with LUTS and relatively small prostates not responding to management or medical treatment based on clinical examination.
- The committee recommends to consider UDS for objective diagnosis of LUT function in men with prostate enlargement to ensure specific management of the dysfunction causing the LUTS.

3. URINARY INCONTINENCE AFTER TRANSURETHRAL RESECTION OF THE PROSTATE AND OPEN PROSTATECTOMY FOR BENIGN DISEASE

3.1. Conclusions and Recommendations 2013

Case series have concluded that UI after prostatectomy may be attributed to bladder storage dysfunction and can exist in association with (neo-bladder neck) BOO although the most prevalent cause is sphincteric dysfunction. Retrospective studies have shown that UDS cannot predict which patient will develop SUI or DO (with or without UUI) after surgical treatment for prostatic BOO. Studies have shown that UDS can identify the aetiology(ies) of UI (or other LUTD) after surgical treatment for prostatic BOO, however the predictive value for the outcome of subsequent treatment is unknown. Good evidence shows that more than 90% of post prostatectomy UI is SUI, with or without co-existing LUT dysfunction.

The ICI2013 recommended (grade C) to consider UDS for the diagnosis of concomitant LUT dysfunction in patients with clinical stress UI after prostatectomy, but especially if further surgical or invasive treatment is considered. The ICI2013 committee also recommended definition of UDS cystometric capacity (technique, ‘end of filling’ and evaluation) specific for patients with post prostatectomy UI.

3.2. New Evidence 2016

The most common aetiology of UI after surgery for BPH-BOO was sphincter weakness or deficiency, followed by sphincter weakness plus DO, reduced compliance alone. Approximately 1% of patients who have undergone TURP or laser TURP suffer from UI. Kuo urodynamically evaluated 185 men aged from 55 to 91 years who had variable LUTS after TURP and found that UI was present in 74 patients (40%), BOO and DO with DU were the most common findings associated with UI, followed by DO. UDS in UI showed no significant change in filling or voiding parameters when suburethral male-slings were implanted.

3.3. Conclusions 2016

Many case series show that sphincter weakness is the most common aetiology of male UI after prostaticctomy (TURP). However, case series and reviews show that other LUTD besides sphincter incompetence play an incident role in post prostatectomy UI. Case cohorts show conflicting evidence whether DO before prostatectomy is an important indicator for the postoperative persisting incidence of UI, or for the outcome of interventions to treat the UI.

3.4. Recommendations

- The committee recommends UDS when elderly male patients have persisting LUTS and/or UI after surgical treatment for prostatic BOO if further surgical or invasive treatment is planned.

4. (ROBOT ASSISTED) RETROPUBIC RADICAL PROSTATECTOMY

4.1. Conclusions and Recommendations 2013

Case series and reviews show that the main cause of UI after RRP is sphincter weakness and that DO contributes in only a small proportion of those patients and show also that higher maximal urethral closure pressures or abdominal LPPs, indicating greater urethral sphincter resistance is not of utmost clinical relevance. UI after RRP will improve with time. A study concluded that postoperative urethral pressure profile after 6 months may be predictive for persistent UI. The ICI2013 recognised that UDS for UI after RRP is not particularly important for the diagnosis of sphincter dysfunction (SUI) in patients with post RRP UI. However, the ICI2013 recommended that UDS is considered in patients where other dysfunctions of the LUT (obstructed voiding, significantly reduced bladder compliance and/or DO) cannot be excluded on the basis of signs and symptoms.

4.2. New Evidence 2016

UI after retropubic (robotic assisted) radical prostatectomy (RRP) is prevalent despite improvement in surgical techniques. Changes of the detrusor and
urethral function after RRP deserve attention to improve continence. Approximately 10-14% of patients, suffer UI 2-5 years after RRP.\(^{168}\) UI after brachytherapy was reported by 4 to 6% of patients at 1 to 2 years after treatment.\(^ {169}\) Comparative studies indicate that UI is the most common adverse effect of RRP.\(^ {170}\)

Preoperative DO was not associated with worse post RRP UI outcomes, or increased incidence of UI. Single centre observations suggest that even if DO is present in men with USUI after RRP they may be considered for a male sling procedure.\(^ {171}\) After RRP, Q\(_{\text{max}}\) was reported to increase, and detrusor voiding pressure and the urethral resistance factor to decrease significantly. In univariate analysis, DO was found in 34% of patients who were still incontinent 6 months postoperatively and only in 5% of patients who were not.\(^ {172}\) After RRP, the functional profile length (FPL) decreased by 64%, because the prostate was removed, but also maximum urethral closure pressure (MUCP) decreased by 41% on average. Non-nerve sparing technique was a prognostic factor for a higher relative decrease of MUCP after RRP.\(^ {173}\) UDS can identify aetiologies of post RRP UI such as sphincter weakness. Neo bladder neck outflow obstruction, DO and mixed symptoms of UI may also be contributing to post RPP UI.\(^ {174}\) UDS parameters change after RRP by reducing BOO without affecting overall detrusor contractility. Urinary continence rates were gradually improved to a satisfactory level in more than 80% of patients by 12 months after RRP.\(^ {175}\) DU is relatively common in patients with post RPP UI, 40% of patients demonstrating an isovolumetric detrusor pressure of <50 cmH\(_2\)O.\(^ {176}\) Although DU was found in 49% of patients preoperatively, DU did not affect UDS parameters and LUTS improvement after RRP.\(^ {176}\) Another large cohort study also demonstrated DU and Valsalva voiding was observed in 41% of patients after RRP, which might reduce (longer term) success of treatment for post RPP UI.\(^ {178}\) In a longitudinal observational cohort study, patients with bladder neck contracture after RRP presented with preoperative DU.\(^ {179}\)

Urethral sphincter insufficiency was the most common UDS abnormality after RRP (88%), followed by DO, neo bladder neck obstruction, impaired detrusor contractility, and normal findings.\(^ {180}\) Co-existing detrusor dysfunction had to be taken into consideration, as well as intrinsic sphincter deficiency, in order to properly treat persistent post RPP UI\(^ {181}\) 182 but also postoperative UPP after 6 months may be predictive for persistent UI.\(^ {183}\) The abdominal LPP was considered a relatively poor predictor of UI severity and, therefore, is reported to have limited value in the UDS evaluation of post RPP UI.\(^ {184}\)

Preoperative UDS may help to estimate the likelihood of postoperative UI\(^ {185}\) 186 187 although it remains underdetermined how to clinically implement this knowledge.\(^ {188}\) In robot-assisted RRP series, the outcomes of continence rate improved from 75% to 93% for cases 501-700, suggesting that surgeons experience is relevant (or ‘confounding’ UDS evaluations).\(^ {189}\) The role of UDS on predicting continence outcome after RRP remains controversial. Small cohort studies drew different conclusions that preoperative UD DO may have influence on post RRP UI.\(^ {190}\) \(^ {191}\) Investigation before and after RRP revealed 25% of patients had DO in associated with decreased bladder compliance, diminished FPL and MUCP after operation, 22% of patients had detrusor hypoactivity.\(^ {192}\)

Nerve sparing (NS) RRP significantly affected urine loss immediately after RRP compared with non-NS surgery.

Increased urine loss immediately after RRP was noted in 86% of patients, which could be attributable to decreased MUCP and abdominal LPP.\(^ {193}\) In addition to a lower MUCP, a reduced bladder compliance was shown in 27% and idiopathic DO in 31% of patients with post RRP UI.\(^ {194}\) Chronological UDS of patients with UI after RRP revealed that LUT worsens immediately after RRP and recovers over time.\(^ {195}\) In one small cohort study, 21% of patients had UI at 1 year after RRP. Bladder compliance \(<28\text{ml/cmH}_2\text{O}\), MUCP\(<50\text{cmH}_2\text{O}\) and BOO are reported to be independent UDS factors correlating with UI after RRP.\(^ {196}\)

The aetiology of UI following RRP, either stress or UUI, also cannot be predicted by the ICIQ-UI-SF survey.\(^ {197}\) UDS have been done to demonstrate the UI in many reports but also recently, to better show the detrusor storage function, mimicking the situation after AUS placement (and preventing incontinence during cystometry). In practice, this may be more relevant than the demonstration of UI in patients with post RPP UI.\(^ {198}\)

In patients receiving radiotherapy for prostatic cancer, patients with larger prostatic volumes (> 35 mL) and/or with UDS confirmed BOO were more prone to problems after brachytherapy.\(^ {199}\) A high PVR (> 100 mL) is associated with slower resolution of voiding symptoms, prolonged (more than 3 days) catheter dependency, and increased post-brachytherapy surgical intervention for BOO.\(^ {200}\) Men after brachytherapy were, in a single centre retrospective cohort, reported to have a relatively high incidence of DO, prostatic and urethral strictures and prostatic urethral stones.\(^ {201}\) Compared to patients with prostate cancer receiving RRP, high dose external beam radiation therapy and brachytherapy iodine implantation as monotherapy had a better rate of urinary continence and sexual function however more bowel and urinary irritation.\(^ {202}\)

UDS prior to AUS implantation revealed that DO was much more prevalent in the group with radiation (26%) than in group without radiation (5%). Post-operative urinary urgency with or without UUI was found in similar proportions of the 2 groups, suggesting that pre-operative DO did not predict outcome in this group.\(^ {203}\) Patients with post RRP UI, with adverse UDS findings such as DO, low compliance, low detrusor contractility, or decreased cystometric capacity and first sensation of filling were reported to have similar outcomes after AUS implantation to those just with USUI.\(^ {204}\) 205 The presence ofLUTD was also not predictive
of surgical outcome in one other series and preoperative use of few pads, less severe post RPP UI, and a longer interval between RRP and post RPP UI surgery were associated with a successful outcome.\textsuperscript{206} Patients with postoperative retrograde LPP < 50 cm H\textsubscript{2}O and DO were however seen to be associated with failure in another series.\textsuperscript{207} The transobturator tape for treatment of post RPP UI was shown to be effective with an improved mean MUCP and high cure rate.\textsuperscript{208} UDS after a bulbourethral composite suspension revealed a significant increase of MUCP (40 v 58 cmH\textsubscript{2}O), and functional urethral length (31 v 40 mm), the Q\textsubscript{max} was slightly reduced (16 v 12 ml/s); however pressure flow study was reported to show not obstructive voiding in all patients.\textsuperscript{209} A functional pelvic cine-MRI study in patients with a bulbourethral composite suspension revealed that this procedure was associated with an increase in urethral length, urethral coaptation zone and bladder neck elevation, implying a non-compressive mode of action. However, no difference on imaging was noted between patients showing clinical success or failure.\textsuperscript{210, 211} Using the Argus T adjustable system for treatment of post RPP UI, at 30 month follow-up 88% of patients were dry or improved. The retrograde LPP increased from 18 to 35 cmH\textsubscript{2}O after intraoperative adjustment. Transient inguinal or perineal pain was reported by 61% of patients and postoperative infection occurred in 6%.\textsuperscript{212} The overall cure rate for the AdVance and AdVanceXP transobturator male sling was reported to be 80%. This procedure was safe and efficient in patients with mild UI after RRP.\textsuperscript{213} Using an Advance transobturator male sling for post RRP UI, among 38 patients 28 (74%) reported successful 3 months after operation. A small cystometric capacity was reported to have potential impact on the success of the procedure.\textsuperscript{214} Patients with a preoperative Valsalva LPP of >100 cmH\textsubscript{2}O have a high degree of predictability for success for AdVance sling procedure.\textsuperscript{215} Among 35 patients who underwent AUS implantation for post RPP UI, 16 (46%) had postoperative urinary retention requiring CIC but this resolved within 7 days with no reported effect on continence outcome.\textsuperscript{216} A cadaver model demonstrated that a tandem cuff as such did not improve retrograde LPP, but that proximal bulb urethral circumference was greater than distal circumference and therefore the addition of a more proximal cuff was improving efficacy.\textsuperscript{217} In men who failed to demonstrate incontinence during intubated UDS prior to AUS placement for post RRP UI a high rate of anastomosis stricture (and history of radiotherapy treatment) was observed, but anti-incontinence outcome for these was not affected by this.\textsuperscript{218} However, another study showed, although transobturator male sling provides good continence outcomes for post RPP UI on average, previous pelvic irradiation seems to compromise the effectiveness of the procedure.\textsuperscript{219} Volume adjustable balloons implantation was used to treat post RPP UI with a success rate of 37/49 (75%). A longer duration of UI, the use of >5 pads daily, and a small cystometric capacity predicted unsuccessful clinical outcome of this technique.\textsuperscript{220}

4.3. 2016 Conclusions (Level 2-3)

The main cause of UI after RRP is sphincter weakness, but reduced compliance and DO with or without neo-bladderneck outflow obstruction contribute in an unknown proportion of those patients.

UDS have demonstrated value to identify the aetiology of LUTD after surgical or radiotherapy treatment of prostatic carcinoma.

Both urethral and detrusor (adaptation) function are prone to be affected after retropubic or RRP. Decreased bladder compliance, lower detrusor pressure during voiding, higher Q\textsubscript{max}, and reduced maximal urethral closure pressure are noticeable immediately after RRP.

DU is commonly observed in patients with UI after RRP, and may be a risk factor for the development of neo-bladder neck (stricture).

Clinical indicators for reduced chance of success of post RPP UI -surgery are lesser amounts of urine loss, less pad use, and higher preoperative Valsalva LPP however precise action limits for these are not available.

Anastomosis stricture (may also prevent UI to be demonstrable during UDS), reduced compliance and DO as well as Valsalva voiding are urodynamic predictors of failure although with unknown specificity.

Retrograde LPP may be a good tool for adjustment of male sling tension to balance the resistance during post RPP UI -surgery.

Anti-incontinence male sling, composite suspension apparatus and AUS device have been shown good surgical outcome for post RRP UI.

4.4. Recommendations (Grade 3)

- This committee recommends that UDS should be performed when RRP UI has not spontaneously improved and conservative measures have failed.

- The committee recommends that UDS for patients with RRP UI is not only done to evaluate USUI but that it is also done specifically to evaluate bladder storage function. (Thus: to do cystometry with the prevention of early/massive leakage during the test and with filling until practically acceptable volumes, e.g. 3-400mL, to predict the situation after regaining continence).

5. UDS FOR PATIENTS WITH POST (RADICAL) PROSTATECTOMY

622 | COMMITTEE 6. URODYNAMIC TESTING
5.1. Conclusions and Recommendations 2013

ICI2013 concluded that studies LPPs and urethral pressures, measured in their various ways, are consistently reported to be improved after anti-incontinence treatment using different surgical techniques, and their improvement is associated with cure or reduction of UI volume and/or pad usage. Most single centre reports conclude that UDS variables, used to evaluate voiding, do not show clinically significant change after suburethral sling procedures or AUS implantation. The ICI2013 committee recognised (grade B) that UDS for UI after RRP is not particularly important for the diagnosis of sphincter dysfunction (SUI) in patients with post RRP UI but recommended that UDS is considered in patients where other dysfunctions of the LUT (BOO, valsalva voicing, significantly reduced bladder compliance and/or DO) cannot be excluded on the basis of signs and symptoms.

5.2. New Evidence 2016

Other dysfunction may be more prevalent in patients with persistence of LUTS and or UI after surgical management of their post RRP UI. The committee has however not found specific (new) evidence. Recent series and reviews have little or not elaborated on UDS evaluation for recurrent LUTD and or UI after RRP.221 222 223 224

Recommendation

• The committee recommends that UDS is considered in patients with post RRP UI.

• The committee recommends UDS for patients with post RRP UI when co-existing dysfunctions of the LUT (neo bladder neck BOO, valsalva voicing, significantly reduced bladder compliance and/or DO) cannot be excluded on the basis of clinical history, e.g. radiotherapy, signs and/or non-invasive UDS and symptoms.

6. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

6.1. Recommendations 2013

The ICI2013 found expert agreement, on the basis of many case series, that UDS is of great relevance to establish the management and to achieve the best long term clinical outcome for patients with NLUTD and found also that VUDS is necessary when anatomical information is deemed clinically relevant.

ICI2013 concluded that case series have indicated that it is possible to monitor patients without anatomic abnormalities (absence of a high likelihood of VUR and or bladder diverticulae) of the LUT (especially adult age SCI and unaffected LUT function before the lesion) with cystometry and ultrasound of the UUT.

No specific reports about the optimal frequency and techniques of follow-up UDS in patients with NLUTD has been available at the time of ICI2013. No conclusive evidence exists about the predictive value for treatment with regard to ice-water testing, or of ambulatory monitoring of patients with NLUTD. Some evidence from centres of excellence indicates that ‘one channel, cystometry’ can be applicable in the monitoring (follow-up) of a selected group of patients with complete SCI.

The 2013 committee recommended that patients with signs and symptoms of LUTD and relevant neurological abnormalities should receive UDS (including filling and voiding cystometry) if initial treatment will be affected as a consequence of the diagnosis, or if ‘simple’ first line diagnosis and management have been unsuccessful.

This committee also recommended that at least at a baseline, to establish the state and function of the LUT in patients with NLUTD, VUDS evaluation is indicated if relevant anatomical abnormalities are to be expected.

The 2013 committee recommends that the frequency of testing and the techniques applied in the follow-up of patients with NLUTD be critically analysed and optimised, and recommended to develop guideline recommendations on the basis of those analyses. The committee recommended that UDS in patients with NLUTD be done with special attention to the specific needs of the patients. It is highly preferable that all professionals involved are specifically trained for that purpose.

6.2. New Evidence 2016

Any disturbance of the nervous system, can result in signs and symptoms of LUTD. The extent and location of the neurological dysfunction will determine the type of LUTD, which can be symptomatic or asymptomatic. Neuro-urological symptoms can cause a variety of long-term complications; the most significant being deterioration of renal function.225

Neurogenic lower urinary tract dysfunction applies to a spectrum of clinical conditions and refers to the presence of LUTD symptoms ‘when there is a relevant neurological condition’.226 UDS can measure LUTD caused by a lesion in the brain and or spinal cord or peripheral nerves; associated with a congenital condition (e.g. MMC), an acquired, stable condition (e.g., stroke, SCI), or an acquired, progressive condition (e.g., multiple sclerosis [MS], Parkinson’s disease, dementia).227 Because not all patients with neurogenic conditions develop LUTD or have abnormal UDS findings, a specific understanding of the dysfunction in each individual is a prerequisite for the....
correct choice of therapy. The aim of the diagnostic tests is to describe the (dys)function of the bladder, the urethra and the pelvic floor, their coordination during filling and voiding and their influence on other conditions (e.g. autonomic dysreflexia) or organ systems (e.g. renal function). Patients with neurologic disease known to be associated with NLUTD should be evaluated for the presence of LUTD.228

6.3. Urodynamics in NLUTD

A lesion above the lumbosacral cord level (e.g., due to SCI or MS) is characterized by UI due to NDO and the loss in voluntary control of micturition, initially, in the spinal shock phase, leading to an areflexive bladder and urinary retention due to detrusor sphincter spasm.237 In the case of suprasacral lesion above the lumbosacral cord level, the patient will lose voluntary and supraspinal control of micturition, and this usually leads to NDO which is characterized by spinal reflex pathways mediated by formerly silent capsaicin-sensitive unmyelinated C fibres.229 In these cases, bladder contractions are poorly sustained and there is dyssynergia between the urethra and bladder.237

DO in association with neurological disease, may lead to UI. Observed during UDS, this type of UI is termed neurogenic DOI. The corresponding clinical sign or symptom is however variable: if the DO is accompanied by sensation (desire to void) it might be termed UUI; frequently however any sensation is absent, and so the term urgency incontinence is an incorrect description of the situation. For this reason, the term reflex incontinence was introduced by Abrams in 1988,230 implying uncontrolled but complete emptying of the bladder without sensation. However, this term is no longer recommended.254 NDO is often accompanied by DSD, which is a neurogenically determined failure of pontine coordination of detrusor and bladder outlet. In DSD the failure of the urethral sphincter and/or the pelvic floor to relax completely and sustained, when the detrusor contracts, causes a dynamic type of BOO which may not only prevent complete bladder emptying, but can also lead to chronic and/or intermittent high detrusor pressures observable with UDS. Overflow incontinence263 is another term that is no longer recommended.264 It meant continuous or intermittent (-stress ‘like’) leakage from a constantly overdistended bladder.263 However, neither what constitutes ‘overdistended’ nor the cause of the leakage are defined by the term overflow incontinence. The presenting symptom is usually characterised by small amounts of UI, exacerbated by increased abdominal pressure, together with an inability to empty the bladder by voiding. Whilst UI appears as a problem of LUT storage function, overflow incontinence originates from a dysfunction of voiding. Overflow incontinence can exist in combination with BPE and BOO but also exists in conditions with relevant neurologic pathology. Incontinence due to neurogenic DU (or acontractility) or DSD, with incomplete emptying, and neurogenic incomplete voiding with UI, are clinical (UDS) descriptions and have not been officially defined in the current standardization documents.

During UDS a frequent observation is low compliance and little or no detrusor activity until it reaches a pressure value sufficient to overcome urethral resistance and open the urethral sphincter with urine loss as the consequence. Clinically, this variable is usually reported as the detrusor LPP. If this pressure is elevated, and if similar pressures are attained during UI in daily life, then renal function is endangered because the constantly high detrusor pressure hinders outflow of urine from the ureters into the bladder. Conventionally, DLPP’s of 40 cm H2O or more are believed to increase the likelihood of UUT deterioration. There is evidence (mostly from paediatric studies with children with MMC) that UUT deterioration is more probable when DLPP is elevated above that 40 cm H2O.231 However, the evidence for a cut-off at 40 cm H2O seems less clear and an expert opinion appears to introduce ‘as low as reasonably achievable’ and a ‘safe’ detrusor pressure of below 20 cm H2O, over the entire ‘daily’ volume range, when CIC is part of the treatment, is advised.232

Except in diseases where empirical, conservative therapy can safely be instituted (e.g. post-stroke or Parkinson’s disease, some MS patients), UDS is usually deemed to be required, based on clinical practice guidelines and expert reviews. In the appropriate clinical setting, a neurological evaluation may be recommended in a patient with unexplained LUTS and no known neurological disturbance. This is particularly true in the case of a young patient with idiopathic LUTS after proper office evaluation for common aetologies. Relevant investigations include: voiding diary, UDS (cystometry EMG, VUDS, uroflowmetry, pressure-flow study), diagnostic imaging with voiding cystourethrography and ultrasonography.

Urodynamics is advised to provide the understanding of the situation on which rational treatment must be based. UDS is the only method that can objectively assess the function and dysfunction of the LUT. In patients, with NLUTD, UDS may be more provocative than in patients without relevant neurology. Even when empirical therapy is instituted without UDS, experts usually agree that the patient must be carefully monitored to determine whether and when UDS is needed.227 223 234 235 UDS involve functional and dynamic assessment of the LUT and are used to assess detrusor and bladder outlet function.

In patients at risk for autonomic dysreflexia, it is advisable to immediately stop filling when this occurs, and it may be prudent to measure blood pressure during the UDS.236 The rectal ampulla should be empty of stool before the start of the investigation. All UDS findings must be reported in detail and performed according to ICS technical recommendations and standards.227 236 237

A large proportion of patients with congenital neurologic conditions show anatomical abnormalities that
involve the LUT, especially those born with abnormal neurology (MMC-see in children section of this chapter), and do have congenital relevant ‘end organ (LUT)-sequela’ that can be demonstrated by imaging. VUDS is the test of choice usually advised on the basis of expert opinion when anatomic information is needed to establish treatment.\textsuperscript{268} VUDS combines a fluoroscopic voiding cystourethrogram with multi-channel UDS, allowing anatomic and functional assessment of the bladder and outlet. VUDS importance has been recently underlined by Marks et al who assessed that it should be considered in patients with neurologic findings or diseases as well as those with obstructed voiding, congenital genitourinary anomalies, or a history of genitourinary reconstruction.\textsuperscript{238}

6.4. Special Tests

LUT function or dysfunction can be provoked by coughing, triggered voiding, or anal stretch. Fast-filling cystometry with cooled saline (the ‘ice-water test’) is sometimes used in an attempt to identify NDO or to demonstrate the integrity of the detrusor muscle function and/or its innervation.\textsuperscript{239, 240} Patients develop a detrusor contraction reaction on cooling if the detrusor and or the reflex pathway are intact. Patients with myogenic dysfunction or (iatrogenic) detrusor muscle damage, will not demonstrate contraction. Hüsch et al in their recent review assessed that the ice-water test is a reliable possibility to identify NDO subsequent to standard cystometry,\textsuperscript{23} the clinical relevance of the ice-water test is however undetermined and in patients with high level SCI the test can aggravate autonomic dysreflexia.\textsuperscript{241, 242}

A positive bethanechol test (detrusor contraction >25 cmH\textsubscript{2}O) was thought to indicate detrusor denervation hypersensitivity and the muscular integrity of an acontractile detrusor. However, in practice, the test has given inconclusive results.\textsuperscript{243}

One channel cystometry is reported to be feasible and reliable in patients with complete SCI that do not generate much (abdominal or other) muscle activity below the lesion level. Intravesical pressure will reasonably adequate represent detrusor (relaxation or) activity and allow cystometry pattern analysis in this situation.\textsuperscript{244}

6.5. Reproducibility and Reliability of Tests

Since many patients with NLUTD have infra-pontine neurology, the influence of the emotional (limbic) nervous system on LUT function is reduced or eliminated; thus, UDS observations may be less influenced by the test circumstances than those made in individuals with an intact nervous system.\textsuperscript{245} Nevertheless, the test conditions (e.g. the rate of filling the bladder) do affect the results, and should be chosen carefully.\textsuperscript{246} Some advocate ambulatory monitoring to increase the representativeness of cystometry.\textsuperscript{247} However, tests of longer duration with natural filling, did not relevantly assist in the diagnosis and selection of treatment in patients with SCI in a single centre prospective comparison.\textsuperscript{248}

6.6. Does Urodynamic Testing Help to Select (Optimal) Treatment?

The aims of therapy for NLUTD are to achieve the most physiological filling and voiding conditions possible, as well as a management situation acceptable to the patient in their daily life. Long periods of elevated detrusor pressure during bladder storage phase or (abnormally prolonged and/or high pressure) voiding put the UUT at risk.\textsuperscript{230, 249} The primary aim of therapy in patients with such problems is conversion to a low pressure bladder during filling,\textsuperscript{233, 250} achieve continence, and to manage incomplete emptying due to (medically induced) DU or detrusor acontractility, with CIC.\textsuperscript{268}

The primary aims for treatment of neuro-urological symptoms and their priorities can be summarized as follows:\textsuperscript{251}

- protection of the UUT
- achievement (or maintenance) of urinary continence
- restoration of the LUT function
- improvement of the patient’s QoL

Adequate management depends on whether the detrusor is overactive or has reduced compliance, and only UDS can answer those questions. Timely and adequate diagnosis is of paramount importance for the patient’s QoL, as well as for safety.\textsuperscript{252, 253} There is expert agreement that UDS is essential to monitor the effects of any treatment and in the follow up of any sequelae of the disease and its management. UDS is certainly needed to document the effects of new treatments or management strategies for patients with NLUTD. Changes in UDS do not always relate to clinically relevant improvements in these patients.\textsuperscript{241, 248}

A retrospective study shows with 80 SCI patients and a minimum follow-up of 5 years that it is possible to manage continence and preserve (100% of) UUT during bladder storage phase or (abnormally prolonged and/or high pressure) voiding.\textsuperscript{254} Another retrospective observation indicates, in a series of 200 children with various types of NLUTD, that the intensity (frequency) of UDS follow up can be adapted according to the estimation of the risk for UUT deterioration on the basis of UDS parameters achieved at a baseline.\textsuperscript{255}

6.7. Conclusions Level 3:

- Case series indicate that it is possible to monitor patients with NLUTD, without anatomic abnormalities of the LUT (especially adult age SCI) with cystometry and ultrasound of the UUT.
- Uncontrolled cohort studies indicate that non-invasive tests are less sensitive to relevant abnormalities in comparison with UDS and investigators have concluded that UDS is necessary when...

COMMITTEE 6

URODYNAMIC TESTING

LUTS arise in patients with neurologic abnormalities.

- No specific reports about the optimal frequency and techniques of follow-up UDS in patients with NLUTD exist.

- No conclusive evidence exists about the predictive value towards better diagnosis or (the outcome of) treatment with regard to ice-water testing or ambulatory UDS of patients with NLUTD.

- Nocturia, nocturnal enuresis or LUTS may be the first, or an early, sign of Parkinsonism in elderly male patients, and may occur also in patients e.g. with MS, or other neurology and UDS is of value to establish a diagnosis of the LUT dysfunction(s) responsible for the symptoms.

- LUTD in male patients with Parkinsonism (or MS, or other neurology) can be the result of DO, (benign prostatic) BOO, dyssynergic voiding or PVR or any combination thereof.

- DO and DU, with or without urethral sphincter dyssynergia, are commonly found in male patients with Parkinson's disease.

- BOO is not specific to Parkinson's disease. For male patients with Parkinson's disease and LUTSD, UDS and evaluation of prostate size are recommended to select appropriate treatment strategy.

- This committee recommends that UDS evaluation should be considered at the time of first evaluation of patients with signs and symptoms or with suspicion of NLUTD and that VUDS is considered when anatomical abnormalities with the NLUTD are not unlikely.

- The committee recommends that the frequency of testing and the techniques applied in the follow up of patients with NLUTD be critically analysed and optimised, and continues to recommend that guideline recommendations on the basis of those analyses should be developed.

- The committee recommends that UDS in patients with NLUTD is done with special attention to the specific needs of the patients. It is highly preferable that all professionals involved are specifically trained for that purpose.

6.9. Recommendations for Research

- Comprehensive UDS should remain an integral part of the evaluation of new therapies and management strategies for NLUTD whether conservative, medical or surgical. The first goal of this should be to monitor the safety of the (developed) approach for the patient and the secondary goals of this UDS should be the efficacy outcomes (preferably on predefined UDS criteria).

- The frequency of UDS in the follow up of patients with NLUTD should be evaluated and optimised in the different neurologic conditions.

- Specific UDS diagnosis categories and diagnostic techniques need to be developed to quantify detrusor sphincter dyssynergia and neurogenic DU. Diagnostic techniques need to be developed to objectively evaluate bladder sensation.

VIII. PATIENT EVALUATION: CHILDREN WITH URINARY INCONTINENCE

1. INTRODUCTION

1.1. Conclusions and Recommendations 2013

ICI2013 concluded that retrospective and prospective studies have shown that symptoms and signs (in UI) do not adequately represent LUT dysfunction and UDS diagnosis in children. This is observed in otherwise healthy children with LUT signs and symptoms, in children with MMC, with ARM, with SCI, spinal cord tethering, cerebral palsy / spasticity, sacro-coccygeal teratoma, and also in children with urethral valves, VUR or bladder extrophy. Retrospective and prospective studies have shown that management of children with MMC is depending on UDS diagnosis and expert consensus exists in this regard and single centre retrospective (selected) series have shown that UDS-diagnosis is frequently relevant in children with the above-mentioned pathology but also that initial conservative management of (otherwise healthy) children with UI is possible without UDS-diagnosis. No good evidence existed in 2013 to support optimal selection of VUDS (versus UDS) in most situations of children with UI, apart from MMC and VUR or to support individual decisions regarding UDS or VUDS (technique and timing) for follow-up in children. At the previous consultation also no positive evidence existed for the routine use of any of the new non-invasive UDS methods in children. Some (expert and/or single centre) evidence has been emerging for flow + EMG evaluation and follow-up in children.

The 2013 committee recommended managing children with UI, with a minimum of a bladder diary plus 3 representative flow-PVR –measurements and to use this information also to act as a reference for cystometric capacity and/or filling rate.

The committee also recommended to consider VUDS (only) when relevant anatomical abnormalities are (to be) expected and recommended the need to improve pelvic patch EMG technique, standards and evaluation/reporting.

The 2013 committee recommended that patients with symptoms and signs of LUT dysfunction with relevant
neurologic abnormalities receive (V)UDS when it is considered possible to initiate treatment as a consequence of the diagnosis based on the (V)UDS and when first line management has failed. The committee recommended to use bladder diary as the basis for cystometry but for patients with relevant neurologic abnormalities also or specifically to use the catheterisation volumes (also). The ICI2013 committee does not recommend routine use of non-invasive UDS or ambulatory UDS in patients with relevant neurologic abnormalities.

The committee recommends that UDS in patients with NLU TD is done with special attention to the specific needs of these patients and recommended specific (V)UDS – practice guideline(s) and training for (V)UDS in patients with (LUTD and) relevant neurologic abnormalities.

1.2. New Evidence 2016

The indications for UDS evaluation in children are usually neurological, anatomical and/or functional abnormalities, with the types of studies to be performed being based on the presumed underlying patho(physio)logical conditions rather than on the presenting symptoms. UI in children is relatively more often seen (compared to adults) in combination with other LUT (or lower bowel or pelvic floor) dysfunctions. On the other hand, urinary continence and the development of ‘full-grown’ LUT function are the result of a normal maturation process that can be delayed in some, and may ‘spontaneously cure’ (or ‘resolve’) without requiring medical intervention. UDS is used to establish as clearly as possible the baseline situation where needed, so that changes as a result of treatment and/or growth can be assessed, and some guidance is obtained in the choice of treatment. Perhaps more clearly than in any other patient group, the aim of UDS in children is to provide objective knowledge about LUT function and dysfunction as well as to provide understanding to the care-giver and to the patient (and her or his parents).

Paediatric UDS implies a different approach than in adults and applications are unique in this population. Nevertheless, there has not been a validated guideline on the use of UDS in children but a publication of 2015 by the International Children Continence Society summarized the available evidence and expert based knowledge, and provided expert recommendations. Also a specific standardized expert report for VUDS was presented in 2016.

More extensively than in other ages, non-invasive UDS are initially explored, not only because they are more easily accepted and more applicable for children, but also to have comparable parameters during follow-up, and to exactly identify those children and clinical conditions that will benefit from further invasive exams. Essential are a meticulous and complete history, physical examination including clinical neurological testing and assessment by voiding diaries. The exact role and reproducibility of uroflowmetry have been strongly under consideration during the last years, especially if associated with pelvic floor EMG. Additionally, flow plus EMG is recommended in the ICS- Childrens Good Urodynamic Practices.

Furthermore, ultrasonography is considered a useful tool with acceptable reproducibility for initial assessment when evaluating LUTS in children. Ultrasound LUT-studies in children include not only PVR and bladder volume but also bladder wall thickness (BWT). The use of ultrasound is not only limited to a morphological analysis of the LUT, but also a dynamic one, with evaluation of the full and of the empty bladder, and evaluation of the pelvic floor muscles movements and contraction endurance.

2. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

2.1. Myelodysplasia

2.1.1 ICI2013 Conclusions and Recommendations

Retrospective and prospective studies have shown that the UDS diagnosis of (neurogenic) DO and/or reduced detrusor compliance in patients with myelodysplasia or (occult) spinal dysraphism is not predictable on the basis of clinical signs or symptoms. Many retrospective and prospective studies have shown that regularly repeated UDS in patients (children) with MMC reveals clinically relevant results regarding medical and surgical management. Based on expert opinion, VUDS testing is preferable above UDS without X-ray video; however, the exact advantage (e.g. in repeated investigation) is not substantiated. Various studies have shown that LUT function in children with MMC may change over time and with physical growth. No studies have been published that are a help to determine the optimal timing and frequency of UDS follow-up. ICI2013 recommended (grade B/C) that comprehensive UDS is advised in all patients with MMC throughout the entire life on a regular basis from earliest childhood and further that on indication, unscheduled UDS should be considered when relevant lower body half and/or LUT clinical or neurological signs or symptoms arise or when significant management, medical or surgical treatment changes have been instigated.

ICI2013 also recommended that the advantages and disadvantages of the addition of x-ray to UDS should be considered in children with MMC on an individual basis. Timing and technique of UDS in patients with MMC must be selected on an individual basis. To help identify children at risk for subsequent UUT and/or LUT deterioration or a changing neurological picture, initial UDS, very early in the neonatal period, are recommended for children with MMC. The ICI2013 recommended on the basis of expert opinion that anorectal function or dysfunction is simultaneously evaluated with LUT function in children with MMC (see also the chapter on faecal incontinence).
2.1.2 Discussion and New Evidence 2016

Treatment of NLUTD by intradetrusor BoNT-A injection gained growing consideration, also in children, with the mechanism of action now better known.262 Despite studies attesting to the good results of BoNTA in adult neuropathic DO and FDA approval, studies on its effectiveness on NLUTD in children remain controversial, and only scarce reports comment on the specific features of the disease process among patients and reasons for failure in some.263 264 The evidence from uncontrolled studies was recently reviewed.265 In a study aiming to investigate UDS parameters that predict outcome of intradetrusor BoNT-A injection in 37 children with NDO, preoperative bladder compliance (P .030) and open bladder neck (P .031) were found as important predictors of poor response at a regression analysis of outcome.266 In another well conducted study on 16 children with NDO, who underwent intradetrusor BoNT-A injection, the patients with typical DO showed a significant increase in both the cystometric capacity (from 53% to 74% of age related capacity) and the compliance (from 4.7 to 8.6 ml/cm H2O) This resulted in 56% of the patients with complete dryness between CIC. Among (from 4.7 to 8.6 ml/cm H2O) This resulted in 56% of the patients with complete dryness between CIC. Among the patients that displayed (very) low compliance and the compliance decrease in both the cystometric capacity (from 53% to 74% of age related capacity) and the compliance (from 4.7 to 8.6 ml/cm H2O) This resulted in 56% of the patients with complete dryness between CIC. Among the patients that displayed (very) low compliance and no detrusor contraction at all, none demonstrated any notable clinical improvement.267

Another point is that, also because of the extensive use of BoNT-A, some less aggressive surgical procedures (i.e. without bladder augmentation) are attempted, and they may require preoperative UDS. In a cohort of 79 patients studied by UDS before bladder neck surgery without augmentation for neurogenic sphincteric incompetency, despite sustained pressures >40 cmH2O and then assessed at 3 years, UUT changes developed in only 35% of patients, and resolved with medical management or minimally invasive interventions. This provided evidence for a statement that end pressures should not be used as an independent indication for augmentation.268

For children followed since birth, initial UDSin the neonatal period had been recommended for children with myelodysplasia, the basis being that they help identify children at risk for subsequent urinary tract deterioration or a changing neurological picture.269 270 This concept has been confirmed by the recent ICCS recommendations for initial diagnostic evaluation and follow-up of congenital neuropathic bladder.270 Approximately 90% of children born with MMC will have a preserved UUT at birth. Over time, many children who have not received proactive urological care develop UUT and/or LUT deterioration, as an acquired phenomenon secondary to the development or progression of various LUT hostility factors such as DO, reduced bladder compliance, detrusor-sphincter dyssynergia and/or high LPP. The main identified risk factors from UDS which relate to increase of the occurrence and grades of UUT dilatation are decreased bladder compliance of <9 ml/cmH2O, increased DLPP of >40 cmH2O and acontractile detrusor.271 The presence of severe bladder trabeculation has been coined as a parameter of BOO in incontinent children with NLUTD.272 Bladder wall thickness measurement was also found as a predictor of LUT impairment in a case-control study on 80 children with myelodysplasia, decreasing the need for UDS.273 When conservative treatment - as CIC, anticholinergic drugs and BoNT-A injections – are not sufficient, bladder augmentation is performed to relief or prevent UUT deterioration and/or VUR, usually without necessity of simultaneous anti-reflux repair.274 Cystometry follow-up should be used to evaluate the effect of this treatment.275 276

Single centre studies suggest that prevention of high bladder filling pressure (before UUT dilatation is observed) is necessary and feasible even before any UDS diagnosis.277 278 Expert reviews have recommend period cystometry when new onset hydrenephrosis, VUR or UI develops.279 280 A considerable number of myelodysplastic children can develop a change in neurological impairment, early in infancy or as they grow up and reach puberty, thus they need UDS follow-up to check changes281 282 however, the interval and frequency of follow up UDS are not precisely established. In closed MMC, as lipomeningocele, UDS and the presence of neurological impairment were considered to have had crucial roles in determining the optimal timing of surgery in patients with lipomeningocele, and in diagnosing the onset of tethered cord, 283 UDS is also reported to be more relevant towards the outcome of neurosurgical interventions (untethering) than pelvic floor muscle needle EMG.284 In a long-term perspective of drugs use, UDS has been relevant to evaluate the treatment efficacy and tolerability of propiverine285 and, over a period of 15 years, intravesical oxybutynin treatment showed adequate suppression of detrusor activity, cystometric capacity increase from the 5% percentile to the 25-50% percentiles for age, mean end-filling pressure from 24.5 ± 14.4 cm H2O, had returned to the safe zone.286

Because renal transplantation in patients with myelodysplasia and persistent LUT dysfunction carries increased (post –renal) risks for the grafted kidney, the existence or creation (augmentation cystoplasty) of a UDS confirmed low pressure bladder with adequate cystometric capacity before transplantation is deemed necessary.287

2.2. Occult spinal dysraphism

Lumbar cutaneous stigmata in infants may be associated with occult spinal dysraphism and often prompt urological evaluation, including UDS is needed. Series of children with occult spinal dysraphisms have documented abnormalities in striated urethral sphincter function (denervation and/or detrusor-sphincter dyssynergia) in 20 - 35% of babies under 2 years of age with normal neurological examinations in; thus emphasising the need for UDS in these children.288 289 290 There is however also a correlation of 70–90% between an abnormal neurological examination and...
the likelihood of finding an abnormality on UDS in older children.\textsuperscript{291, 292} In the past, several studies demonstrated the usefulness of UDS to diagnose sacral cord function; better EMG activity (in up to 60\%) of the children corrected before 2 years of age) and or progressive changes in urethral sphincter function with very few of these patients having detectable alterations on physical examination.\textsuperscript{293, 294, 295} A UDS before neurosurgical intervention was found to identify LUTD in clinically silent cases and also identified deterioration in these patients.\textsuperscript{296} The usefulness of UDS in detecting lesions and during follow-up in children with known spinal cord abnormalities and/or tethered cord is still controversial. The association between abnormal UDS findings and need for tethered cord release was studied in a large series of 123 children, mainly (91\%) non toilet trained infants. 19\% of these had abnormal UDS, 85\% abnormal spinal MRI and 96\% abnormal spinal ultrasound: a significant association was found between abnormal UDS (P \textless .002) and MRI (P .05), while ultrasound of the spine, was not associated with intervention for tethered cord release (P 1.0).\textsuperscript{297} Taking into account the large spectrum of spinal cord lesions, a multivariate analysis was carried out on a uniform set of 59 patients with a fatty filum terminale and/or low-lying cord: UDS results were categorized by three urologists, blinded for the neurological diagnosis and it was found that pre and post untethering UDS do not predict continence status.\textsuperscript{298} In a retrospective study on 149 tethered cord patients, operated also if asymptomatic when primary and also the symptomatic ones with re-tethering, UDS and prone MRI were considered to be the best tools for screening those patients at risk of symptomatic retethering.\textsuperscript{299} The utility of UDS in preoperative work-up, monitoring for retethering, and long-term urologic follow-up is confirmed but requires further examination.

2.2.1 Conclusions (Level 2/3)

- Retrospective and prospective studies have shown that the UDS diagnosis of (neurogenic) DO and/or reduced detrusor compliance in patients with myelodysplasia or (occult) spinal dysraphism is not predictable on the basis of clinical signs or symptoms.
- Many retrospective and prospective studies have shown that UDS in patients (children) with meningomyelocele or (occult) spinal dysraphism, both initial as well as in the follow-up reveals clinical relevant results with regard to management and surgical or medical treatment.
- Evidence for the optimal interval and frequency of (V)UDS follow–up in patients with children with NLUTD is lacking.
- On the basis of expert opinion, VUDS testing is preferable above UDS without x-ray video, however the exact advantage of repeated VUDS in the follow-up of children with known (morphological or anatomical) abnormalities is not substantiated.
- Various studies have shown that LUT function in children with myelodysplasia or (occult) spinal dysraphism may change over time (and physical growth) (Level of Evidence: 3)
- No studies have been published that help to determine the optimum of timing and frequency of UDS follow-up.

2.2.2 Recommendations (Grade B/C)

- Comprehensive UDS is advised in all patients with myelodysplasia or (occult) spinal dysraphism throughout the entire life on a regular basis from earliest childhood.
- UDS should be also be considered by a change in signs and symptoms, when relevant lower body half and/or urinary tract clinical or neurologic signs or symptoms arise or when significant (surgical or medical) treatment changes have been instigated.

2.2.3 Recommendations (Grade C)

- The advantages and disadvantages of the addition of video (x-ray) to UDS should be considered in children with myelodysplasia or (occult) spinal dysraphism on an individual basis.
- Timing and technique of UDS in patients with myelodysplasia or (occult) spinal dysraphism must be selected on an individual basis.
- To help identify children at risk for subsequent urinary tract deterioration or a changing neurologic picture, initial UDS very early in the neonatal period (e.g. starting from 3 months age), should be considered for children with myelodysplasia or (occult) spinal dysraphism.
- The committee recommends on the basis of expert opinion that anorectal function or dysfunction is simultaneously evaluated with LUT function in children with myelodysplasia or (occult) spinal dysraphism (see also the chapter on faecal incontinence in the book).
- The committee recommends research to determine the optimum of interval and frequency of follow up UDS in children with NLUTD.

2.3. Sacral Agenesis

2.3.1 ICI2013 Conclusions and Recommendations

ICI2013 concluded (Grade 3) that case series have shown that UDS evaluation of LUT function in children with (partial) sacral agenesis reveals a substantial incidence of clinically hidden dysfunction. It is shown that approximately one third of children with

PATIENT EVALUATION: CHILDREN WITH URINARY INCONTINENCE | 629
ARM have spinal dysraphism and/or tethered spinal cord associated with UDS demonstrable LUTD.

ICI2013 recommended that clinicians should consider UDS in children with sacral agenesis and also after (surgery for) sacrococcygeal teratoma, and that clinicians must consider that in children with LUTD, otherwise clinically silent sacral agenesis can exist.

### 2.3.2 Discussion and New Evidence 2016

No significant new evidence or observations arose during the last 3 years. Sacral agenesis, absence of the lower most vertebral bony segments, is a rare lesion that can be missed in infancy because of its sometimes subtle, clinical manifestations, with generally no loss of lower extremity motor and sensory function.\(^\text{300}\) Urinary and/or faecal incontinence usually manifests at an older age when the child fails to toilet train on time. A careful physical examination noting flattened buttocks and a short gluteal crease is pathognomonic for the diagnosis. UDS studies had been shown to be 90% accurate in delineating the neurological deficit, which could not be predicted by the level of absent vertebrae. Sacral agenesis also shows variable association with ARM and/or spinal cord anomalies.\(^\text{301, 302}\) These studies reveal that 30 to 40% of these patients have a lesion type with DO and an intact, but dyssynergic, sphincter while 25 to 40% of these patients have a lesion type with DO.\(^\text{303}\) When MRI shows the extension of the sacral defect as a prognostic factor for retethering. When MRI shows sacral or spinal cord anomalies, UDS should be considered, preceded by neurological exam and considering neurophysiological (evoked potentials) testing. The authors of this and subsequent studies recommend a non-invasive evaluation for all other children, and UDS when NLUTD is suspected.\(^\text{306}\)

### 2.3.3 Conclusions (Level 3)

- Case series have shown that UDS of LUT function in children with (partial) sacral agenesis reveals a substantial incidence of clinically hidden dysfunction.
- It is shown that approximately one third of children with ARM have MMC and/or tethered spinal cord have UDS demonstrable and clinically relevant NLUTD.

### 2.3.4 Recommendations (Grade C)

- Clinicians should consider UDS in all children with sacral agenesis and also after (surgery for) sacrococcygeal teratoma. (see section f – Tumours)
- Clinicians must consider that in children with LUTD, otherwise clinically silent sacral agenesis can exist.

### 2.4. Spinal Cord Injury

#### 2.4.1 ICI2013 Conclusions and Recommendations

Retrospective studies have shown that UDS of all children with SCI is relevant. Retrospective studies have shown that UDS of children with SCI results in diagnoses and treatment similar to adults with SCI. The ICI2013 recommended that UDS in children with SCI is planned on an individual basis, but no earlier than 6 weeks after injury.

#### 2.4.2 Discussion and New Evidence 2016

No further studies with evidence are available during the last three years. The scarcity variability of SCI in children makes it difficult to propose any one treatment program unless the specific type of LUT function is known on the basis of UDS.\(^\text{307}\) It is important to measure detrusor compliance in order to determine the potential risk for VUR and hydrourteronephrosis.\(^\text{308}\) All studies are single centre, retrospective and use historical controls for comparison. In the presence of elevated UDS filling and voiding pressures, a 30% incidence of UUT deterioration can be expected,\(^\text{309}\) while effective voiding with pressures below 40 cm H\(_2\)O in the absence of detrusor-sphincter dyssynergia ensures a stable UUT.\(^\text{310}\) UDS monitoring has been demonstrated to be relevant in the follow up and prevention of UUT deterioration.\(^\text{311}\) In another study on 17 children aged 6 months-18 years with cervical (4), thoracic (8) and lumbar (5) SCI, all but one showed DO on first evaluation, which was changed to acontractile and/or compliant detrusor pattern by medical treatment; 7 had increased cystometric capacity and 8 decreased DLPP at follow-up; only 2/17 developed minor UUT impairment.\(^\text{312}\) UDS, undertaken no earlier than 6 weeks after injury, allows for the manifestation of the extent of the neurologic injury.\(^\text{313}\) As in adult patients autonomic dysreflexia can occur also in children and adolescents.\(^\text{314}\)

### Conclusion (level 2/3)

- Retrospective studies have shown that UDS of all children with SCI is relevant.
- Retrospective studies have shown that UDS of children with SCI results in diagnoses and treatment similar to adults with SCI.

#### 2.4.3 Recommendations (Grade C)

- The committee recommends that UDS in children with SCI is planned on an individual basis, but no earlier than 6 weeks after injury.

### 2.5. Cerebral Palsy

#### 2.5.1 ICI2013 Conclusions and Recommendations

ICI2013 has concluded on the basis of cohorts with historical/literature -control groups that clinically unexpected LUTD – predominantly dysfunctional voiding and reduced cystometric capacity - can occur in
children with cerebral palsy an has recommended that clinicians should carefully evaluate voiding in children with cerebral palsy and should consider complete UDS when dysfunction is suspected. ICI2013 recommended that UDS is considered in all patients with spastic cerebral palsy.

Discussion and New Evidence 2016

A recent systematic review on 27 studies, describing prevalence of LUTS or UDS findings, found that 55% of the patients have at least one LUTS: storage symptoms are more common, and patients with pelvic floor overactivity are more prone to progress to UUT dysfunction in adult life.318 Bladder (cystometric) capacity is decreased in most children with cerebral palsy, and PVR is present in an important proportion. Uroflowmetry and PVR are considered first line evaluation of LUT function in children with cerebral palsy. UDS can direct management; Negative prognostic factors are the spastic subtype with quadriplegic distribution, moderate to severe functional impairment (Gross Motor Function Classification System [I-V; V= Severely handicapped/wheelchairbound] III or higher) and severe cognitive impairment.317 A careful study by uroflowmetry on 57 patients showed that the symptomatic children (52%) had lower Q_{max} (P .013) and abnormal flow rate curves (P .022) indicating non-invasive testing as a good screener tool. The vast majority of the children with cerebral palsy tend to gain normal LUT function, but often at an age that is later than expected for from DO.319 A meta-analysis of UDS performed in 117 children with either persistent UI despite frequent toileting, or UTI, revealed normal function in 15% or DO in 73%.320 In some recent studies, detrusor-sphincter dyssynergia was present in higher prevalence then earlier reports (11% versus 5%),321 and normal function was less prevalent (only 15%) in the more recent case series.322 Therefore, it has been suggested on the basis of expert opinion that cystometry and sphincter EMG are to be considered, but only when frequent toileting or anticholinergic therapy fails to control incontinent episodes, the child develops UTI from ineffective voiding, or when ultrasonography reveals hydronephrosis.

VUDS assessment can be considered in all patients with infantile cerebral palsy. The decision should not be based on clinical symptoms because at least half of the children with spastic cerebral palsy have clinically silent bladder dysfunction. 100% of children had clinical improvement postoperatively (selective dorsal rhizotomy), 71% who were incontinent preoperatively became continent and none had deterioration on UDS.323 324 Some studies have shown that clinically unexpected LUTD can occur in children with cerebral palsy, especially when voiding symptoms are present.

2.5.2 Conclusion (Level 3)

- Some studies have shown that clinically unexpected LUTD can occur in children with cerebral palsy, especially when voiding symptoms are present.
- Observation and non-invasive testing are helpful, but UDS should be considered when UTIs or UUT dilation occurs in children with cerebral palsy.

2.5.3 Recommendations (Grade C)

- Clinicians should evaluate voiding in children with cerebral palsy and should consider complete UDS when dysfunction is suspected.
- UDS is to be considered in all patients with spastic cerebral palsy. Undiagnosed and untreated patient’s bladder dysfunction remains pathological and potentially dangerous, and may damage the UUT.

2.6. Tumours

2.6.1 ICI2013 Conclusions and Recommendations

According to ICI2013, it was shown in single centre cohorts that UDS testing is relevant after resection of a sacrococcygeal teratoma. A study showed that all children with central nervous system tumours can have LUTD regardless of the location of the tumour. LUTD exists after sacrococcygeal teratoma resection and recently again it was proposed, on the basis of a single centre cohort, that UDS is necessary for those children.327 A recent study showed that children with central nervous system tumours can have UDS abnormalities, whether the tumour is in the spinal cord or not. A single centre and selected cohort study concluded that a child with a central nervous system tumour needed urological investigation including UDS regardless of tumor location.328

2.6.2 Conclusion (Level 3)

- It was shown in single centre cohorts that UDS is relevant after resection of a sacrococcygeal teratoma.
- A study showed that all children with central nervous system tumours can have LUTD regardless of the location of the tumour.

3. ANORECTAL MALFORMATION AND PERSISTENT CLOACAL ANOMALIES

3.1. ICI2013 Conclusions and Recommendations

ICI2013 concluded that various studies have shown that a significant proportion of children with an ARM
have primary or secondary dysfunction of the LUT and/or LUT innervation abnormalities or pelvic floor dysfunction. ICI2013 recommended that clinicians should consider UDS in children with imperforate anus or ARM when clinical signs of LUTD exist and also should consider UDS in children where, on the basis of an MRI, or on the basis of clinical examination, relevant neurological structural abnormalities exist, before and/or after reconstructive surgery independent of (the existence of) LUTS.

3.2. Discussion and New Evidence 2016

In the past, imperforate anus repair for high lesions frequently resulted in (stress-) UI due to a pudendal nerve injury that often occurs from surgical perineal approach. With the advent of the posterior sagittal anoplasty this complication has been eliminated as a cause for subsequent UI, although bladder neck incompetence may be a consequence of extensive mobilisation of the sigmoid colon to transfer the rectum to its final location.\(^{330}\)

UI and LUTD may result from iatrogenic injury or from a pre-existing congenital neurological lesion. UI after definitive repair is reported as to be the result ineffective emptying causing ‘overflow urinary incontinence’ and underactive or acontractile detrusor, rather than urinary sphincter injury. Similarly, it has been reported, on the reconstruction of cloacal anomalies, that the main clinical characteristic of bladder dysfunction was a failure to empty,\(^{331, 332}\) presumably due to iatrogenic injury from extensive dissection, which can lead to peripheral nerve damage. In 2004, Warne et al prospectively studied the effect of surgical reconstruction by posterior sagittal approach and total urogenital mobilisation in either causing or worsening bladder dysfunction, in new patients with cloacal anomalies and ARM: those with cloacal malformation had a high incidence of innate LUTD, and a significant deterioration (frequently a change to DU) in bladder function.\(^{333}\) In a prospective study on children with ARM, prior to, and following definitive procedure, only 9 of the 19 patients had normal UDS pre-operatively, and LUT function worsened postoperatively.\(^{334}\)

UDS is required to evaluate LUTD in patients following repair of ARM (and Cloacal anomalies). The reliability and reproducibility of findings among the various studies analysed confers an important role for VUDS as an integral part of the evaluation and management of these children.

Moreover, reports of spinal MRI’s reveal a 35% incidence of distal spinal cord abnormalities in children with an imperfect anus\(^{335}\) NLUTD occurs in 50%,\(^{336}\) and 40-60% of those patients who have tethered cord needed untethering.\(^{337}\) Evaluation of all patients with ARM using MRI is recommended and when MRI shows sacral or spinal cord anomalies, non-invasive should be done, and UDS when NLUTD is suspected.\(^{338}\) To detect spinal cord abnormalities in neonates, spinal ultrasound has been largely used as a screening test up in children to 5 months of age; a study on 244 ARMs showed a 100% specificity but a very low sensitivity (15%), thus stating that ultrasound is not suitable as a screening test for MMC in ARM, with MRI being necessary when symptoms occur.\(^{339}\)

In summary; imperforate anus may occur as an isolated lesion but also in conjunction with spinal cord pathology and/or sacral anomalies (and associated cardiac, esophageal, bony ones), which was reported to occur in 38% of cases of ARM.\(^{340, 341}\) By combining the incidences in 3 studies it was found that the presence of an abnormal sacrum increases the likelihood of LUTD to as high as 76% (38 of 50 children).\(^{342, 343}\) When the rectum ends above the levator ani muscle there is a much greater chance of LUTD than when it ends below the pelvic floor\(^{344}\) and the older the child is at the time of UDS the more likely he/she is to have abnormal LUT function.\(^{345}\)

3.3. Conclusions (Level 3)

- Various studies have shown that a significant proportion of children with ARM has primary or secondary dysfunction of the LUT, LUT innervation abnormalities or pelvic floor dysfunction.

3.4. Recommendations (Grade C)

- Clinicians should consider UDS in children with imperforate anus when clinical signs of LUTD exist.
- Clinicians should consider UDS in children where, on the basis of an MRI, or on the basis of clinical examination, relevant neurological abnormalities exist, and/or after reconstructive surgery independent of (the existence of) LUTS.

4. ANATOMIC ABNORMALITIES

4.1. ICI2013 Conclusions and Recommendations

ICI2013 has observed that many case series have demonstrated frequent UDS abnormalities, predominantly DO and reduced bladder compliance or large capacity bladder with impaired filling sensation, in children with PUV, urethral stricture, ectopic ureterocele, VUR or bladder extrophy and that proper UDS has been shown to be of help to determine when further medical or surgical management is indicated in children with these abnormalities. ICI2013 concluded that the use of UDS has aided in an objective measurement of success or failure of treatments for these abnormalities.

ICI2013 recommended that clinicians should consider complete UDS of the filling and voiding phases, at least once, in children with PUV, urethral stricture, ectopic ureterocele, VUR or bladder extrophy and also that clinicians should consider regular uroflowmetry and PVR assessment in the follow-up and further management of children with PUV, urethral stricture ectopic ureterocele, VUR or bladder extrophy.
4.2. Discussion and New Evidence 2016
No further major evidence arose during last 3 years regarding usefulness of UDS in congenital anatomical anomalies, apart from the general tendency to use non-invasive tools as much as possible in conditions which are not treated with surgical correction (i.e. VUR and/or valve patients); while major abnormalities (i.e. extrophies or ARM or clocal anomalies) need UDS evaluation prior to decide complex corrections. The evidence still consists of uncontrolled case series and expert opinions although many clinicians now feel its usefulness is beyond question.

4.3. Posterior Urethral Valves
In the past UDS had been essential to understand (functional) obstruction, LUT dysfunction, persistence of UI and UUT (and renal) impairment evolution in boys with PUV.347 348

The importance of bladder neck secondary obstruction remains one of the principal issues,349 which may require further intervention on the basis of the UDS observation that DO and high maximum voiding detrusor pressures decreased consistently after bladder neck incision.350

In a series of UDS after valve ablation, the type of bladder function observed, correlates with the time elapsed from surgery; DO was the predominant pattern initially,351 but changes are noted in both DO and compliance over time.352 353 354 Myogenic failure, in conjunction with increasing capacity and poor emptying, are primarily a later phenomenon, and are most likely to be secondary to increased urine production and decreased frequency of voiding with advancing age.355 Despite early valve ablation, a large proportion of boys treated for PUV have gradual detrusor ‘decompensation’ and/or secondary bladder neck outlet obstruction leading to obstructive voiding and finally DU or acontractility.

The persistence of UUT changes is related to the bladder’s unresponsiveness to medical therapy for the DO and/or for DU(usually CIC). However, it is possible that this condition is secondary to insufficiently frequent voiding in the face of increased urine production. BOO from a secondary hypertrophied bladder neck can also occur, requiring further intervention.356 Several studies have shown the predictability of the development of renal failure based on specific detrusor patterns seen on UDS: persistent poor compliance, high detrusor pressures, BOO and/or chronic failure of the detrusor to adequately contract during voiding with increased PVR.357 358 The extended use of antenatal diagnosis selected a ‘new generation’ of patients with PUV, who undergo proper early ablation of obstructing valves allowing normal cycling, which helps ‘bladder healing’.

Nowadays, knowing the LUT conditions which are at risk for UUT deterioration, it is reasonable to follow the patients who underwent neonatal valve ablation and aggressive and early bladder training, by non-invasive UDS exams. In a case-control study two age-matched group of patients were followed by cystometry and pressure-flow study at least every 3 years or were monitored annually by non invasive tests from age 5: neither the prevalence of LUTD nor late onset renal failure differed significantly between the two groups.359 In another multivariate analysis study, detrusor thickness greater than 1.3 mm was considered the only independent risk factor for later impaired bladder function.360 Noninvasive UDS seems to be as safe and effective as invasive UDS in the long-term management of boys with PUV, and invasive UDS may be reserved for cases of progressive deterioration of LUTD or renal function.

4.4. Bladder Exstrophy
Once the exstrophied bladder is closed it may be difficult to manage persistent UI, UUT dilation or VUR. Whether and when to further improve continence function and whether to perform augmentation cystoplasty for a small capacity, poorly compliant bladder are challenging issues. In addition, as more children undergo complete primary repair of the exstrophic bladder in the neonatal period, the most accurate assessment of bladder function is by UDS; compliance reduces in up to 50% after surgery.361 362 Studies have correlated UI with age related cystometric capacity, compliance, DO and/or LPP.363 UDS remain helpful to evaluate LUT before (and after) further surgical procedures and for research matters. To check potential injury to pelvic neurourological anatomy after complete primary repair of bladder exstrophy, needle -EMG was done on 13 children to evaluate the external urethral sphincter response to sacral reflex stimulation and during voiding, finding normal individual motor unit action.364

4.5. Ectopic Ureterocele
UDS in babies with an ectopic ureterocele had shown that several cases had a larger than normal cystometric capacity and DU,365 but in a multicentre analysis of 616 children it was found that LUTD is present only in ectopic ureterocele.366 Recently, there is an increasing agreement in favour of conservative management of paediatric duplex system ureteroceles, by mean of simple endoscopic puncture followed by close surveillance: VUR can resolve spontaneously in a significant number of patients, and bladder function should be conserved,367 and even if secondary bladder surgery is needed, significant bladder dysfunction is rare.368

4.6. Vesicoureteral Reflux
It had been shown that VUR may be a secondary phenomenon resulting from LUT dysfunction and not (only) a primary anatomical abnormality at the ureterovesical junction in a significant proportion of children.369 370 371 There is evidence that DO may lead to VUR in a marginally competent ureterovesical junction mechanism.372 373 This DO may be a natural phenomenon in the infant bladder, especially in boys,
due to the presence of higher voiding pressures and/or a learned dysfunction in older children. DO tends to resolve with increasing age, going from an immature pattern with high pressure levels in the first two years or life, to a high capacity bladder with incomplete voiding. Among UDS parameters, high bladder pressure at the onset of VUR was found a positive prognostic factor for spontaneous resolution of VUR (P <0.005), independently of VUR grade. The highest degree of VUR was found associated with highest detrusor pressure (P <0.038) in the group with 'urgency syndrome', and no differences in resolution rates observed from grades I to V VUR in children with LUT conditions, patients with dysfunctional voiding having the most improvement and greatest (70%) resolution of VUR. Another prognostic finding regarding the spontaneous resolution of VUR is intravesical volume at the onset of VUR: large cystometric capacity correlated with VUR during filling, while VUR at voiding correlated with low cystometric capacity, with the first pattern showing a lower resolution rate within the third year of life, in a longitudinal study by videocystometry. There is ample evidence to show that treating the DO and/or voiding dysfunction leads to a faster rate of resolution of VUR (63-92% within 1 year) than treating only with antibiotics (25-54%). UUT damage is more likely to occur in children with abnormal LUT function. In this setting, history taking about voiding habits and accurate non-invasive UDS evaluation become paramount. Question remains if cystometry with pressure flow studies in older children are advised. In a study on 40 patients, VUDS showed LUTD in 76% of the children, and in a recent prospective study of 147 children with high grade VUR, normal patterns were found in only 23% of them. In patients who had post-treatment UDS, biofeedback, pelvic floor muscle training and treatment with antimuscarinics effectively decreased detrusor pressure, increased cystometric capacity and maximum flow rate, and reduced the grade of VUR. It is nowadays reasonable to diagnose LUTD by non invasive tests and to consider VUDS in therapy resistant patients, paying attention to bladder neck dysfunction, which was shown to be relevant in a randomized trial. Many clinicians advocate UDS especially for those patients that still have UI, renal damage, or who are about to undergo surgical correction, even if precise UDS (pressure flow) criteria for outlet conditions in children are still undefined.

4.8. Conclusions (Level 3)

- Many case series have demonstrated frequent UDS abnormalities, predominantly DO and reduced bladder compliance or large cystometric capacity with impaired filling sensation, in children with PUV, urethral stricture, ectopic ureterocele, VUR or with bladder extrophy.
- Proper UDS has been shown to be of help to determine when further medical or surgical management is indicated in children with these abnormalities.
- The use of UDS has aided in an objective measurement of success or failure of treatments for these abnormalities.

4.9. Recommendations (Grade C)

- Clinicians should consider complete UDS of the filling and voiding function, at least once, in children with PUV, urethral stricture, ectopic ureterocele, VUR or with bladder extrophy.
- UDS in children should be done with special attention to their specific needs, and with careful attention to minimize mental trauma and to ensure representativeness as much as possible.
- Clinicians should consider regular uroflowmetry and PVR assessment in the follow-up and further management of children with PUV, urethral stricture ectopic ureterocele, VUR or with bladder extrophy.
- Clinicians should consider the necessity of follow-up UDS on an individual basis and as less frequent as possible.

5. FUNCTIONAL DISORDERS OF THE LOWER URINARY TRACT

5.1. ICI2013 Conclusions and Recommendations

ICI2013 found that various studies had been showing that treatment of children with functional UI (and of the, frequently associated, bowel elimination problems) can be initiated on the basis of history, clinical exam, bladder diaries, bladder ultrasound and (free) uroflowmetry with PVR assessment. Furthermore various studies, reviews and guidelines agree on the relevance of UDS in children with UI and nocturnal enuresis resistant to initial (conservative) treatment. The ICI2013 recommended (Grade B) uroflowmetry and PVR assessment (until -for the individual child-representative values are obtained, if possible) as 'non-invasive urodynamic'-screening and evaluation
in all children with LUTS, UI and/or with nocturnal enuresis resistant to first line therapy. ICI2013 suggested urological signs and symptoms assessment in children with chronic constipation and ICI2013 recommended complete UDS in children with UI and/or with nocturnal enuresis resistant to conservative treatment, if invasive or clinical (dry-bed training) treatments are contemplated.

5.2. Discussion and New Evidence 2016

When assessing functional disorders involving the LUT in children, one must take into account the dynamics of the maturing nervous system, learned habits of elimination for bladder and bowel function and social influences.

5.3. Diurnal Incontinence

UDS (invasive) has a limited place in diurnal (day and night) UI. This condition is not considered worrisome before age 5 or 6. UI in children can have many causes, and history and clinical investigation are very important in this regard. Therefore, it is imperative to formulate a ‘urodynamic question(s)’ following a comprehensive history, careful physical examination, and standard urological investigations, possibly with the aid of validated questionnaires. It is well known since several years that UI can also coincide with dysfunctional voiding and/or bowel elimination problems. Treating these bladder and bowel dysfunctions, with behavioural modification, biofeedback training, drug therapy, is necessary before considering UDS. Nowadays, the expression ‘Elimination syndrome’ has been substituted by Bowel/Bladder Dysfunction (BBD), to better underline a clinical condition involving abnormal habits and dysfunction of both the lower urinary and bowel tracts.

Uroflowmetry with a PVR urine and simultaneous EMG determination are the tests of choice, and results from uroflowmetry should be compared with information from the patient’s Frequency/Volume Charts. Bladder volume may affect uroflowmetry: it was theorized that $Q_{\text{max}}$ is physiologically dependent on bladder volume, thus researchers are trying to identify other factors that may be more important in what determines $Q_{\text{max}}$. Sonographic estimation of PVR volume should complete the assessment: in children <6 years, a repetitive PVR of >20 ml or >10% cystometric capacity is considered elevated; while in children >7 years, repetitive PVR >10ml or 6% cystometric capacity is regarded as elevated. Some (expert and/or single centre) evidence is emerging for uroflowmetry + EMG evaluation and investigators have looked at the time differential between relaxation of the external urethral sphincter (as measured by patch perineal electrodes) and the opening of the bladder neck on VUDS. This parameter (labeled ‘lagtime’) was not corrected for meatus to flowmeter distance but was nevertheless considered a sign of DO, when prolonged >2 seconds and it was suggested that this lag time could also indicate bladder neck dysfunction if the time exceeded 6 seconds.

In all children with non-neurogenic LUTS non-invasive UDS is warranted to determine the presence of different forms of LUTD, and to assess bowel dysfunction as well. Bowel dysfunction, in the absence of any anatomical or neurological deficit, often affects LUT function and contributes to UI in a number of ways. Constipation had been shown in the past to be associated with DO and a reduced functional bladder capacity. Understanding and eliminating this possible aetiology can normalise LUT function, as stated by the report from the Standardisation Committee of the International Children’s Continence Society. In a recent prospective study from urological and gastroenterological clinics in one center, 68% of subjects referred with UI, and/or constipation and/or faecal incontinence and included, had at least a 50% reduction in number of daytime UI episodes and 27% became completely urine -continent by successful relief of bowel (constipation and/or faecal incontinence) dysfunction.

Persistent daytime and night-time UI, resistant to conventional therapy may require (V)UDS. In several reports over 20 years, different UDS findings had been found, with DO (in 57%), dysfunctional voiding (in 22%) and also normal findings in 14%. Dysfunctional voiding was also reported associated with DO in up to in incidence of 76%. Many of those studies use terms that are outdated now and those should be replaced (‘transformed’ where possible) with the new.

Apart from the above mentioned NLUTD, co-morbidities other than bowel dysfunction may be present such as psychiatric and psychosocial ones. Several recent studies well designed by validated questionnaires, were conducted, including a case-controlled one on autism spectrum disorders which showed a significant incidence of LUTS, with a total problem score of 70% (versus 2% in controls) and concluded that screening for UI and, if indicated, treatment of the dysfunction(s) is recommended. In a study on 68 children with attention deficit-hyperactivity disorder (ADHD), the total dysfunctional voiding score in the ADHD symptoms group was significantly higher (P < 0.05) than in non-ADHD children. Other social and behavioral conditions were investigated in children referred with sings and symptoms of LUTD, such as obesity or underweight, bullying (a quarter of American school children are regularly bullied), and sexual abuse and found these to have a higher LUTS-score and/or a higher incidence of UI. Regarding bullying, UI is more frequent in females and in those children with higher bulling scores; physical forms of bullying accounted for worse voiding severity scores.

Greater attention has been recently paid to check the prevalence of LUTS and UI in a series of genetic dis-
orders with cognitive/behavioral or potential neurological problems, in order to reassure the families and to screen the cases which may require treatment. For example, in a case-control study, out of 326 children with Down’s syndrome, it was found that there is a marked delay in toilet training (average 5.5 years), and UI was reported in 46% of (versus 24% in controls) previously toilet trained children. Children with Williams syndrome, which comprises mild intellectual disability, have high rates of daytime UI and enuresis, reducing with age: daytime UI decreased from 18% in children to 0% in adults, while enuresis, reducing with age:

UDS has clearly improved our understanding of the aetiology of diurnal UI but no study has shown that UDS characterisation of any abnormality has improved the efficiency of treatment for these children. In any case, pretreatment UDS is considered to be required before invasive treatments in children with therapy resistant diurnal UI. Sacral neuromodulation has been demonstrated to improve refractory bowel bladder dysfunction, with more benefit if DO is shown on UDS.

5.4. Enuresis (Nocturnal)

Night-time wetting (nocturnal enuresis) is a condition that is common in children aged 5 years but which improves with time, so that less than 15% of pubertal boys and 5% of pubertal girls continue to be affected. Multiple causes for the persistent wetting have been implicated, ranging from genetic factors, to maturational delays, sleep disturbances, social causes, psychiatric conditions (as attention deficit disorders), to LUTD and/or abnormal vasopressin secretion.

It is now commonly considered essential to discriminate Monosymptomatic Nocturnal Enuresis (MNE) from Non-Monosymptomatic one (NMNE). According to the ICCS definitions, NMNE consists of two different disorders: nocturnal enuresis and LUTD identical to those with daytime UI except that daytime UI does not occur. It is generally not necessary to conduct UDS until adolescence, to determine why the UI has not abated. Non-invasive exams are important for enuresis subtyping, relevant for selection of treatment modality. An abnormal micturition history, or dys-functional voiding symptoms like squatting and/or abnormal voiding charts, predicted abnormal UDS results correctly, with a sensitivity of 81% and specificity of 86%. A bladder volume and bladder wall thickness index less than 70 was a predictor for the presence of DO at cystometry in one cohort. A bladder capacity at night (enuretic capacity) was significantly less in those with nocturnal enuresis versus those without. A recent study from a series of 720 children showed significant differences between MNE and NMNE patients as both maximal VV and nocturnal urine volume, which were lower (P < 0.001) in NMNE patients. Out of 500 patients who were initially referred as desmopressin resistant, 33% of these became dry on desmopressin monotherapy, demonstrating how relevant is the UDS diagnosis of enuresis subtyping for selection of treatment. On this regard, it was shown that treating the non monosymptomatic child using antimuscarinic agents can be very effective (as high as 77% cure) when based on the findings of UDS.

An emerging issue which requires further research, is the progression of enuretic children into adulthood. Enuretic children were found more likely to have nocturia and urinary urgency if they had nocturnal enuresis when > 12 years of age. In a retrospective case-control study, 57 women were investigated using a validated questionnaire. The results demonstrated that the prevalence of LUTS was much higher (mainly UI, P .0001) in patients who initially presented for LUTS/UI in childhood than in age-matched controls (school nurses).

5.5. Conclusions (Level 2/3)

- Various studies show that treatment for children with functional UI (and of the, frequently associated, bowel dysfunction) can be initiated on the basis of history, clinical exam, bladder diaries, bladder ultrasound and uroflowmetry with PVR assessment.
- Various studies, reviews and guidelines agree on the relevance of UDS in children with UI and nocturnal enuresis resistant to initial (conservative) treatment.
- There is evidence from epidemiological studies, carried out by validated questionnaires, that several neurological/cognitive/behavioural disorders (i.e. genetical diseases, autism, ADHD) have an association with LUTS and UI.
- There is evidence that also social and/or behavioural conditions (i.e. obesity, bullying) have a significant incidence of high LUTS-score and/or UI.
- The neurological diseases and social conditions with potential LUTS and UI should be evaluated at least by bladder diaries and questionnaires, possibly by non-invasive UDS.
- The potential risk factor for adult women to have UI if they suffered from LUTS as girls may require long-term accurate follow-up.

5.6. Recommendations (Grade B/C)

- The committee recommends uroflowmetry with pelvic floor EMG and PVR assessment as ‘non-invasive urodynamic’-screening and evaluation in all children with LUTS, UI and/or with nocturnal enuresis resistant to first line therapy.
- The committee suggests urological signs and symptoms assessment in children with chronic constipation and/or fecal incontinence.
The committee recommends complete UDS in children with UI and/or with nocturnal enuresis resistant to conservative treatment, if invasive or clinical (dry-bed training) treatments are contemplated.

5.7. Suggestion for Research

The committee suggests that further integrated approaches to the diagnosis (and management) of children with bowel dysfunction, in combination with LUTD are undertaken.

Longitudinal studies on persistence of LUTS/UI in adults are suggested, to be integrated with retrospective studies in adults suffering of UI, in order to evaluate if having LUTS in children is a risk factor for UI in adulthood.

6. TECHNICAL CONCERNS: RELIABILITY AND REPRODUCIBILITY OF TESTS

6.1.ICI2013 Conclusions and Recommendations

The ICI2013 concluded (on the basis of various studies to determine normal and test retest values for UDS in children) that, within the limits also provided for adults, UDS in children is reliable and reproducible. Although it is plausible and considered useful to reduce filling speed and catheter size in relation to patient size, the exact values can not be given and the influence of the transurethral catheter size on (children's) voiding is unknown. The ICI2013 concluded that standards for pressure flow analysis in children are lacking.

The ICI2013 recommended (Grade C) that the specific demands of children, physically, as well as psychologically, be taken into account, before UDS is carried out, as well as during the testing. The ICI2013 advises specialised workers, units and equipment to ensure this. The ICI2013 recommended that invasive diagnostic tests should be done if indicated by the results of non-invasive procedures and should be done only when the outcome will or can alter management and recommended that clinicians take into account the variability and test retest differences of UDS in children and also take into account the effect of the (apparent psychologically stressing) laboratory-situation on the child’s behaviour, and the implications for the results of the tests.

6.2. Discussion and New Evidence 2016

Often, differences in UDS parameters exist from one study to another. In pediatric patients there is concern that the reliability of measurements could be influenced by development effects and measurement variability, as well as by the unfamiliar clinical environment. A recent study, comparing (conventional) UDS with Ambulatory UDS: even if flow rates were similar between methods, more diverse voiding patterns were identified in AU, suggesting that UDS may not be sensitive enough to the variability of LUT pathology in children. Functional bladder capacity (as derived from the voiding diary, without the first void in the morning) is presented as a relevant parameter for the clinician in the ICCS definitions. Confirmed by the subsequent ICCS revised document.

In the UK health care system a minimum number of tests is considered of relevance for the maintenance of sufficient expertise which is also specified for the number of children (30 /annum) to ensure quality.

Following the above clinical assessment by diaries - as underlined in the paragraph *Diurnal Incontinence - efforts have been done in the recent years to better standardize non-invasive tests. Uroflowmetry, which is the indispensable first-line test for children with suspected LUT dysfunction, must be accompanied by ultrasound PVR measurement. Uroflowmetry should be evaluated according to precise criteria and may be performed in conjunction with pelvic floor EMG. More accurate nomograms were recently stated for uroflowmetry analyzing, 721 records, and for PVR, analyzing (single and dual) PVR in healthy school children. Unfortunately, there is still a tremendous amount of intra- and interobserver variation in defining the shape of curves, but studies are showing how uroflowmetry-analysis can be more reproducible using standardized evaluation and using a "flow index". Uroflowmetry may be also more reliable if performed with simultaneous EMG; inter-rater agreement in a study on 84 uroflow-EMG studies was suboptimal and disagreement may be lowered by simplifying diagnostic criteria and allowing assignment of multiple diagnoses. Ultrasound bladder wall thickness measurement is gaining interest: in a prospective study on 324 children; healthy and dysfunctional voiders, a good sensitivity (based on anterior wall thickness: 67% and based on posterior wall thickness 83%) for symptoms of dysfunctional voiding was obtained. Another study in children with BOO (PUV), found detrusor thickness greater than 1.3 mm in a multivariate analysis as the only independent risk factor (P .004) for later impaired bladder function. Dynamic pelvic floor ultrasound is under evaluation for normative values of endurance and direction of pelvic floor movements. A cut-off diagnosis for specific non-neurogenic dysfunction for any of the non-invasive tools would be desirable.

Invasive UDS are considered to be indicated when non-invasive investigation raises suspicion of neurogenic detrusor-sphincter dysfunction (occult spinal dysraphism), obstruction (i.e., PUV), genitourinary abnormalities (i.e., extrophy, epispadias), profound non-neuropathic detrusor-sphincter dysfunction (children with dilating VUR and recurrent febrile UTI), or significant PVR of unknown cause. To assess the voiding phase, pressure flow studies are performed immediately after filling cystometry. In children, the
transition from filling to voiding is not as easily managed as in adults. To avoid missing this important transition, cystometry and pressure-flow/EMG measurements should preferably be performed as one continuous study. Available reports on detrusor pressure during voiding in symptom free children is reported to give a wide range, that is between ± 50-60 cmH2O in one study. In infants the average detrusor pressure at voiding was reported another study to be 127 cmH2O in boys and 72 cmH2O in girls on standard fill cystometry, similar to what found in another study by natural fill cystometry.

When filling by catheter, slow fill cystometry (5–10 percent of estimate bladder capacity per minute, or <10 ml/min) is recommended, as compliance (predominantly) and DO (possibly) may be significantly altered by faster rates of filling. In infants, temperature of the infusate may influence cystometric capacity and DO; however, its clinical relevance remains unknown. Most children readily tolerate a 6- or 7- Fr. double lumen transurethral catheter to fill the bladder and record pressure. In selected cases, a suprapubic catheter may be inserted under general anesthesia the previous day or several hours earlier on the same day, but risks need to be juxtaposed against benefits of this approach. It has been postulated that transurethral catheters (6 or 7 Fr.) do not significantly obstruct the urethra.

Avoiding general anesthesia is important as this affects the natural state and eliminates the chance for voiding. Most children can undergo UDS without pre-medication; only the most agitated may require some degree of sedation. To reduce anxiety, the study may also be performed with the child seated, watching a video or DVD and accompanied by one or both parents. Following previous consultation recommendation, the ICCS standardisation on UDS studies of the LUT in children confirmed that UDS in children are best performed under the auspices of a knowledgeable urologist or trained urodynamacists; so that children should receive comprehensive UDS in a laboratory that is specialised in paediatric UDS with appropriately trained personnel.

6.3. Conclusions (Level 3)

- The committee concludes that standards for pressure flow analysis, and information on non-invasive PFS in children are lacking.

6.4. Recommendations (Grade C)

- The committee recommends that the specific demands of children, physically as well as psychologically are taken into account, before UDS is carried out as well as during the testing. The committee advises specialised workers, units and equipment to ensure this.

- The committee recommends that clinicians take into account the variability and test-retest differences of UDS in children and also take into account the effect of the (apparent psychologically stressing) laboratory-situation on the child’s behaviour, and the implications for the results of the tests.

6.5. Suggestion for research

- The committee suggests to elaborate on standardisation of UDS evaluations and on criteria to judge how the 'laboratory' circumstances have influenced the child's (LUT) behaviour, with the aim to better include how well UDS have represented the actual LUTD, in the evaluation of the test.

- The committee suggest to verify if, how and when non-invasive tests can substitute UDS in the accuracy of diagnosis of functional LUTD in children.

IX. PATIENT EVALUATION: FRAIL ELDERLY

1. INTRODUCTION

ICI2013 concluded that UI in the frail elderly commonly has diverse and multiple coexisting factors. Retrospective ('clinical cohort') single centre reports confirm that general health, mobility neurologic diseases, medications and 'direct' effect of aging on the LUT all have effect on LUT function. Also in the frail elderly, symptoms and signs are unreliable to predict LUT (UDS) dysfunction. The committee concluded that bedside UDS (one channel cystometry) has inherent unreliability and no evidence exists to quantify the risks (of false positive diagnosis) versus the advantages ('simplicity'). The committee concluded also
that determination of PVR is considered relevant in all frail elderly with LUT dysfunction on the basis of expert opinion and good clinical practice-guidelines.

The 2013 committee recommended that frail elderly, with UI, are evaluated by a clinician skilled in the care of those patients and that all contributing factors are managed, before further urological diagnostics are started. The committee recommended also that (standard) UDS should be offered to all elderly regardless of the comorbidity (not responding to relevant management) if specific further treatment is deemed appropriate (possible).

1.2. New Evidence 2016

Also in the elderly UI is associated negatively with HRQoL and with similar impact in both men and women, mostly noticed in the dimensions of energy, social isolation, and physical mobility.\(^{467}\) OAB-S is common in older adults and associated with impairment in mental health and HR-QoL, but rates of treatment seeking behavior are low.\(^{468}\) OAB-S and UUI symptoms severity progress dynamically and are also sustained over time, although in a 5 years period also symptoms reduction may be observed.\(^{469}\) Elderly patients with OAB-S and DU might also develop a large PVR volume after antimuscarinic treatment.\(^{470}\) The role of urothelium is, also in the elderly, considered of relevance in the pathophysiology of LUTD\(^{471}\) and urinary inflammatory proteins have generated some attention.\(^{472}\) The frail elderly are reported to have a higher risk of developing DO and/or DU.\(^{473}\) UDS findings in the (frail) elderly tend to demonstrate DO.\(^{474}\) Even in individuals that do not spontaneously report symptoms or bother. There may also be a reduction in cystometric capacity, urinary flow rate and detrusor contractility.\(^{475}\) The invasive nature of conventional UDS becomes a relatively more important factor in the old or frail elderly, who may be more vulnerable to any intervention than younger people. There was a significant association between age and the presence of asymptomatic bacteriuria before cystometry and between the bacteriuria and urinary urgency (without DO) on cystometry.\(^{477}\) Elderly patients with DU may have large bladder volume, but small VV and large PVR volume, suggesting diminished central sensitivity to volume afferent activity in the aged bladder.\(^{478}\) In patients with DM, the PVR volume was significantly increased, in addition to OAB-S in the elderly.\(^{479}\)

Some recent reviews have summarized medication use, especially polypharmacy and the effect on the lower urinary tract. Contrary to, or before adding another medicine (or management) in a frail elderly person with LUTS or LUTD, it might be wise to consider reducing other medication to ameliorate medicine (side effect) associated-LUTD and symptoms.\(^{480}\) \(^{481}\) \(^{482}\)

UDS is reserved for patients in whom conservative medical and medical management, directly or indirectly aimed at LUT-function improvement, has failed or has proved inadequate, and in whom more intensive or invasive therapy is being considered. The place of UDS in the frail elderly with UI is less precisely established. There is very little objective evidence for or against clinical UDS in this population group. UDS should be performed in the workup of vulnerable elders when surgical intervention is considered according to the guideline of American geriatrics.\(^{483}\)

- As UI in frail elderly people may be the result of a number of contributory factors, many of which are reversible by simple measures, such patients should be first evaluated by a clinician skilled in the care of older people before any invasive investigations or more potentially harmful medications are given.

- There is direct and indirect evidence that UI in the (frail) elderly often has diverse and/or multiple coexisting factors.

- Apart from general health, mobility, neurological diseases and medications, the LUT is directly affected by aging of the detrusor, and the detrusor muscle function can be (come) both overactive during storage as well as underactive during voiding. Furthermore growth of the prostate; aging of the bladder outlet and decline in striated pelvic floor muscle function are commonly of relevance.

- In common with all patients, but maybe even more relevant; symptoms are not synonymous with the abnormalities that can be measured with UDS.

- Every test or (invasive) procedure can cause harm in the (vulnerable) elderly but there is no published evidence that UDS cause significantly more harm in the elderly.

- Simple bedside UDS has an inherent unreliability, and it is unclear whether the risk of misdiagnosis outweighs the ‘simplicity’ over conventional UDS.

- Especially, but not exclusively, male elderly patients, with central neurological disease, can have urologic disease (e.g. prostatic BOO) as a cause for UI or other LUTD.

1.3. Recommendations (Grade B-C)

- PVR measurement by a non-invasive method is recommended before institution of pharmacological or surgical treatment of UI. It should be repeated to monitor the effect of such treatment. Uroflowmetry should be used to screen for voiding abnormalities prior to invasive treatment in the elderly.

- Simple cystometry can be considered as a ‘screening test’ for non-invasive, or other low risk treatments, when a urethral or suprapubic catheter is already present for management.
1.4. Urinary Urgency Incontinence in Frail Elderly Patients

1.4.1 Recommendations 2013

In non-systematic reviews on pharmacotherapy UDS do not play an important role to initiate treatment for OAB-S in the frail elderly. Among the frail elderly, UI is the paramount troublesome symptom, in both men and women, with a steeply rising incidence after age 80. The type of UI appears to be predominantly UUI.

The symptoms of UUI are, also, or especially, in elderly women, frequently the result of DO, which can be shown with filling cystometry. The reason to perform UDS might therefore be to confirm this abnormality but identification of coexisting or alternative abnormalities may be of importance. Two industry supported reviews have found a paucity of specific evidence for the risks and efficacy of pharmacotherapy for DO or OAB-S in the frail elderly but have also not found that pharmacotherapy or conservative (behavioural) management is very risky in these patients. Reduced bladder sensation or ‘awareness’ in the frail elderly may lead to reduced warming (time) of impending leakage, and it is postulated that a (cognitive/cerebral) neurological cause may be co-existing and responsible for LUT symptoms in the elderly.

In symptomatic elderly people, UUI frequently coexists with incomplete bladder emptying. Incomplete emptying may be a sign of impaired bladder contractility, now termed by the ICS as detrusor underactivity. The UDS abnormality underlying UUI with incomplete emptying (assuming no BOO) has been introduced some decennia ago as ‘DHIC (detrusor hyperactivity with impaired contractile function)’. Its significance is that the standard pharmacological treatment of UUI – with antimuscarinics – may affect bladder emptying thus reducing the effect on symptoms of frequent voiding, by increasing PVR. In frail elderly women, DO is reported to be the commonest UDS diagnosis in a large retrospective series of referred elderly women.

With regard to male elderly patients, a total of 185 men who had persistent LUTS after TURP were evaluated with VUDS in one single center study. A normal VUDS tracing was found in 9%, pure DO in 10%, DU in 19%, DHIC in 14%, poor relaxation of the urethral sphincter in 19%, and recurrent or remaining BOO in 28%. A significant proportion of patients might develop (transient) de novo UUI after photosensitive vaporization of the prostate. Pretreatment UDS demonstrated that small bladder volume at first desire to void and small maximal cystometric capacity are predictive factors for this. Older age was, apart from UDS predictors also a risk factor for posttreatment UUI in this study but transurethral laser treatment is not considered extremely risky in the very old in another evaluation. A lower long-term success rate and an increased risk of large PVR after intradetrusor BoNT-A injection for refractory idiopathic DO has however been noted in frail elderly patients although safety and short time efficacy were similar between elderly patients without frailty and younger patients.

1.4.2 Conclusions

- No evidence exists that age by itself or frailty are contraindication to UDS and guidelines recommend UDS for the elderly following the principles similar to the younger; in general UDS is reserved for patients in whom non-invasive diagnosis and conservative and/or medical management have failed and in whom more intensive or invasive therapy is being considered.
- DO, DU and/or reduced filling sensation may coexist also in elderly or frail patients with UI. In addition, elderly men (and lesser prevalent, women) may have BOO.
- It has been shown that voiding efficiency and PVR should carefully be monitored in the elderly patients and especially in frail elderly men during treatment with antimuscarinics as well as with intradetrusor BoNT-A injection.

1.5. Stress Urinary Incontinence in Frail Male Elderly Patients

Among older men, SUI is almost entirely confined to RRP patients. Approximately 1% of patients who have undergone TURP or laser TURP suffer from post RPP UI. The majority of SUI after RRP is caused by urethral sphincter damage during operation the effect of exercise programs was not observable in urethral pressure profile measurements. UDS in post RPP UI showed no significant change in filling or voiding parameters when suburethral ‘male’ slings were implanted. Sequential UDS evaluation of patients with post RRP UI revealed urethral sphincter and bladder function worsen immediately after RRP and recover over time. The urinary continence rates were gradually improved to a satisfactory level in more than 80% of patients by 12 months after RRP. In addition to a lower MUCP, a reduced bladder compliance, de novo DO, and DU are commonly observed in patients with post RRP UI. However, DU did not affect UDS parameters and LUTS improvement after RRP.

1.6. Conclusions

- UI in elderly men may be the consequence of ineffective emptying and BOO.
UI in elderly is however also frequently iatrogenic; caused by RRP or transurethral resection of the prostate.

UI after prostate surgery may recover spontaneously and/or with conservative management within a period of 12 months in the predominance of men.

Patients with post RPP UI might have a low MUCP, a reduced bladder compliance, de novo DO, or DU, and UDS may have an important role in identifying the bladder and urethral dysfunction in patients with prolonged post RPP UI in order to establish appropriate treatment strategy.

UDS may have a role in identifying the bladder and urethral dysfunction in patients with prolonged post RPP UI in order to establish appropriate treatment strategy.

There is paucity of evidence about reproducibility and reliability of UDS in the elderly.

2. TESTS IN THE GERIATIC OR FRAIL ELDERLY POPULATION

2.1. Filling Cystometry

In a prospective 3 arm study with oxybutynin, biofeedback-assisted behavioural training and a placebo control condition in women with a mean age of 67 years, UDS parameters (filling sensation, cystometric capacity and voided volumes) improved in all. The improvement in UI was however related to the UDS changes observed in this small series, probably because of diverse UDS diagnoses at inclusion, as well as a consequence of the variability of the UDS outcome.505

2.2. Post-Void Residual Urine

PVR is believed to depend on the presence of BOO as well as to relate to DU.506 Thus, in a man, the presence of substantial PVR (> 100 mL), in the absence of a large prostate, and/or severe BOO, may suggest that the increased PVR is mainly due to a reduction in detrusor contractility.507 PVR volume varies in a given individual and can wax and wane over time. Significant daily variations have been observed in elderly patients of both sexes, with larger PVRs (up to 40% greater) being measured in the early morning.508 Elderly patients with DU may have small VV and large PVR volume, suggesting diminished central sensitivity to volume afferent activity in the aged bladder.509 In patients with diabetes mellitus, the PVR volume was significantly increased, which might increase the distress of voiding dysfunction, in addition to OAB-S in the elderly.510

2.3. Pressure-Flow Studies

Driving a contraction to its maximum load (and zero contraction velocity) is a manner to evaluate muscle force, and stop-flow test is the practical way to do this.

Voluntary stop test are not clinically validated to evaluate DU, but occlusion stop tests can be of relevance to evaluate the effect of treatments that affect detrusor voiding contraction in the elderly.511

3. EVIDENCE THAT PERFORMING URODYNAMIC STUDIES IMPROVES CLINICAL OUTCOMES IN THE GERIATRIC POPULATION

Pre-operative UDS was not able to predict the outcome of a popular SUI procedure in older women in this single centre uncontrolled cohort.512 Regarding the diagnostic evaluation of LUTS in older men, an International Consultation on New Development in Prostate Cancer and Prostate Diseases concluded that the frequency volume chart is recommended when nocturia is a bothersome symptom to exclude nocturnal polyuria. The use of UDS and transrectal ultrasound can be limited to situations in which the results are likely to benefit the patient such as in selection for surgery.513 DO or LUTD with or without BOO are present in patients with Parkinson’s disease. UDS is recommended for men with Parkinson’s disease with symptoms of LUTD since early and effective treatment can improve the bladder function and quality of life.514

The therapeutic efficacy and tolerability of a beta 3 adreno antagonist (mirabegron) were similar between patients with >65 and >75 years of age with OAB-S (with and without UI); UDS evaluation was not performed in this study.515 In a randomized trial for men with LUTS and BOO, mirabegron was demonstrated not to adversely affect voiding UDS (maximum urinary flow and detrusor pressure at maximum urinary flow) compared with placebo after 12 weeks of treatment.516

4. THE PRACTICAL INDICATIONS FOR URODYNAMIC STUDIES AND WHICH TESTS ARE NEEDED

4.1. Post-Void Residual Urine

In the elderly, PVR urine measurement is indicated before treatment of UI either with anticholinergic medication or by SUI surgery. A consistently large PVR certainly is a reason for caution, and careful monitoring of bladder emptying is needed.517 After intradetrusor BoNT-A injection for OAB-S, large PVR volume (greater than 150 ml) after BoNT-A injection was significantly higher in the frail elderly group than in the non-frail elderly or younger patient groups (61% versus 40% and 36%, respectively, (P .018).518 PVR monitoring was considered to be relevant after intradetrusor BoNT-A injections in the frail elderly.
4.2. Uroflowmetry

Uroflowmetry is a simple and non-invasive test. A normal uroflowmetry pattern without much PVR probably rules out significant BOO or DU, but this finding is unusual in the elderly. Uroflowmetry (with PVR measurement) may be a useful screening tool prior to instituting therapy. However, in a retrospective study of hundred women tested, the first free flow was inconclusive in 44% but was interpretable in 91% on the second free flow.519

4.3. Pressure-Flow Studies

There is weak evidence to suggest that prostatectomy may improve the continence if UDS shows ‘severe’ BOO in Parkinson’s disease patients.520 If BOO is equivocal or absent, then there is little point in performing surgery in an attempt to alleviate the signs and LUTS (presumed to be) ‘related to BOO’. After screening with uroflowmetry and PVR measurement, pressure-flow studies may be indicated in older men in whom BOO cannot be ruled out otherwise and surgery is at least contemplated.

4.4. Recommendations (Grade C)

- PVR measurement by a non-invasive method is recommended before institution of physiological or surgical treatment of UI. It should be repeated to monitor the effect of such treatment.
- Uroflowmetry should be used to screen for voiding abnormalities prior to invasive treatment in the elderly.
- Filling cystometry, as a single investigation, has limited value in this patient population. ‘Simple cystometry’ is not recommended.
- Simple cystometry can be considered as a ‘screening test’ for non-invasive, or other low risk treatments, when a urethral or suprapubic catheter is already present for management. However, the low specificity and sensitivity towards complete UDS diagnosis must be taken into account.
- The ICI2013 recommended offering comprehensive UDS to all elderly, with due consideration of any co morbidity, that have not responded to management of relevant contributing factors, and/or behavioural or pharmacological therapy, and in whom further invasive therapy is considered.
- The ICI2013 recommended that comprehensive UDS be performed in centres with a special interest in UI in the frail elderly, by trained and certified staff who frequently perform UDS of patients referred with suspected LUTD.
- To maintain adequate expertise in this difficult-to-examine patient population and to provide a background of ‘regular’ patients against whom specific patients can be judged, it is essential that centres examine substantial numbers of patients for LUTD; frail elderly as well as ‘routine’ patients.

5. THE URODYNAMIC PARAMETERS IMPORTANT IN VARIOUS GERIATRIC CONDITIONS

UDS can be of relevance to determine the most important cause of the LUTS in the elderly, where central nervous system disease is a frequently occurring comorbidity and where clinical signs and symptoms of LUTD are regularly more difficult to obtain or to isolate. Brain disorders such as stroke, Parkinson’s disease and white matter disease may decrease the tolerance of bladder filling and also increase the prevalence of OAB-S in the elderly population.521 522 In a community health survey, 31% of patients with central nervous system disease reported OAB-S, and the overall prevalence of neurogenicOAB-S was 1%. Patients with neurogenicOAB-S have a poorer HR-QoL compared to patients with ideopathic OAB-S.523 The pathogenesis ofOAB-S in cerebral events involves not only sensory perception but also the impairment of detrusor (voiding) contractility. Patients with a cerebrovascular accident or Parkinson’s disease have DO and inadequate contractility or DU resulting in increased PVR volumes.524

5.1. Parkinson’s Disease

DO associated with Parkinson’s disease is reported to occur at smaller bladder volumes than DO in BOO-related DO. The duration and severity of Parkinson’s disease were reported not be related to the UDS results. Patients with Parkinson’s disease have a higher risk of falls and falls, but not the frequency of urination were associated with urinary urgency in a prospective observational study.525 DO or LUTD, with or without BOO, are present in patients with Parkinson’s disease. UDS is recommended in men with Parkinson’s disease with LUTD. Early and effective treatment can improve theLUT function and quality of life.526 Another group found that the majority of patients with Parkinson’s disease (72%) or multiple system atrophy (100%) had symptoms of LUTD. DO was more common in Parkinson’s disease and DSD was reported to be specific for multiple system atrophy in this cohort. BOO (pressure flow BOO> 40) was more common in Parkinson’s disease than in multiple system atrophy. DU was less common in Parkinson’s disease than in multiple system atrophy and PVR (> 100 mL) was only present in (47%) patients with multiple system atrophy.527 By correlating the LUTD and motor function impairment in patients with Parkinson’s disease, detrusor weakness was found relevant to motor impairment, and OAB-S were found relevant to (disease specific) quality of life.528
5.2. Other CNS Disorders

Acute urinary retention and/or voiding difficulty are frequently encountered signs of LUTD in stroke patients. The majority of stroke patients (±60%) had remained able to void spontaneously at rehabilitation admission. During rehabilitation this percentage increased, partially because UDS had provided the arguments to remove the indwelling catheter. At discharge ±20% of the patients depended on intermittent or indwelling catheter or on condom conduit.529

The most common type of UI in patients with Alzheimer’s disease is UUI. In a cohort of 144 Alzheimer’s disease patients with UI, DO was found in 58% of patients on UDS. The presence of DO could be predicted using Clinical Dementia Rating and Barthel’s Activity of Daily Living Score.530

Patients with central nervous system lesion and OAB-S might also have DU. One recent study of 100U BoNT-A injected to the detrusor, including the trigone, in 20 patients with Parkinson’s disease with PVR <50% on free flowmetry, demonstrated a small reduction of voiding frequency, a reduction of voided volume and some increase of PVR, however without the need for CIC.531 The efficacy and safety of intradetrusor 100U BoNT-A treatment was also evaluated in 40 elderly patients with chronic LUTD after cerebrovascular accident or Parkinson’s disease and/or dementia. Intradetrusor BoNT-A injections reduced OAB-S and UUI. The treatment resulted in UDS cystometric capacity increase, with modest change in pressure flow parameters and some increase of PVR, but without the occurrence of urinary retention. An increased need to strain-void was noted in the (23) patients with LUTD after cerebrovascular accident. The long-term effects had been comparable to a retrospectively assessed cohort of patients with OAB-S managed with ‘standard’ treatment in the same clinics. Nonetheless the authors of this study stress the need for careful evaluation before choosing intradetrusor BoNT-A injections for this very vulnerable population.532

5.3. Topics for research

- Establishment of the reproducibility and reliability of UDS specific for the frail elderly.

- Further investigation of the associations between clinically observed LUTD and UDS assessed DO; DU and/or PVR in the frail elderly.

I. INTRODUCTION

The Committee was given the task of updating the evidence on imaging, neurophysiological testing and other tests in the field of urinary and anal incontinence. The Medline, Embase and Cochrane databases were searched for the relevant subjects from February 2012 to January 2016. All references obtained from the database search were screened for relevance, full text papers were obtained and reference list were used as additional source of evidence where appropriate.

The chapter covers different issues including: imaging, neurophysiological testing, and other investigations (laboratory tests, tissue analysis and pad test) in the paediatric and adult population, male and female subjects, neurogenic and non-neurogenic patients.

The following keywords were used for the difference subjects:

- Imaging: the Medline database was searched using the following keywords: imaging, urinary incontinence, continence, anal incontinence and faecal incontinence; the search has been limited to period from 2012 to 2016.
- Neurophysiology: clinical neurophysiology, conventional urodynamics, neurourology, urinary dysfunction.
- Other investigations: keywords including urinary incontinence, continence, pad test, urinalysis, urine culture, cystoscopy and tissue analysis were used.

Members of the committee were allocated the different topics of the chapter based on their specific expertise in the field. The first draft of the chapter was reviewed by all committee members, the final draft was then edited first by the Committee Chair and then by the book Editors.

Diagnostic techniques were evaluated with reference to the technique and its standardisation, intraobserver and interobserver variability, diagnostic accuracy, cost/benefit ratio and clinical benefit. The level of evidence was graded taking into consideration that imaging, neurophysiological testing and the other tests pertain to the area of “diagnosis” and the quality of the published papers was graded according to the criteria specific for this area. Areas of future research were identified.

Notwithstanding the large body of evidence, research on imaging in anal and urinary incontinence, its clinical benefit remains questionable. Test-retest, intraobserver and interobserver accuracy are often provided for diagnostic tests although diagnostic accuracy is difficult to evaluate due to a lack of a gold standard. When ultrasound is used to measure bladder volume, catheterisation can be used as a reference standard and accuracy can be easily calculated but when sphincter volume is calculated with ultrasonography, there is no solid reference standard except another imaging technique (e.g.: MRI) or the validity of an imaging measurement is tested against another weak test such as Valsalva Leak Point pressure or the maximum urethral closure pressure. Imaging can either be performed to better understand the pathophysiology of incontinence and pelvic organ prolapse and it may be of importance, although no immediate clinical benefit is evident (e.g.: calculation of sphincter volume with ultrasound). It can be performed as a diagnostic test in patients undergoing surgery so that quantification of the clinical benefit requires complex clinical trials (e.g.: MRI of pelvic organ prolapse in patient undergoing prolapse repair) in which different reference standards can be used (e.g.: physical examination or anatomic finding during surgery). Although imaging can sometimes offer a better understanding of the anatomy underlying the condition (e.g.: presence of an enterocele) the clinical benefit of this additional information may not be observed in all patients.

Although imaging is clearly a difficult area for research, the consensus regarding introduction of a diagnostic test into our daily practise must rely on the evidence of clinical benefit in terms of safety, outcome or cost-benefit ratio.

Imaging studies belong to the area of diagnostic studies, they should follow the suggestions of the STARD initiative and they differ substantially from other types of clinical trials (1). The aim of clinical studies of diagnostic tests should be to provide information regarding the diagnostic accuracy of the proposed test although, this is not always possible.

A few considerations regarding the levels of evidence in imaging studies may be instrumental in reading this chapter and are summarised herewith.

Imaging of parameters with known prognostic value (e.g. PVR)

- The first issue is to prove that imaging studies image what they are supposed to image. Although the issue may be trivial in case of PVR imaging or anal sphincter imaging, the issue is relevant in other areas (eg: enterocele imaging) and should be approached by using imaging in cadavers or other approaches such as intraoperative confirmation of the observed condition as a gold standard.
- When the imaging is quantitative, accuracy versus a quantitative gold standard technique should be provided. When the imaging is qualitative (e.g. presence or absence of vaginal vault prolapse) the diagnostic value should be provided (sensitivity, specificity, positive and negative predictive value, accuracy, interrater and intrarater variability).
- Once validity has been proven, one can assume that the predictive value of the imaging study is
equal to that observed for the parameter measured with the gold standard. The same applies to its value for patient management.

Imaging of parameters with unknown prognostic value (e.g. MRI of the pelvic floor)

- When the imaging is qualitative (e.g. intact versus damaged levator ani), once validity is proven, the diagnostic value should be investigated providing sensitivity, specificity, positive and negative predictive value, accuracy, interrater and intrarater variability in cadavers or patients undergoing surgery.

- Once validity is proved, the prognostic value for patient management should be investigated.

- Confirmation of the proposed imaging study by independent groups is required ideally for both validity and prognostic value or at least for the latter parameter (we can assume that confirmation of the prognostic value is obtained, validity of the imaging technique can be inferred).

II. IMAGING IN URINARY INCONTINENCE AND PELVIC FLOOR DYSFUNCTION

This is a broad area that often requires a multiprofessional and multidisciplinary approach. The patient population is heterogenous including children, female and male subjects suffering congenital malformation of the genital and urinary tract, neurogenic disorders, iatrogenic conditions and traumatic lesions. Clinical guidelines always refer to the so called “standard patient” but the majority of subjects referred to secondary and tertiary referral centres cannot be defined as such and their management sometimes requires deviation from guideline recommendations. The large variability and the uniqueness of the observed cases may justify the adoption of a knowledge-based management in the absence of proven clinical benefit. Research on imaging of urinary incontinence (UI) and genital prolapse remains very active. Although all guidelines recommend not to use imaging in the evaluation of the standard patient, many clinicians believe this is an ideal adjunct to physical examination in evaluating the anatomical condition of the individual subject.

1. IMAGING OF THE UPPER URINARY TRACT

Urinary incontinence is defined as the complaint of any involuntary leakage of urine, it can be urethral or extrarethral (1). This latter condition either results from congenital anomalies such as ectopic ureters (inserting in the female distal urethra or vagina), iatrogenic or traumatic conditions such as fistula. In some patients, lower urinary tract dysfunction (LUTD) causing UI, might compromise the transport of urine from the kidneys to the bladder resulting in hydronephrosis and renal failure. The relationship between high bladder storage pressure and renal deterioration was first identified in myelodysplastic children and then considered to apply in all neurogenic patients (2) and automatically transferred to male and female patients with or without neurogenic problems; the value of 40 cmH2O of bladder pressure as threshold value at which the upper urinary tract (UUT) is at risk should therefore be used with caution. In male patients, chronic retention of urine can be associated with UI and lead to chronic renal failure. Lewis et al. reported that renal function at baseline and at the time of catheterisation were significantly worse in patients with chronic retention than with acute retention (3). Therefore, UUT imaging is needed in patients with urinary retention, especially with chronic retention. In women, severe urogenital prolapse may cause angulation of the pelvic ureter by the uterine arteries leading to hydronephrosis (4)

1.1. Indications

Generally speaking, there is no need for UUT imaging in patients with UI unless any of the previously described conditions is suspected or diagnosed. In children with extrarethral incontinence imaging of the UUT helps to identify the underlying cause.

The objectives of UUT in the incontinent patient are as follows:

- Evaluation of the UUT when the presence of an ectopic ureter or ureterovaginal fistula are suspected.
- Evaluation of the kidneys whenever UI is related to bladder dysfunction with high storage pressures (e.g. in neurogenic voiding dysfunction, chronic retention with overflow or low compliance bladders)
- Exclusion of hydronephrosis in cases of UI associated with severe uterine prolapse

1.2. Techniques

UUT imaging modalities include intravenous urography (IVU), ultrasound sonography (USS), computerized tomography (CT scan), magnetic resonance imaging (MRI), and isotope scanning. No data regarding reproducibility, specificity, sensitivity, positive and negative predictive value in relation with the diagnosis and management of UI are available. The choice of the imaging modality also depends on availability, expertise, and local management policies. Generally speaking, low cost and low risk techniques such as USS are preferred. Unless otherwise described, the following considerations regarding the different imaging modalities are based on expert opinion.

1.2.1 Ultrasonography

USS is the gold standard technique for primary imaging of the UUT because of the relatively low cost of the equipment and the examination, its wide
availability, the lack of any exposure to ionizing radiation. Renal USS is independent on kidney function and provides a good evaluation of kidney morphology. Concomitant renal disorders such as urinary lithiasis and neoplasms can also be diagnosed. In patients with LUTD, the detection of hydronephrosis is of importance and it can be related to either vesico-ureteral reflux or obstruction. USS is used for the first line evaluation of the UUT conditions in neurogenic patients. Sixteen percent of chronic spinal cord injured patients with hyperreflexic bladder had UUT deterioration revealed by USS, while 17.5% of patients with areflexic bladder also had it (5). UUT deterioration more frequently occurred in hyperreflexic bladder with higher reflex detrusor contraction pressure (115 vs. 72 cm H2O) mostly accompanied by type 3 detrusor external sphincter dyssynergia, and in areflexic bladder with higher storage detrusor pressure (58 vs. 24 cm H2O). In patients adequately managed with clean intermittent catheterization annual USS monitoring without routine urodynamic testing was suggested to be an effective surveillance strategy (6). UUT deterioration was demonstrated in 70 of 193 myelodysplastic patients who underwent USS, voiding cystourethrography, DMSA scan, and urodynamics at three years old (7). The sensitivity and specificity for UUT damage were 91.4%and 22.3% in DLPP >20 cm H2O, 77.1% and 32.0% in DLPP>30 cm H2O, and 52.9% and 51.8% in DLPP >40 cm H2O, respectively. Therefore, a DLPP cut-off value of 20 cm H2O showed a higher sensitivity to predict UUT damage instead of 40 cm H2O. In the cross-sectional survey of Dutch urologists 91.5% of them performed USS at least once every 1-5 years during the follow-up of adult myelodysplastic patients (8).

USS is also used to detect hydronephrosis in prolapse patients. Hydronephrosis was revealed by USS in 5%-50% of patients with pelvic organ prolapse (POP) that reconstructive surgeries were indicated for (9). The proposed mechanisms for hydronephrosis are 1) ureteric compression between the uterine body and the urogenital hiatus, and 2) ureteral kinking caused by the cardinal ligament (9). It was reported that hydronephrosis occurred in 12.6%-22.4% of patients with severe ureterovaginal prolapse as well as 3.9%-7.1% of patients with severe vault prolapse, indicating that hydronephrosis developed after hysterectomy (10, 11). It was supposed that the ureters may be pulled down and kinked by the downward traction of prolapse upon the bladder (9). Dancz et al. reported that 30.6% of their POP patients had hydronephrosis, and that Ba-point (OR 1.68, 95% CI, 1.22-2.12), not C-point, and maximum cystometric capacity (OR 1.50, 95% CI, 1.08-2.07) were associated with hydronephrosis on a multivariate analysis (9). On the other hand, Beverly (11) and Gemer (12) reported that 7.7% and 17.4% of patients, respectively, had hydronephrosis, and that ureterine prolapse was associated with hydronephrosis on multivariate analysis (OR 3.8, 95% CI, 1.4-10.5 and OR 1.9, 95% CI, 1.1-3.2, respectively). The presence of hydronephrosis do not affect the surgical procedures for POP repair and hydronephrosis improves in 70-100% of patients after surgery (10, 13). Therefore, USS should be performed in women with advanced POP, especially when surgical intervention is not indicated or delayed (9).

Although, no strict correlation exists between the degree of dilatation and the severity of obstruction, the grade of hydronephrosis is correlated with the extent of cortical damage (14). In children, kidneys with a pelvic diameter >20 mm are considered to be at risk for deterioration and require intervention (15). Measurement of the resistive index in the interlobar and arciform arteries of the kidney has been proposed for the diagnosis of urinary obstruction but this is rarely used in the evaluation of the incontinent patient (16). Whenever hydronephrosis is diagnosed on USS, other imaging modalities are often used to evaluate renal function, the degree of obstruction or vesico-ureteral re ux. USS is an ideal technique to follow the degree of hydronephrosis over time or the response to treatment.

### 1.2.2 Intravenous Urography

IVU is the original radiographic examination of the UUT which allows evaluation of UUT anatomy and function. Recent Canadian guidelines recommended that a serum creatinine level (SCr) should be obtained, and an estimated glomerular filtration rate (eGFR) should be calculated within 6 months as an outpatient who is stable or within 1 week for inpatients and patients who are not stable (17). Patients with an eGFR of ≥60 mL/min have an extremely low risk of contrast-induced nephropathy (CIN) (17). Fluid volume loading remains the single most important measure, and hydration regimens that use sodium bicarbonate or normal saline solution should be considered when GFR < 45 mL/min in patients who receive intravenous contrast (17). Patients are most at risk for CIN when eGFR< 30 mL/min (17). Additional preventative measures include the following: avoid dehydration, avoid contrast medium (CM) when appropriate, minimise CM volume and frequency, avoid high osmolar CM, and discontinue nephrotoxic medications 48 hours before administration of CM (17). Also, Japanese guidelines showed that chronic kidney disease (CKD, eGFR< 60 mL/min/1.73 m2) is the most important risk factor to predict the risk of CIN in patients receiving iodinated contrast media (18). In addition, aging and diabetes associated with CKD are risk factors for the development of CIN (18). Recent systematic review recognised pre-existing CKD, diabetes, age, and cardiovascular comorbidity as risk factors (19). The existing guidance documents agreed in recommending pre-hydration as the main preventive measure, but there was difference in recommended total volumes, composition, rate and duration of the infused solutions (19). There was no consensus on the use of sodium bicarbonate and none recommended N-acetylcysteine as solitary preventive measure (19). Recent guidance
documents recommend avoiding hypertonic contrast media, but did not recommend preference of iso-osmolar over low-osmolar contrast media (19). During IVU successful examination is dependent upon adequate renal capacity to concentrate urine, the poor concentration capacity of an impaired kidney limits the possibility to delineate the collecting system. A number of different conditions such as renal dysfunction, obstruction, congenital anomalies, fistula, stones and tumors may be detected. IVU is the appropriate first study in cases of extraurethral incontinence. When ectopic ureter is suspected (although this condition can also be responsible for urethral incontinence), delayed films and tomography are important because the renal unit or moiety associated with an ectopic ureter is often poorly functioning. In fact, IVU is sometimes unable to detect a small, malfunctioning moiety associated with a duplication and ectopic ureter or a poorly functioning or abnormally located kidney with a single ectopic system (20-22). In such cases where the diagnosis of ectopia is still suspected after IVU, another imaging modality such as CT, MRI or isotope scanning should be considered (23-25). IVU is the appropriate first imaging study when uretero-vaginal fistula is suspected, usually after pelvic surgery. Typically, one sees ureteropelvocaliectasis proximal to the level of the fistula. This finding has been reported in 84-92% of cases (26, 27). Sometimes extravasation can be seen. Confirmation of the presence of the fistula, its size and exact location is often obtained with retrograde ureteropyelography.

1.2.3 Computerised Tomography (CT scan)

High quality information of the UUT anatomy can be obtained using multidetector helical CT scans and 3D reconstruction software. Differently from IVU which only acquires images in the anteroposterior or oblique CT acquires images in the axial plane. Pictures can then be reconstructed in 2D along any plane or in 3D whenever required. CT scan can be used irrespective of renal function when no iodinated contrast medium is used. Whenever hydronephrosis is present, urine can be used to delineate the collecting system reducing the need for contrast agents. In general, intravenous contrast medium is required to highlight specific anatomic characteristics. CT scan is often used after the first line evaluation with USS and it has replaced IVU almost entirely. Several authors have reported the use of CT scan to detect ectopic ureter, in cases where the diagnosis is suspected, a normal IVU and ultrasound (28). In these cases the small size and poor function of the ectopic moiety make diagnosis difficult by IVU.

1.2.4 Magnetic Resonance Imaging (MRI)

MRI shares some of the advantages of CT over IVU in the evaluation of the UUT. Furthermore acquisition can be performed along any plane and pictures can then be presented in a 2D or 3D fashion. The paramagnetic contrast medium is free of allergic reaction risk although its use in the UUT remains dependent upon renal function and concerns about its nephrotoxicity have been recently raised (29). Low risk gadolinium contrast agents should be the choice, and dosage should be kept to a minimum, as higher doses have been linked to the development of nephrogenic systemic fibrosis (NSF)(30). While a pre-existing pro-inflammatory state in the renal impaired is a high risk factor, liver insufficiency in itself is not a contraindication; however, patients may also have coexisting renal insufficiency and thus carry a risk of NSF (30). The development of the uro-MRI technique has gained an increasing role for the technology in the evaluation of hydronephrosis and urinary tract anomalies as an alternative to IVU. The use of MRI in the diagnosis of ectopic ureter has recently been described (31-35).

1.2.5 Isotopes

Isotopes are used primarily to examine morphological and functional characteristics of the upper urinary tract. Isotope scanning can be used to identify the location of a small kidney which is otherwise difficult to image with radiological techniques. Renography is used to examine the differential function of the two kidneys, to identify disorders of urine transit and to quantify obstruction of the upper urinary tract. There are many physiological factors and technical pitfalls that can influence the outcome including the choice of radio-nucleotide, timing of diuretic injection, state of hydration and diuresis, fullness or back pressure from the bladder, variable renal function and compliance of the collecting system (36, 37). Diuresis renography with bladder drainage is recommended when obstructive uropathy is suspected (38). Renal scintigraphy may be useful in the evaluation of ectopic ureters associated with hypoplastic kidneys (39). Detection rates of dysplastic kidney in single system ectopic ureter were 95.5% on DMSA, 95.5% on CT scan, 50% on USS, and 50% on MRI (40). DMSA would be a preferred option in this setting, because of its high detection rate and not requiring contrast medium.

1.2.6 Conclusions

Imaging of the UUT is rarely required in UI unless the condition originates from a malformation, a traumatic or an iatrogenic problem of the UUT. More rarely a condition of the lower urinary tract may endanger renal function, the preservation of which is required to guarantee a normal life expectancy in patients with UI.

1.2.7 Consensus Statement

- Imaging of the UUT is NOT indicated in the evaluation of non-neurogenic stress, urgency or mixed UI. (Level of Evidence 3, Grade of Recommendation C)
- Imaging of the UUT is indicated in cases of:
  - neurogenic UI with high risk of renal damage (due to high storage and/or voidingdetrusor pressure, e.g. myelodysplasia, spinal cord
In males the purpose of voiding cystourethrography has been mainly to locate infravesical obstruction separating the bladder neck from benign prostatic obstruction although it may play a role in the management of post-prostatectomy incontinence (1). In children the diagnosis and classification of reflux and diagnosis of posterior urethral valves have been the primary goals (2). The severity of the vesicoureteric reflux on one side determines the development of contralateral reflux and indicates a poorer resolution rate for reflux (3).

Positive-pressure urethrography has been used for the diagnosis of female urethral diverticula, it was shown to be more sensitive than voiding cystourethrography (4-6) although MRI is the gold standard for the diagnosis of diverticula and planning surgical repair (7, 8).

The rationale for imaging studies of the lower urinary tract in this field derives from the hypothesis that stress UI is caused by urethral hypermobility. This was the theoretical basis of the classification of UI published by Green in 1968 and then modified by Blaivas and Olsson in 1998 (9, 10). Investigation into cohorts of continent and incontinent patients failed to provide evidence to support the hypothesis and imaging techniques aiming at measuring bladder neck displacement during straining have been abandoned. The same applies to outcome research in urinary incontinence where surgery that limits bladder neck displacement does not necessarily lead to cure of the condition. A renewed interest derived from the availability of USS which took imaging out of the radiology suites and moved it into the urological and gynaecological outpatient clinics opening new opportunities for clinical research in this field. The possibility of imaging what was usually perceived during physical examination such as bladder neck mobility or POP increased the usefulness of USS. Research in the field of MRI first assessed the possibility of fast dynamic acquisition to image the displacement of visceral organs during effort to better quantify POP and then the morphological imaging of the pelvic organs muscular support to investigate the physiopathology of genital prolapse.

2.1.1 Female Cystourethrography

X-ray imaging of the urinary bladder and urethra has been used to assess the female urinary tract in women suffering UI to evaluate urethral/bladder neck hypermobility and to assess associated conditions such as urethral obstruction, vesico-urethral reflex, diverticula, fistulae, stones and tumours. In males the purpose of voiding cystourethrography has been mainly to locate infravesical obstruction (1, 11).

The diagnosis and classification of reflux and diagnosis of posterior urethral valves in children have been the primary goals (2). In a study comparing cystourethrography with direct radionuclide voiding cystography and voiding urosonography with contrast

2. IMAGING OF THE LOWER URINARY TRACT

The use of imaging of the LUT in patients with UI dates back 40 years more than that e.g. Jeffcoate 1950’s, particularly in female patients. The techniques have changed, over the decades from static to dynamic imaging, from qualitative to quantitative information. Although some of the techniques are now more than 50 years old their clinical value remains at best, unclear.

2.1. X-Ray Imaging

Voiding cystourethrogram (VCUG) was the mainstay of x-ray imaging of the LUT but it has been replaced almost entirely by USS because of its ease of use, low cost and availability. While CT has not gained acceptance because of the exposure of ionising radiation, MRI took the lead as the most promising imaging modality because it offered a comprehensive view of the pelvis and enabled visualisation of the position of visceral organs in relation to bony reference points. 3- and 4D USS recently offered volume acquisition with limitations in the depth of ultrasound wave penetration and the volume that can be imaged. Progressive technical developments in imaging technology and techniques have made this research area particularly interesting.
medium were compared. Voiding sonography and direct radionuclide voiding cystography were shown to be the most sensitive (12).

2.1.1.1 Background

History and methodology of cystourethrography in females had been reviewed by Olesen (6). The technique is now over 70 years old. Voiding cystourethrography with lateral projection was first done by Mikulicz-Radecki in 1931 (13). The use of a metallic bead chain to identify the urethra was introduced by Stevens and Smith in 1937, and in 1956 Ardran, Simmons and Stewart reported on a cinematographic technique with contrast media also in the vagina and rectum (14, 15). In an attempt to combine qualitative and quantitative information regarding the function of the lower urinary tract, the combined used of fluoroscopy and pressure-flow recordings was proposed during the nineteen sixties and seventies (16-20).

2.1.1.2 Methodology (projection, positioning and exposures)

Bladder neck displacement is best viewed and quantified in true lateral projection although image quality is sometimes poor because of the increased body mass and the overlap of bony structures with the bladder neck area. Consequently, oblique projections are sometimes used notwithstanding the lack of quantitative information. Achieving a quasi-physiological voiding in a radiology suite is difficult because of the inevitable impact of the environment. The use of a sitting position is recommended for micturition studies as voiding while standing or lying will increase the embarrassment and therefore many impair the quality of the examination (13). Especially in patients with large body mass index, imaging of female urethra in a true lateral projection is difficult, it necessitates high radiation doses as the central x-ray beam must penetrate the trocanteric regions and further because the urethrovesical junction is sometimes overshadowed by the lateral parts of the bladder. A significant improvement in this area has been brought about by digital imaging which allows the subtraction of the bony structures. The position and mobility of the urethrovesical junction as well as urine leakage are supposed to be influenced by the filling volume as has been demonstrated on ultrasonography and leak point pressure measurements (21, 22). However, in VCUG the bladder is filled to capacity. Addition of a urethral bead chain or catheter and vaginal contrast to improve the visualisation of the urethra, bladder neck and trigone has been abandoned. Contrast in the rectum is not necessary for urinary incontinence purposes. Exposures at rest should be supplemented with provocative manoeuvres to test bladder neck mobility by contracting and relaxing the pelvic floor (e.g. coughing, straining, and squeezing). Whenever possible, pictures while the patient is voiding should be obtained. It is important to consider that coughing and straining result in a different effect on the pelvic floor. Straining might be associated with relaxation or contraction of the pelvic floor, and the imaging can change accordingly.

During coughing there is a reflex contraction of the pelvic floor, but coughs are of a short duration and difficult to capture on spot films. Bladder suspension defects were diagnosed at rest in 49% of 420 examinations, while coughing and micturition disclosed a further number of 20% and 4% respectively (13). Squeezing can demonstrate pelvic floor awareness and contraction (23).

2.1.1.3 Combined imaging and urodynamics

Videourodynamic has been regarded by some as the “gold standard” in the evaluation of LUTD (23). Reproducibility of the combined examination has not been assessed and further the radiation dose has to be considered (15,20,24-26). One study has attempted to compare videourodynamic with saline cystometry (23). Independent observers carried out the two procedures with 75 women having the saline cystometry first and a further 75 women had videourodynamic first. The degree of bladder descent noted on screening was greater than on clinical examination. Nineteen women had trabeculation and a further 11 women had bladder or urethral diverticula, urethral stenosis and vesicoureteric reflux (1,11,14). Only seven of the eleven women could have been predicted by a selective imaging policy based on history alone which would image 43% of the 150 women. This suggests that a selective policy of screening will unnecessarily expose patients to radiation while not using the optimal technique for investigation for all patients who need the test. Nevertheless simultaneous videomonitoring along with tracings of pressure and urine flow rate are important to ensure that the exposures are made at appropriate moments so that the radiographs can be representative of the various functional states (13, 18, 27, 28).

Patients with Parkinson’s disease and multiple system atrophy are best evaluated by videourodynamic with sphincter motor unit potential analyses to identify the characteristic features of these conditions including: external sphincter denervation, neurogenic sphincter motor unit potentials, open bladder neck at rest and detrusor-external sphincter dyssnergia (29). Neurogenic patients show severe bladder trabeculation with diverticula and pseudodiverticula, pelviureteric reflex, widening bladder neck and proximal urethra, and narrowing at the level of the membranous urethra can suggest, the presence of neurogenic dysfunction of the lower urinary tract (occult spinal dysraphism, non-neurogenic neurogenic bladder (also known as the Hinman syndrome)) even in the absence of neurogenic symptoms and signs (30-32). Urodynamic parameters in children do not discriminate between those with or without vesicoureteral reflux thus videourodynamic has been considered essential. Additionally children with non-neurogenic voiding dysfunction are found to have a number of
abnormalities with videourodynamics (33,34). Indications for videourodynamics include previous continence and vaginal surgery, neurological disorders and suspicion of urethral diverticula.

2.1.1.4 Normal and defective bladder support

The whole issue about the clinical value of VCUG is about the pathophysiology of defective bladder support in the pathophysiology of SUI in female patients and the relation between the surgical correction of such a defect and cure. The concept of urethral hypermobility was central to the classification of SUI and the concept that impaired transmission of abdominal pressure to female urethra could be responsible for the observed leakage. Little remains regarding the concept of urethral hypermobility in a modern view of female SUI and this contributed to the decreasing use of VCUG in the evaluation of a standard female patient.

The normal resting bladder has a smooth surface although bladder trabeculation is often seen in elderly women and not necessarily related to any pathological condition. The internal urethral orifice is located just above a horizontal line through the lowermost part of the symphysis in a coronal projection. The urethra is straight and runs anteriorly and caudally toward the external meatus.

On coughing and straining, relaxation of the pelvic floor results in downward movement of the bladder neck, which can be associated with a backward movement of the bladder neck resulting in a change in urethral axis. Squeezing (and sometimes also straining) results in contraction of the pelvic floor muscle with a cranial movement of the bladder neck. During voiding the bladder base is usually lowered about 1 cm, the angle between the urethra and the trigone is straightened, making a funnelled appearance of the proximal urethra and the bladder base, the bladder contour is rounded and a fine sawtooth irregularity of the mucosa becomes visible above the trigone. Angles and distances between the urethra, bladder base and symphysis pubis have been assessed radiologically. The following parameters have been assessed for reliability:

1. The posterior urethrovesical angle (PUV) is defined by lines along the posterior urethra and the trigone (35). Cut off values were usually 115° or more (36, 37);
2. The urethral inclination is between the proximal urethral axis and the vertical plane, which is a plane outside the patient and, therefore, the angle also varies with pelvic inclination. In Green type I and type II descent the angle is less or more than 45° respectively (37);
3. The urethropelvic (UP) angle is measured during voiding as the anterior angle between a line through the middle of the internal urethral orifice and the urethral knee and a line through the posterior surface of the symphysis through the lowermost part of the obturator foramen closest to the film. In normal subjects the mean UAR is about 95° and the cut off point for bladder descent are values below 70° (13);
4. Symphysis orifice (SO) distance is measured at rest as the distance on a horizontal line from the symphysis to the internal urethral orifice. Normal values are 31 ± 6 mm (mean ± SD) and values less than 20 mm are the cut off points for descent (13);
5. The urethral axis at rest (UAR) and during straining (UAS)

Funnelling of the proximal urethra and flatness of the bladder base (both anterior and posterior to the internal urethral orifice) and the most dependent portion of the bladder base (the urethrovesical junction or a point posterior to that) are important qualitative parameters estimated on straining films (36).

Anterior bladder suspension defects or bladder base insufficiency (BBI) is defined as SO < 20 mm with a normally positioned vagina at rest, during coughing or micturition and/or funneling of the bladder base at rest or with coughing. BBI can be graded 1-3, which corresponds to Green's type I descent (13, 38). The supportive defect is supposed to be in the fascial and ligamentous system and their abnormal detachments (eg., paravaginal defects).

Posterior bladder suspension defects are defined as a posterior-inferior bladder displacement and a UP of less than 70° (13). It corresponds to Green's type II (39). Sometimes only the trigone and posterior part of the bladder is involved. The supportive defect is supposed to be in the muscular pelvic floor, that is, the pubo-vesical part of the pubococcygeus muscle or in paravaginal detachment.

Interestingly, when UAR and UAS were examined in a group of 76 continent women and correlated with age, a perfect linear regression was noted between UAR and age (R$^2$ = 0.28). Patients with stress urinary incontinence were found to have an average UAR value of 25° with a mean UAS of 43° leading to a threshold value of hypermobility of about 20°. When standing cystourethrograms were repeated 3 to 6 months after surgery for SUI, UAR and UAS values were found to be close to normal suggesting a relation between the correction of the defective bladder support and cure (39). A more structured definition of cystocele (ranked by height in centimetres) was also obtained, adding to the emerging data that the reliability of the pelvic organ prolapse quantification (POP-Q) system increases when measurements are performed in a more upright position (39).

2.1.1.5 Reproducibility

The observer variation has been evaluated in four university uro-gynecological units (Table 1) (23, 36, 40, 41). The inter-observer agreement was 43-79%
and the intra-observer agreement was 53-99%. These figures are in the same range as has been found for other diagnostic tests (42).

### 2.1.1.6 Accuracy for the diagnosis of SUI and post-operative results

Evaluation of accuracy is the mainstay in the evaluation of a diagnostic technique. The sensitivity and specificity of a diagnostic technique depend on intrinsic factors such as reproducibility (as measured by intraobserver and interobserver variation) and extrinsic factors such as the characteristic of the patient cohort used to assess accuracy.

The accuracy of the previously mentioned radiological criteria have been measured by comparing imaging data with the so called index-test which in this case was a clinical diagnosis of urodynamic stress incontinence and expressed as specificity and sensitivity or as predictive values. Unfortunately, the diagnosis of SUI is controversial and might be based on subjective criteria, urodynamic tests, or measurement of leakage. Even radiological criteria have been included in the diagnosis.

Reproducibility (e.g. test-re-test agreement) has not been measured, but intra- and inter-observer variation has been calculated and adjusted for expected chance agreement (kappa coefficient). The predictive values and the kappa coefficient are supposed to depend on the prevalence, and therefore, comparison between different materials are difficult (42).

No consensus has been reached in the peer-review literature as to the lack of discriminant value of VCUG between SUI and continence, the majority of published papers are consistently negative although new promising data have been published (37, 39, 43-45).

1: static bead-chain cystourethrography with straining (36). The 5 landmarks were the posterior urethrovesical angle, urethral inclination, funnelling of the proximal urethra, flatness of the bladder base and most dependent position of the bladder base;

2: voiding colpo-cystourethrography (VCCU) at rest and with coughing, straining, micturition and squeezing; one observer against original diagnosis (that is, normal appearance or anterior, posterior or combined suspension defects) made by a few senior radiologists (22);

3: voiding colpo-cystourethrography at rest and with coughing, straining, squeezing and micturition. Possible diagnoses were: normal appearance or anterior, posterior or combined descent respectively (41).

4: voiding colpo-cystourethrography at rest, coughing, with holding and voiding. Possible diagnoses were: normal appearance and anterior or posterior descent respectively (40);

5: standing voiding cystourethrography, urethral angle was measured at rest (UAR) and during straining (UAS) (39).

The specificity of 5 radiological parameters on static bead chain VCUG was 44-76% and the sensitivity 53-100% (45, 46). Neither was the degree of SUI correlated with the type or degree of suspension defects (23, 40, 47). The positive and negative predictive values for a bladder suspension defect were 0.70 (95% C.I.: 0.62-0.78) and 0.52 (95% C.I. 0.41-0.63) respectively on voiding colpo-cystourethrography (38, 48).
In a later publication on 159 women, positive and negative predictive values of 0.56 and 0.74 were obtained (45). Evaluation of the urethral angle at rest and during stress in controls and in patients with SUI and various grades of anterior vaginal prolapse show a significant relationship between UAR and aging (from 2.4° ± 14.9° in the third decade to 29° ± 9.2° in the 9th decade; r² = 0.28). In patients with SUI, UAR and UAS decreased from 25.7° ± 13.6° and 42.6° ± 15.9° to 16.6° ± 14.7° and 23.8° ± 17.5°, respectively; the observed changes were found to be statistically significant. A similarly significant difference was found in patients with moderate to grade 3 cystocele and urethral hypermobility (at least 5 cm descent of the bladder base below the inferior ramus of the pubic symphysis on the lateral view of a standing VCUG): UAR and UAS decreased from 48.1° ± 16.5° and 64.4° ± 16.8° to 22.3° ± 26.9° and 29.8° ± 22.8°, respectively.

Comparison of a randomly selected control cohort (aged-matched) with patients suffering SUI showed a significant difference of UAR and UAS at diagnosis while similar values were found after surgery. This was similar to patients with grade 3 cystocele in whom both UAR and UAS were significantly different from controls at baseline while showed similar values in the postoperative follow-up.

Measurement of the cystocele height obtained as the distance between the inferior border of the pubic symphysis and the inferior edge of the cystocele in controls and patients with mild and severe cystocele showed a significant difference between the two cohorts (16.63 ± 10.9 versus 27.4 ± 12.3 mm versus 73.4 ± 15.6 mm, respectively). Following formal cystocele repair, a significant change of cystocele height was found in patient with mild and severe cystocele (from 27.4 ± 12.3 mm to 13.9 ± 18.0 mm and from 73.4 ± 15.6 mm to 25.4 ± 24.6 mm, respectively (p<0.001).

These are the first data supporting the use of standing VCUG as an outcome measured, previous peer-review papers suggested the inability of its technique to distinguish postoperative failures from success (13, 23, 42, 44, 46, 49-52).

2.1.1.7 Comparison of cystourethrography and ultrasonography

The development of USS techniques for the evaluation of the lower urinary tract raised the question of the relationship between X-ray and USS imaging. Static bead chain cystourethrography has been compared with transrectal and perineal USS and voiding colpo-cystourethrography has been compared with perineal USS (46, 47, 53, 54). The findings correlated well regarding bladder neck position and mobility, PUV, urethral inclination, SO distance and rotation angle.

Specificity, sensitivity and interobserver agreement were also comparable for the two methods. All the authors seem to prefer the sonographic modality because imaging can be performed at the same time as the physical examination. This has also been the case in men with neuromuscular dysfunction (11). Simple and extensive funnelling is more easily imaged in upright patients during cystourethrography than in the supine position frequently used for ultrasound studies (30).

2.1.1.8 Comparison of cystourethrography and MRI

The introduction of MRI in the assessment of the LUT required adequate comparison of this technique with standard X-ray imaging. The comparison of cystourethrography and colpocystourethrography with dynamic MRI showed comparable data on bladder neck position and cystocele extension (55, 56). Although there is an obvious concern about the fact that dynamic MRI imaging is usually performed with the patient lying in a dorsal lithotomy position, comparison of standing and lying colpocystourethrography did not show any significant difference (56).

2.1.1.9 Conclusions

VCUG does not have a major role in the evaluation of the standard female patient with UI confirmatory results on the clinical utility of measuring urethral angle and cystocele height in patients with UI and POP who are scheduled for surgery still missing. Defective bladder support can be diagnosed on VCUG with a reliability comparable with other diagnostic tests.

Dependent on local facilities the method might be considered if the choice of a surgical procedure is based on type and degree of supporting tissue deficiencies and possibly if new procedures are evaluated for the ability to restore this deficiency.

2.1.1.10 Consensus statement

Cystourethrography is NOT indicated in primary uncomplicated stress, urgency or mixed female urinary incontinence (Level of Evidence 3, Grade of Recommendation C).

Cystourethrography may be a reasonable option in the preoperative evaluation of complicated or recurrent female urinary incontinence (Level of Evidence 3, Grade of Recommendation C).

Variation of VCUG parameters in patients with SUI +/- ISD and prognostic value for surgical repair.

VCUG parameters in re-do surgery for SUI compared with controls

2.2. Ultrasoundography

Ultrasoundography has been used in the evaluation of urinary incontinence as early as 1980 (1). Over the past three decades the quality of the ultrasound image and its processing has improved beyond what could have been imagined during the 70’s. Various
new developments, such as the use of contrast medium, colour Doppler, 360 degree transducers and three- and four dimensional imaging have been introduced and have led to the more widespread use of ultrasonography in the evaluation of the lower urinary tract and pelvic floor disorders.

A number of studies have reported good correlations between ultrasonography and x-ray in the evaluation of urinary incontinence (2-11). In particular, the position of the bladder neck at rest and during Valsalva (10, 12) manoeuvre has frequently been compared, and all authors agree on a good correlation. Some authors even found better accuracy for ultrasound (5), especially in obese women (2). Ultrasonography is cheaper than X-ray imaging, it is often preferred by physicians because the imaging studies can be performed in their own office as part of the physical examination and it is also more acceptable to patients because of the lack of radiation exposure. However, ultrasound itself produces problems by needing the probe to be in direct contact with the patient even during dynamic manoeuvres and the resolution is dependent on the frequency of the probe used. The higher the ultrasound frequency, the better the resolution but there is reduced penetration into the tissues.

2.2.1 Types of Ultrasonography

Different imaging approaches have been used, such as abdominal, transvaginal, transrectal, perineal and transurethral. Synonyms for the perineal approach are transperineal, introital, labial or translabial access, all use a similar method and there does not appear to be a substantive difference between these terms, a common agreed term needs to be decided upon.

Abdominal ultrasonography is generally not considered to be helpful in pelvic floor and urethral imaging because of the acoustic shadow caused by the pubic bones particularly in the obese patient (1). All approaches in ultrasound have a problem of distorting the tissue being imaged due to compression. With vaginal ultrasonography this risk is probably highest (13), although this has also been denied (14). Most recent studies report on perineal ultrasonography that allows the visualisation of all three compartments in one image but again compression of the urethra may occur and imaging is impaired with vaginal prolapse or gas in the rectum.

The development of three-dimensional ultrasonographic systems has brought increased accuracy to measuring volumes of irregular structures as well as reconstructed images from novel directions and allowing pelvic floor imaging. Three-dimensional ultrasonography was first described for the female urethra in 1999 (15); the three-dimensional image can either be evaluated as a separate entity on the screen, or in combination with each of the two-dimensional planes from which it is derived (Figure 1). These three two dimensional planes are at orthogonal to each other being the sagittal, coronal and axial planes. Three-dimensional images are built up as a rendered image of a self defined region of interest, major advantages over 2D imaging include the possibility of reviewing the acquired images from any investigator and the ability to analyse the acquired volume through any plane (similar to CT scans or MRI) (Figure 2).

This means that the levator ani muscle can be easily visualised. However interest has focused on the absence of the pelvic floor being imaged and a defect being implied.

Ultrasound produces images by its waves being reflected by a tissue. These reflective surfaces produce images of great clarity and resolution which are independent of the ultrasonic frequency. However once the tissue is perpendicular to the direction of travel of the ultrasound waves axial resolution is effective, limiting the accuracy and the ability for tissues to be imaged. This highlights the importance of testing all ultrasound imaging modalities against a gold standard such as cadaveric dissection or comparing them to another medium such as MRI or CT. Four-dimensional imaging involves a volume of tissue being continuously scanned, thus inevitably involving time delay; albeit not truly “real-time”, it incorporates the enormous improvement in speed of three-dimensional systems over the last few years and it makes three-dimensional assessment of the dynamic relation of the pelvic organs on Valsalva manoeuvre and pelvic floor contraction possible.
Figure 1: Perineal midsagittal two-dimensional view and three-dimensional rendered image. Normal anatomy.

Figure 2: Perineal midsagittal two-dimensional view. Normal anatomy of the levator ani muscle.
2.2.2 Standardisation

No consensus has been reached as to the standardisation of image orientation. Some prefer orientation with cranial structures above (Figure 3a) (15) whereas others prefer presentation of the cranial parts below (Figure 3b) (16-17). All authors agree that the symphysis pubis, and its inferior border in particular, is a well recognisable and fixed reference point. This point can be used in the evaluation of the various aspects of relevant structures at rest and during dynamic imaging. In general, ultrasonographic studies are performed in the supine position (Figure 4). Small differences between the supine and standing position of the patient have been documented, although these differences disappeared during a Valsalva manoeuvre (18). Only a few studies have been performed in the standing position (19). There is no clear consensus on the amount of bladder filling, some authors prefer significant bladder filling, others prefer a nearly empty bladder because an empty bladder seems to descend more on Valsalva manoeuvre compared with a full bladder (19,20). Attempts to standardise Valsalva manoeuvre, ideally with intra-abdominal pressure measurements, has not been widely accepted (14,21). In one study (19), a peak flow meter has been used, where women were asked to “huff” maximally and to reach the same force during a number of “huffs”. It has been shown that the mobility of the bladder neck differs between coughing and Valsalva manoeuvre (22). Co-activation of the pelvic floor muscles during Valsalva manoeuvre has been documented and is one of the reasons for the lack of standardisation (22, 23).

2.2.3 The Urethra and Bladder Neck

When collagen fibres and muscle fibres are located parallel to the ultrasound beam, the structure becomes hypoechoic. These same structures will become hyperechoic, however, when the fibres are located perpendicular to the beam. Ultrasonography may result in variable images of the urethra, since the echogeneity of the structures depends on the position of the transducer in relation to the urethra. This may produce confusing images, especially in the dynamic process of pelvic floor contraction and Valsalva manoeuvre. In the midsagittal plane on perineal ultrasonography, and with normal anatomical position of the urethra at rest, the internal sphincter and inner urothelial layer of the urethra will appear hypoechoic (Figure 1), thus making these structures indistinguishable on ultrasonography. In the midsagittal plane and with normal anatomical position of the urethra at rest, the striated external sphincter or rhabdosphincter will appear hyperechoic, and can hardly be distinguished from the surrounding structures. It will, however, be easily visible as a hyperechoic circular structure in the axial plane as seen on three-dimensional ultrasonography (24,25). The rhabdosphincter has been found to be thinner dorso-laterally (15), and both ventrally and dorsally (26) by various authors and more difficult to distinguish from the internal sphincter ventrally and dorsally compared with laterally (27). These differences may be due to the approach used to image the structures as well as types of probes applied but this has not been addressed in any study to date.

Figure 3b Perineal midsagittal two-dimensional ultrasound view on three compartments and reference lines according to Tunn and Schaer.

A= horizontal reference line
B= central line of the symphysis as reference line for bladder neck descent

With the use of ultrasonography, thickness and length of the urethral sphincter muscle can be measured and urethral volume calculated (17,27-28).
Intra-urethral ultrasonography has been used for this purpose although complete imaging of the lateral parts of the sphincter are difficult due to the higher frequencies emitted by these probes (29), others have used two- or three-dimensional ultrasonography of the urethra (15, 24,26,30).

Comparison of transvaginal and transrectal approach showed a lower degree of urethral compression with the latter approach (26,31). Ultrasound measurement of the female urethra has been found to be reproducible (15, 24,32). Sphincter volume may differ significantly when 2D or 3D imaging is used (24). Urethral volumes, measured by 3D ultrasonography, were positively correlated with the actual volumes in cadavers (30,32). A significant and positive correlation between rhabdosphincter volumes and symptoms and signs of urinary incontinence has been reported (15); correlation with the urethral pressure profile (UPP) measures has also been found (25,27,28,30) but these data could not be reproduced (33). Ultrasoundography imaging during micturition has been explored with the aid of a remote control systems (34).

The advantage of preoperative and intraoperative three-dimensional ultrasound scanning in women with urethral diverticula has been outlined by Yang et al. (39-40).

2.2.4 Bladder Neck

The bladder neck and proximal urethra are easily visible on all types of ultrasonography without the need for catheterisation (Figure 1). Measurements are usually taken at rest, during straining (Valsalva manoeuvre), and sometimes during a cough and squeeze. The position and movements are measured in relation to the lower margin of the symphysis pubis. The difference between rest and strain is referred to as the bladder neck descent (the distance between the bladder neck and a horizontal line through the lower end of the symphysis pubis) (Figure 5). On Valsalva manoeuvre the bladder neck rotates in a posterior and inferior direction away from the symphysis pubis. The axis of the urethra in relation to a vertical or horizontal line can be measured in degrees and provide the degrees of urethral rotation or bladder neck mobility. Other parameters are the posterior urethrovesical angle and the anterior urethrovesical angle. A number of studies have validated the use of ultrasonography in the assessment of the position and mobility of the bladder neck and proximal urethra. Good results for this validity testing have been reported although the clinical value of such measurements is still elusive (4, 14, 41-43). Normal values of bladder neck mobility have not been fully defined, since there is a great range in mobility even in young nulliparous women. In one study amongst nulliparous continent women of approximately 20 years of age, the bladder neck descent varied between 1mm and 40mm (44).

Others (41) found an average descent of 15 mm on Valsalva manoeuvre and 8 mm on a cough. Brandt et al. have found an average bladder neck descent of only 5 mm in 16 year old girls (45). More recently Naranjo-Ortiz et al proposed 25mm of bladder neck descent as cut off for “normality” as further descent was associated with SUI and USUI (46).

Racial differences have been demonstrated, with white women having greater bladder neck mobility compared with black women (47). Genetic determination of bladder neck mobility has been suggested (48). Numerous studies have found greater bladder neckmobility in parous compared with nulliparous women (14, 33, 49-51). Bladder neck hypermobility, however defined, is considered to be related to stress urinary incontinence (17,33,46). A large number of studies have correlated ultrasonographic findings with urodynamic parameters (46, 51-60). Specificity and sensitivity of ultrasonography for the diagnosis of stress incontinence were 83 and 68% in one study (54) and 92 and 96% in another study (61). Other studies have demonstrated that ultrasonographic findings of bladder neck descent and rotation of the retro-vesical angle increase the odds for SUI by 2.5, however they concluded that ultrasonography’s low a diagnostic value does not allow it to replace urodynamics (62). In one study in which ultrasound-measured movement of the bladder neck on coughing and Valsalva was used as a marker inpatients undergoing pelvic floor exercises, response to treatment was not associated with changes to the bladder neck mobility (63) underlining this is probably an associated phenomenon and not the cause for stress urinary incon- tinence.
Figure 5 Perineal midsagittal two-dimensional view at rest and on Valsalva manoeuvre. Bladder neck descent. (S= symphysis pubis; U= urethra; B= bladder; A= anal canal.)

Figure 6 Perineal midsagittal two-dimensional view. Urethral funnelling.
Other researchers have contradicted these data by demonstrating that women with SUI who conducted physiotherapist-guided pelvic floor exercises showed reduced bladder neck mobility during coughing and increased cross-sectional area of their urethra as compared to before the training (64).

Further data from a RCT in primigravidae suggested that PFMT can play a preventative role in reducing the risk for SUI despite not conveying a significant change in bladder neck descent (65).

One research group has specifically investigated simultaneous perineal ultrasonography and urethrometry. They demonstrated that the variations in urethral pressure were caused by the activity of the urethral sphincter as well as the pelvic floor muscles (66). The contractions from the urethral sphincter during acute stress events such as coughing are thought to be due to fast contractions. Some studies have used ultrasonography to optimise patient management, but despite the abundant literature on the use of ultrasonography in the investigation of women with urinary incontinence, disappointedly, a clinical advantage in terms of patient outcome has not been reported until now (67,68).

Urethral funnelling can be observed on ultrasonography (Figure 6) particularly with the use of contrast agents. It is a typical finding in women with stress urinary incontinence but can be seen in asymptomatic women as well (69-71). In a study on stress incontinent women, funnelling was found to be present in nearly all women (70,72). Urinary incontinence can be demonstrated by the use of colour Doppler of the urethra (73-74). Colour Doppler has, furthermore, been used to visualise the perirectal vasculature in nulliparous women (75) and differences have been described between continent and incontinent women (76-77) and before and after oestrogen supplementation in postmenopausal women. More recent data with the use of high frequency endovaginal ultrasonography have highlighted differences in urethral vasculature amongst continent women with parity (78). Doppler velocimetry has recently been used in a study on the vascularisation of the levator ani musculature and a correlation has been found between the absence of an end-diastolic flow and the presence of stress urinary incontinence (79). The blood flow around the urethra and bladder has been studied with Doppler before and after insertion of tension-free vaginal tape and the transobturator tape. The blood flow decreases only after insertion of the transobturator tape which may relate to the direction of urethral compression (80). More recent data showed no difference in urethral vascular indices measured by endovaginal ultrasound between women with SUI who were managed surgically or conservatively (81).

### 2.2.5 Determination of the Post Void Residual Urine and Bladder Wall Thickness

Ultrasonography is the gold standard technique for measuring bladder volume and post-void residual urine (82-86). Ultrasonographic data have been compared with residual volumes obtained by in and out catheterisation under ultrasound control and were found satisfactory. Although there is no universally accepted definition of high urine residual volume, there is consensus on the need for a short interval between voiding and post-void residual (PVR) measurement and the preference of ultrasound bladder volume measurement over urethral catheterization (87). However, Khan et al. have challenged the methodology of some studies and found deficiencies in all reports on the topic (88). A simple formula often used is \( \text{Volume} = \text{Height} \times \text{Width} \times \text{Depth} \times 0.7 \) ml in which the factor 0.7 is the correction for the non-spherical shape of the bladder. Automated ultrasound systems for measuring bladder volume and post-void residual have been developed and found to be more accurate than standard ultrasound measurements, furthermore they can be used by health care providers with no training in ultrasound imaging (89). However, measurement of bladder volume can easily and accurately be facilitated by use of cheap, standard 2D ultrasound machines, irrespective of the calculation formula used, even in women with severe pelvic organ prolapse (90). Automated bladder scanners are widely used and are, in general, experienced as reliable enough for clinical use, however, in the case of ascites (91) or an ovarian cyst (92) for example, the estimated urinary volumes can be incorrect, and in post partum women.

Recently the normal values for the post void residual urinary volumes in asymptomatic women have been presented; in 60 year-old women, the median residual volume was 19 ml, and 95% of women had a post void residual volume of less than 100 ml (83). The ICS Urodynamics Committee has recently published its Good Urodynamic Practice recommendations regarding PVR measurement suggesting that for clinical practice a PVR <30 ml can be considered insignificant, while residual volumes persistently >50 ml could be regarded as important. They also suggested that large PVR (>200–300 ml) often indicates LUTD, acknowledging however that no level of residual urine, of itself, mandates invasive therapy and no PVR threshold is yet established for decision-making (87).

Ultrasonic measurement of bladder wall thickness (BWT) and ultrasound estimated bladder weight (UEBW). Ultrasonic measurement of BWT was first proposed as a non-invasive method for diagnosing infravesical obstruction in children (93). More recently, BWT has been used to predict the outcome of children with primary nocturnal enuresis (93-95). BWT has also been proposed as a risk factor for upper urinary tract deterioration in children with myelodysplasia (96). Measurement of BWT was also proposed to diagnose bladder dysfunction (detrusor overactivity

---

IMAGING IN URINARY INCONTINENCE AND PELVIC FLOOR DYSFUNCTION | 689
and detrusor hypocontractility versus normal detrusor function) in children with urinary tract infections (97-98). Additional parameters such as the bladder wall thickness index (length x width x depth of the bladder at full bladder/average BWT) were proposed and a nomogram for the paediatric population provided (99).

In the adult population, higher BWT values have been measured in men than in women. Thickness may certainly differ depending the measurement technique; values of 3.3 +/- 1.1 mm and 3.0 +/- 1.0 mm, respectively were reported by Hackenberg and co-workers (100). Oelke confirmed a significant difference between male and female detrusor thickness (1.4 versus 1.2 mm, respectively) (101). A small increase of detrusor hypertrophy with age has been reported in both genders (99). In men, measurement of bladder wall thickness proved to be the most sensitive parameter (outperforming uroflowmetry) to diagnose BOO in patients suffering LUTS (102-103). These findings were corroborated by the results of more recent ultrasonographic studies by use of automated bladder scanners (104).

Transvaginal ultrasound was first proposed in 1994 for the measurement of BWT in women with bladder volume of less than 20 ml. A significant difference was shown in patients with DO and USI (6.7 +/- 0.6 versus 3.5 +/- 0.6 mm, respectively). Low intraobserver and interobserver variability were measured: 0.02 mm in both with a 95% confidence interval of -0.22 to 0.18 and -0.32 to 0.35 mm, respectively (105). In 1996, Khullar and co-workers showed how ultrasound measurement of BWT is a sensitive method for diagnosing DO in symptomatic women without bladder outlet obstruction with 94% of women with BWT greater than 5 mm having involuntary detrusor contractions on videocystourethrography or ambulatory urodynamics (106). In 2002, the same group showed no overlap in the 95% confidence intervals of BWT between patients with DO and USI in women with storage symptoms, confirming the potential of this parameter for diagnosing DO (107). More recent data on the diagnostic value of transvaginal ultrasound in patients with overactive bladder symptoms confirmed a sensitivity of 90 % and specificity of 78 % for predicting OAB, when a cut off value of 4.78 mm was used (AUC = 0.905) (108). Conversely, a large UK-based cross-sectional test accuracy study found no evidence that BWT had any relationship with DO, regardless of the cut-off point, nor any relationship to symptoms as measured by the ICIQ-OAB; the authors concluded that despite patients’ wide acceptability of the method BWT measurement was not sufficiently reliable or reproducible to predict DO (109).

In 2003, a study on ultrasound cystourethrography in women confirmed a significant association between age and intravesical pressure at maximum flow with BWT (110). Researchers have also demonstrated reduction in BWT following urethrolysis in women with bladder outlet obstruction resulting form anti-incontinence surgery (111). Methodological and technical issues in the ultrasound measurement of bladder wall thickness and weight remain open and constitute a major limitation for a more widespread use of these parameters. In 2005 Chalana and co-workers published an early report on automatic measurement of the ultrasound estimated bladder weight from three-dimensional ultrasound. An average value of 42 +/- 6 g was measured in healthy male subjects. A standard deviation of 4 g was seen among measurements performed in the same subject at different bladder volumes (200 to 400 ml) (112). Normative values for UEBW and BWT in healthy female volunteers were calculated by another group by use of an automated bladder scan device showing mean values of 32.23g (SD +/- 4.9) and 1.62 (SD +/- 0.34), respectively (113). Further research in this area is certainly needed and further improvement in the accuracy of automated systems is eagerly awaited.

Although data published in the peer review literature on this subject are quite consistent, two discordant papers were recently published from Australia. Blatt and co-worker showed uniform values of BWT measured using an abdominal approach among men and women with non-neurogenic voiding dysfunction suggesting this parameter cannot be used to diagnose storage or voiding dysfunction; this may reflect the thinning of the bladder wall with increasing bladder volume (114-116). A retrospective study on women undergoing translabial ultrasonography suggests a significant association between BWT and DO although a low diagnostic accuracy was shown for the diagnosis of DO (117), which could be due to translabial ultrasound being a less reliable technique (118).

The association between detrusor hypertrophy and bladder dysfunction (DO and BOO) is a well established fact in Urology. Ultrasound measurement of BWT and UEBW is an interesting alternative approach that may avoid invasive urodynamics in some patients. (119). As, previously mentioned, The reduction in bladder wall thickness has been found after the relief of bladder outlet obstruction (111). The development of automated ultrasound systems for measuring UEBW is instrumental to foster further research in this area, particularly in the management of patients with LUTS (120) and in the evaluation of bladder response to pharmacological treatment (119).

2.2.6 Pelvic Floor Muscles

Ultrasonography can be used to assess pelvic floor muscles and their function. Contraction of the pelvic floor results in displacement of pelvic structures that can easily be imaged on ultrasound (Figure 7) such as the cranial lift of the urethra in relation to the symphysis pubis during a maximal squeeze (18, 122) but also the dimensions of the genital hiatus or the posterior ano-rectal angle can serve this purpose (123). Comparison with traditional measurements of pelvic floor muscle strength has been performed (122), and good correlations with palpation and perineometry have been found (124-125). Ultrasonography has
been used to evaluate the effects of pelvic floor muscle training. A higher resting position of the bladder neck and a reduction in the rotational excursion of the urethra during Valsalva manoeuvre have been found with pelvic floor training (126). Another research group has reported that the thickness of pelvic floor muscles increased after training (127). A number of studies have assessed healthy female volunteers to establish normal values (47, 127), and one study has specifically compared elite athletes with normal volunteers (128). Measurements of the levator ani muscle, with the use of two-dimensional imaging, has been recently described, and although direct comparisons to three dimensional ultrasonography are lacking, the acquired data were comparable (129). However, one study has compared three-dimensional ultrasound of the levator ani hiatus at rest and during contraction in a number of different groups of women with prolapse, urodynamic stress incontinence and asymptomatic women suggesting that these measurements are not sensitive enough to discriminate between different groups (130).

Almost half of women are unable to perform an optimal contraction of the pelvic floor muscles. Ultrasonography can be used in pelvic floor training to provide women with a visual feedback of their exercise (18, 131). In one study, 57% of the women who were not able to perform a proper pelvic floor contraction, were able to do so with the help of visual biofeedback of ultrasonography to observe bladder neck movement (18). This does not appear to produce better outcomes of changes with pelvic floor physiotherapy (132). Another prospective study in women receiving physiotherapist-guided PFMT due to pelvic floor dysfunction, however, did demonstrate that the vast majority of patients would improve muscle contractility after the programme; amongst the non responders (“non-contractors”) almost 67% were found to have levator ani defects on transperineal ultrasound (133). The contraction of the pelvic floor muscle just before and during a cough, "the knack", can also be visualised (134). It has been demonstrated that the knack can significantly reduce urethral mobility during a cough.

Direct measurement of the pelvic floor muscles is possible with the use of two and three-dimensional perineal ultrasonography. An alternative technique makes use of a 360 degree rectal probe intravaginally (Figure 8) (129). Most studies, however, have used three-dimensional perineal ultrasonography for this purpose (19, 123, 128, 135-136). The thickness of the pelvic floor muscles as well as the hiatal area can be measured. Hiatal dimensions and pelvic floor muscle thickness have been extensively validated and have good test retest and inter observer characteristics (19). There is a learning curve to measurement of the levator ani hiatus needing over ten sets of scans to perform the measurement. However, measurements of the pubic arch were not accurate suggesting that measurements of levator avulsion may require more training (137).

The pelvic floor muscles were thinner in women with pelvic organ prolapse (17, 129, 138) and with urinary incontinence (139), whereas their genital hiatus was larger (140); interestingly this finding does not produce a significantly reduced maximal voluntary contraction even with pubovisceral muscle defects (141). Well trained women have thicker pelvic floor muscles compared with controls (128), and Chinese women had thinner muscles compared with Caucasian women (136). In nulliparous Chinese women, the anterior/posterior hiatal diameter was significantly increased in women with a higher body mass index (136).

Very recent studies looked at the usefulness of real time trans-abdominal ultrasound scan (TAUS) in assessing pelvic floor muscle strength before and after a structured PFMT; a RCT in 140 incontinent women demonstrated that TAUS was accurate in detecting even minor differences in pelvic floor muscle strength between the PFMT and non-intervention groups and this correlated very well with assessment by digital palpation (142). By using this imaging modality as biofeedback, another research group from Japan established that women with postpartum SUI were less successful in achieving good pelvic floor muscle strength following an intensive PFMT in comparison to their continent counterparts, despite no morphological differences in the LAM between the groups before and after intervention (143).

Pelvic floor biomechanics were investigated with ultrasound using the position of the bladder neck in combination with continuous vaginal pressure measurements (144-145). A novel biosensor was used to measure the force as well as the displacement of the pelvic floor during contraction (146). Another research group has inserted a water filled plastic bag to study the shape of the vagina during contraction (147). Others (148) have assessed elasticity by means of the correlation of the dynamic dimensions of the hiatal circumferences and direct palpation of the muscles. Real time biomechanics of the pelvic floor have been compared between women with and without pelvic organ prolapse with the use of translabial 3D ultrasound and standardised Valsalva effort; significant pelvic organ prolapse was associated with a less compliant levator ani muscle close to its origin from the pubic ramus (median maximum strain 26% vs 32%, respectively, P=0.03) (149).

Figure 8 Intravaginal 360 degree ultrasound imaging. Levator ani muscle, urethra and anal sphincter complex.
2.2.6.1 Levator Trauma

Using three dimensional transperineal ultrasound avulsion of the levator ani muscle from the symphysis pubis has been described in up to 36% of parous women (150). The integrity of the attachment of the pelvic floor muscle to the symphysis pubis can be visualised (Figure 2 and 9a).

A systematic review of diagnosing pubovisceral avulsions on ultrasound and MRI has been published which showed an association with pelvic organ prolapse and recurrence after surgery. However there was no association between pubovisceral avulsions and urinary symptoms or anorectal dysfunction (151).

A recent prospective comparative study in primiparous women found that obstetric anal sphincter injuries (OASIS) do not constitute a risk factor for LAM avulsion (152). This is similar to results from MRI studies, where it has been shown that the risk of pelvic organ prolapse further increases when the levator injury goes together with vaginal architectural distortion (153-154).

Although these defects have recently been identified during labour, it is not known whether there is any reasonable (preventive) treatment for these women (155-156). There is an increase of the occurrence of levator muscle trauma with maternal age at first delivery (157). There was a strong correlation between the presence of levator muscle avulsion and poorer muscle strength (158). It has, however, been shown that the correlation between the clinical assessment (palpation of the muscle) and three-dimensional ultrasonographic assessment of muscular defects was only poor (159), as well as the inter-observer repeatability of the palpation of defects (160). A quantification method for levator muscle defects on ultrasonography (tomographic ultrasound imaging) (Figure 9a and 9b) has been described (135). Another parameter, which has been found to be related to the severity of pelvic organ prolapse, was the size of the inner circumference at minimal hiatal dimension of the levator ani muscle on Valsalva manoeuvre (129, 135,155).

The area of the levator hiatus on Valsalva manoeuvre ranges from 6 to 36 cm² in nulliparous women, with an outlier of almost 50 cm² in a young nulliparous athlete (128, 140). An area of more than 30 cm², 35 cm² and 40 cm² on Valsalva manoeuvre has been described as mild, moderate and severe ballooning of the genital hiatus respectively (Figure 10) (161). The assessment of the levator hiatus has been shown to be a reproducible measurement (19, 150), whereas the reproducibility was less for muscle diameter measurements (19, 123, 140). Despite the recommendations for adherence to universal protocols in depicting LAM defects, significant variation in the reported prevalence of LAM defects exists in literature; transperineal ultrasonography 13–36%, needle electromyography 30% and MRI 20% (162). Hence direct comparison between similar studies, which would allow for drawing meaningful conclusions is difficult due to variable patient selection, differences in demographics and most importantly lack of consistency in the definition and classification of LAM injuries. A very recent cadaveric study has questioned the validity of pelvic floor ultrasound in depicting true levator muscle avulsions; whilst 3D introital ultrasound detected complete “avulsion” in 36.7% of the cadavers no detachment of the levator ani muscle from the pelvic side wall was identified in any of the cadaveric dissections with a 0% incidence on both left and right sides. No avulsion was found either upon dissecting an additional thirty-nine cadavers at multiple international centres, raising the hypothesis that what appears to be an "avulsed" LAM on scan most likely represents an imaging artefact due to the inability of the ultrasound to resolve the smaller insertion sites (163). Comparisons of the hiatal diameters and hiatal area as measured by three-dimensional ultrasonography and MRI revealed good correlations, especially for the measurements at rest. The correlation for hiatal diameter at Valsalva manoeuvre was lower, which is most likely due to the difficulty to reach the correct plane of the levator ani muscle on MRI (164). However, at rest using MRI to alter the angle of acquisition plane has been shown to change the area of the levator hiatus by 10% (165). This has been supported by subsequent papers showing a good inter and intra-observer relationship when measuring the levator hiatus with ultrasound and MRI (166) and even with interdisciplinary readers (167) though the latter group did find only fair agreement when measuring the anorectal angle with ultrasound. The width of the levator ani hiatus on 3D transperineal ultrasound has been found to wider in black women than white women and the urethral sphincter volumes were significantly larger in black women than white women (168). The presence and clinical relevance of paravaginal defects represent a controversial issue amongst urogynaecologists, and there is a lack of scientific proof for the concept. In a study by Reisinger et al., an echogenic layer in the lower anterior vagina, which was thought to be a part of the endopelvic fascia, could be identified reproducibly in nulliparous and parous women by transrectal three-dimensional ultrasonography (169). According to more recent insights, however, previously described paravaginal defects with loss of the H-shape of the vagina in the axial plane on three-dimensional ultrasonography (158, 170-171) could represent the detachment of the levator ani muscle from the symphysis pubis (172). In a study comparing ultrasound and MRI to assess levator avulsion there was only a moderate correlation with ultrasound showing a higher number of complete avulsions and MRI showing a higher number of partial avulsions (173).

Vergeldt TF et al confirmed the difference in LAM defects classification between MRI and perineal ultrasound, showing higher grades of LAM damage on US compared with MRI despite the very good agreement in depicting such defects with both imaging modalities (174). In an attempt to increase validity of the levator avulsion diagnosis, a minimum criteria have been set (175), but even with these more stringent rules two out of three normal women were considered false positives, where they were thought to have full avulsions. It is important to note that MRI studies tend to image thinning or aplasia rather than avulsion perhaps indicating that transperineal ultrasound may not have the resolution to visualise very thin levator ani muscles (176). This finding was corroborated in a very recent comparison study by Notten et al, which showed 78% sensitivity and 86% specificity in detecting major levator ani defects with translabial three-dimensional ultrasonography compared with MRI (177).

2.2.7 Pelvic Organ Prolapse

In cases of mild and moderate pelvic organ prolapse, perineal ultrasonography can be used, for the investigation of the prolapse. Ultrasonography should, however, only be used in addition to the patient’s history and clinical examination. In cases of severe pelvic organ prolapse, ultrasonographic assessment is not possible due to transducer dislocation by the prolapse. The ultrasonographic imaging of the anterior compartment (i.e. bladder, bladder neck and urethra) is the easiest to perform and the majority of scientific studies deal with this compartment (Figure 11).

Correlations with clinical examination (154, 155) are also highest for this compartment. Reproducibility of ultrasonographic imaging of prolapse in the anterior compartment were shown to be good (155). This reproducibility has not been studied for the other two compartments until now.

In two studies amongst 83 and 117 women with the uterus in situ, the uterus could be visualized on perineal ultrasonography in 82% and 97% of cases, respectively (Figure 12) (155, 156).

A number of studies have focused on the posterior compartment (157-165). The distinction between enterocele (Figure 13) and rectocele (Figure 14) is known to be difficult on clinical assessment. In these cases, two-dimensional ultrasonographic imaging in the midsagittal plane can be helpful. The ultrasonographic visualisation of an enterocele has been confirmed with defaecography as well as intraoperative findings (157). It has not been shown, until now, however, whether this extra ultrasonographic investigation leads to superior clinical outcomes of prolapse surgery. Interestingly anterior compartment prolapse is related to levator ani area whereas posterior compartment prolapse is not as well as prolapse symptoms not being associated with levator ani hiatus area (166).

In a study on ultrasonography of the posterior compartment a differentiation between true rectocele, enterocele and perineal hypermobility has been made (160). Intussusception can also be visualised on ultrasonography (167). Perineal hypermobility and an enterocele was seen as descent of the rectovaginal septum or abdominal contents on Valsalva manoeuvre respectively, below a horizontal line through the inferior margin of the symphysis pubis (see below for more information on these measurements). Ultrasonographic staging was significantly correlated with clinical staging and the presence of symptoms of obstructed defaecation (15, 161). In one third of the patients with clinically diagnosed rectocele, however, no ultrasonographic abnormality could be found. As far as interrater reliability was concerned, two expert ultrasonographists have reached moderate to good interrater reliability for the detection of a rectovaginal septum defect, descent of rectal ampulla, and the depth and width of a rectocele (160). In one study, rectocele and perineal hypermobility were present in nulliparous women in 12 and 13% respectively the significance of these findings has not yet been determined (162). The posterior anorectal angle, which is the angle between the anal canal and the posterior rectal wall can be measured at rest and under dynamic circumstances such as straining and squeezing. A number of studies have compared these findings with defaecography and found a generally good correlation (164, 165, 168) but one study found poor inter-rater reliability (146).

2.2.7.1 Quantitative Assessment of Pelvic Organ Prolapse

In the quantitative assessment of prolapse in the various compartments, a reference line, such as the hymen in POP-Q is needed. For ultrasonography, a horizontal line drawn from the inferior margin of the symphysis pubis is the most widely used reference line for this purpose (Figure 3a). A disadvantage of this line is that there is only one fixed point through which the reference line can be drawn and the horizontal line may change with the rotation of a handheld transducer.

The effect of rotation is obviously increased with increasing distance from the fixed point, and consequently there is greatest error in the posterior compartment (179). Although this problem has been overcome in research settings with the use of motion tracking systems, at the moment this is not a realistic option for routine use in clinical practice (195). For quantitative assessment of rectoceles, the depths of the rectocele as measured in relation to a line through the anterior anal canal, may be more useful as compared with the descent in relation to the horizontal reference line (196).
Figure 12 Perineal midsagittal two-dimensional view. Cystocele and descending uterus. (S= symphysis pubis; B= bladder; U= Uterus; C= cervix.)

Figure 13 Perineal midsagittal two-dimensional view and three-dimensional rendered image. Enterocele. (S= symphysis pubis; B= bladder; E= enterocele; R= rectum; A= anal canal.)
More recently, Hennemann J et al proposed a new reference line for pelvic floor biometry, which passes between two fixed points on the symphysis pubis and should improve efforts for standardisation of ultrasound measurements of anatomical indices since it has excellent reproducibility, allows for visualisation of markers in all three vaginal compartments and avoids angle errors due to probe movement (197).

Since pelvic organ prolapse can be visualised well with the use of ultrasonography, it raises the question whether this assessment modality is superior to others, such as clinical examination. In a recent study on the relationship between prolapse symptoms and the most dependent point of the prolapse on POP-Q and on ultrasonographic assessment, POP-Q performed better in the prediction of prolapse symptoms with increasing stages of prolapse (196). This finding has been replicated in all compartment underlining the superiority of clinical assessment over ultrasound (180). In a previous study, where only women with a single compartment prolapse were studied, the area under the receiver operating curve was good at 0.86 and 0.82 for the anterior and posterior compartment respectively (198). In both studies the cut-off value for symptomatic prolapse averaged 15 mm below the horizontal reference line through the symphysis pubis. Larger anterior vaginal wall prolapses do have larger levator ani hiatuses and are more likely to have avulsions (69% compared with 35%) (199).

As far as dynamic MRI and X-ray defaecography are concerned, there are only a few studies available as yet, on comparison with ultrasonography. For enterocele detection in women with obstructed defaecation, perineal ultrasonography has been compared with X-ray defaecography, but not with the clinical findings (190). In cases where an enterocele had been detected by either method, an enterocele was detected by both ultrasonography and X-ray in 71% of women. In this study, perineal ultrasonography showed more severe stages of enterocele compared with X-ray defaecography. In another recent study from a different research group, X-ray defaecography has been compared with perineal ultrasonography using a vaginal probe in women with impairment of the posterior pelvic floor. Good to excellent concordance has been found for the assessment of the anorectal angle, rectocele and intussusception. The authors claimed, however, that rectoceles with a depth less than 20 mm could not be detected on ultrasonography (185), which is discordant with most other publications (180-181) on the topic and as well as the authors’ experience.

**2.2.8 Ultrasonography in Relation to Pregnancy and Delivery**

Vaginal delivery is commonly accepted as the major risk factor for the development of pelvic organ prolapse in later life. In nulligravid women, there is a wide variation in pelvic organ descent for all three compartments (146, 182, 200-202). In a study of 169 women who underwent ultrasonography during and after pregnancy, a significant increase in pelvic organ mobility (downwards displacement) was found in all...
